Breeding. Poorly known. Incubation and nestlings recorded in mid-Apr and early May, and nest-building in mid-May. One nest described as a small, neat cup of fibre and fine grass, lined with fine grass, felted with cobweb externally and on to vertical fork of small tree in forest gap, but on this information not distinguished from that of *A. tiphia*, and identification (and site) have been questioned; more recently, a nest located 8 m above ground in forest-edge tree. Clutch probably 2 eggs; no information on incubation and fledging periods; both pair-members tend nestlings, both also brood during rain. Suspected brood host of Banded Bay Cuckoo (*Cacomantis sonneratii*) in forest, but still unproven; apparent pair mobbed an Asian Drongo-cuckoo (*Surniculus lugubris*).
Movements. Resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Common in areas where forest canopy continuous. Formerly more widespread, but huge amounts of range now unsuitable owing to habitat removal; habitat loss greatly accelerated during last decades of 20th century. Little of what remains is still untouched, and stability of this species' presence in plantations is unknown. Nominate race occurs in several protected areas, including Khao Pra-Bang Khram Wildlife Sanctuary, in Thailand, Taman Negara National Park, in Peninsular Malaysia, Way Kambas National Park, in Sumatra, and Danum Valley Conservation Area, in Borneo. Race *thapsina* has very small range, known to occur only on Siantan I, in Anamba Group, but possibly present also on other islands in that archipelago; reported presence on neighbouring Bunguran I (N Natunas) unconfirmed.
Bibliography. Anon. (1999a, 2001b, 2002b), Collar *et al.* (2001), Jeyarajasingam & Pearson (1999), Lamont (1997), MacKinnon & Phillipps (1993), Madoc (1976), van Marle & Voous (1988), McClure (1966, 1967, 1998), Medway & Wells (1976), Nash & Nash (1988), Riley (1938), Sheldon *et al.* (2001), Smythies (1986, 1999), Stattersfield & Capper (2000), Strange (2002), Stuart Baker (1922–1930, 1932), Thompson (1966), Wells (1985c, 2005).

4. Great Iora

Aegithina lafresnayei

French: Iora de Lafresnaye **German**: Großiora **Spanish**: Iora Grande

Taxonomy. *Iora Lafresnayei* Hartlaub, 1844, Melaka, Peninsular Malaysia.
Race *innotata* intergrades with nominate in Malay Peninsula. Three subspecies recognized.
Subspecies and Distribution.
A. l. innotata (Blyth, 1847) – S Myanmar and S China (S Yunnan) S to N Malay Peninsula, S Laos and C Vietnam.
A. l. lafresnayei (Hartlaub, 1844) – extreme S Thailand and Peninsular Malaysia (S to S hills of Johor).
A. l. xanthotis (Sharpe, 1882) – Cambodia and S Vietnam.

Descriptive notes. 13·6–15·4 cm. Male nominate race has anterior face and entire underparts bright yellow; forehead yellow, forecrown black-fringed yellow; rest of crown, ear-coverts, nape and upperparts solidly (slightly glossy) black, or dark olive with broad black tips; wings and tail solidly black; iris grey-white or dark brown (possible sexual difference, not yet clarified); bill pale grey-blue with slaty-black culmen ridge; feet blue-grey. Female has lores and narrow eyering pale yellow, crown, upperparts, wing-coverts and tail olive-green, flight-feathers sooty grey, underparts pale yellow, breast side and flanks suffused green. Juvenile resembles female, but has pale fringing on uppertail-coverts, duller underparts; apparent juvenile male with parti-coloured tail suggests existence of subadult plumage, but this tail pattern occurs also among some adults of supposed intergrades between nominate and *innotata*. Races differ mainly in upperpart coloration: *innotata* is darkish olive-green above, including tail, variably dusted black, with flight-feathers mainly sooty black, tertials sooty olive (female wing all green); *xanthotis* has lores, narrow eyering and short spur behind eye yellow, and cap, upperparts, wings and tail clear lime-green, tail feathers with yellow tips, female duller with olive flanks. Voice. Rapid, high-pitched "chiu-chiu-chiu..." or "chew-chew-chew..."; in Peninsular Malaysia, "pretty song, quite different from *tiphia*" in extreme NW (Perlis), also 4-note whistle and churrs in S (Johor); loud whistling, richer and more powerful than that of *A. tiphia*, described from Myanmar (Tenasserim).
Habitat. Edge and canopy of semi-deciduous to evergreen lowland forest, including crowns of giant emergent trees; said also to enter tall secondary growth and occasionally overgrown plantations (of durian, rubber, etc.). In Malay Peninsula, apparently confined to submontane habitat in S, whereas perhaps mainly at plains level farther N. In N Vietnam, towards N limit of range, found by one observer in 1940s only in lowlands, in forest dominated by bamboo and with dense undergrowth, also in hedges and groves of otherwise more or less cleared country, including around villages.
Food and Feeding. No information on diet and foraging methods. Joins mixed-species foraging parties of insectivores.
Breeding. No confirmed description. Nests collected in early 20th century in Perak (Peninsular Malaysia), reported as of this species, suspected of having belonged to *A. tiphia*.
Movements. Resident.
Status and Conservation. Not globally threatened. Generally uncommon to only locally common; sparse in far S of range. Claimed from coastal strand-woodland casuarinas (*Casuarina*) in SE Sumatra, but evidence is equivocal and habitat atypical; corroborative observations required. As it is more or less tied to inland forests below the ecotone with montane forest, a huge part of the species' original living space was lost to clearance during 20th century, with rate of loss accelerated in recent decades. N of Malay Peninsula, core habitat suspected to have been plains-level or bottomland forest, most of which has disappeared, and remainder now excessively fragmented. Occurs in several protected areas, including Kaeng Krachan National Park, in Thailand, Taman Negara National Park, in Peninsular Malaysia, and Nam Bai Cat Tien National Park, in Vietnam. Although not currently listed as threatened, it seems reasonable to suggest that it may already be Near-threatened.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family PTILOGONATIDAE (SILKY-FLYCATCHERS)

- Medium-sized songbirds with soft, silky plumage, and small bill used for plucking berries; most are slender and crested, with long tail.
- 18–24·5 cm.

- South-west USA and Middle America.
- Montane forests and pastures, deserts, riparian woodlands.
- 3 genera, 4 species, 10 taxa.
- No species threatened; none extinct since 1600.

Systematics

Named for the silky appearance of their plumage combined with their aerial acrobatics in pursuit of insects, the silky-flycatchers make up a small family of oscine songbirds found only in the south-western USA, Mexico, Guatemala and the mountains of Costa Rica and Panama. They are not closely related to the suboscine tyrant-flycatchers (Tyrannidae), and they are more closely related to the waxwings (Bombycillidae) than they are to the Old World flycatchers (Muscicapidae). Although they may engage in extensive flycatching during the breeding season, they are, like the waxwings, frugivorous throughout the year.

From the time when the first silky-flycatchers were discovered, during the early to middle part of the nineteenth century, they were considered to be closely related to the waxwings, a notion upheld by evidence from DNA–DNA hybridization research carried out more than a century and a half later. Waxwings and silky-flycatchers exhibit similarities in a number of morphological characters, such as the conspicuous crest on the head, the texture of the plumage and the shape of the bill. The silky-flycatchers are, however, distinct from the waxwings in such features as the more rounded wings and, for those species for which the information is known, in having downy nestlings and an unstreaked juvenile plumage.

The relationships of the two groups to other families have been a matter of controversy historically, and are still unresolved. Before 1900, most authors classified the silky-flycatchers, the waxwings and an odd Hispaniolan species, the Palmchat (*Dulus dominicus*), in a single family, Ampelidae. In 1904, R. Ridgway recognized each of these groups as separate families, placing the silky-flycatchers in Ptilogonatidae, the waxwings in Ampelidae and the Palmchat in Dulidae. Later, in 1949, J. Delacour and D. Amadon suggested that the first two of these be maintained as subfamilies in a new family, Bombycillidae, along with another subfamily, containing just the Hypocolius (*Hypocolius ampelinus*) of Iraq and adjacent countries, and possibly with the Palmchat as a fourth subfamily. Subsequent taxonomists have continued to issue conflicting opinions about the relationships of the Hypocolius and the Palmchat to the waxwings and silky-flycatchers.

In their 1990 analysis, using DNA–DNA hybridization, C. G. Sibley and J. E. Ahlquist suggested that silky-flycatchers and waxwings diverged from one another more recently than they did from the Palmchat lineage. Unfortunately, these scientists were unable to obtain samples from the Hypocolius for genetic analysis. On the basis of the molecular evidence, they classified the first three as tribes, respectively the Ptilogonatini, the Bombycillini and the Dulini, within the family Bombycillidae, which they placed in a superfamily Muscicapoidea. In the latter, they also included the dippers (Cinclidae), along with a greatly expanded Muscicapidae that contained not only the Old World flycatchers but also the thrushes (Turdidae), and an expanded Sturnidae comprising the mockingbirds and thrashers (Mimidae), as well as the starlings proper.

Townsend's Solitaire (*Myadestes townsendi*) was initially considered a silky-flycatcher, and was described in the genus *Ptiliogony's* [*sic*] by J. J. Audubon in 1838. Twenty-six years later, S. F. Baird suggested that *Myadestes* had affinities with the thrushes, an arrangement adopted in subsequent classifications. In 1973, Sibley advocated the inclusion of *Myadestes* with the Ptilogonatidae, on the basis of electrophoretic patterns of egg-white proteins. No change was made in the 1983 *American Ornithologists' Union Check-list of North American Birds*, however, in part because of differences between the two groups in nesting behaviour.

Another thrush-like bird, the Black-and-yellow Silky-flycatcher (*Phainoptila melanoxantha*), is still included in the family Ptilogonatidae, despite a degree of scepticism by some authors. Among these are Ridgway, who, in 1904, wrote that *Phainoptila* is doubtfully a member of this family and "so far as the adult is concerned might easily be referred to the Turdidae [thrushes] without materially affecting the diagnosis of the latter family". The other silky-flycatchers, the Phainopepla (*Phainopepla nitens*), the Grey Silky-flycatcher (*Ptilogonys cinereus*) and the Long-tailed Silky-flycatcher (*Ptilogonys caudatus*), share striking morphological features and behavioural traits, including a prominent crest, a slender body with a long tail, a preference for high perches and open spaces, and a relatively sociable nature. These characteristics contrast with those of the Black-and-yellow Silky-flycatcher, which has a thrush-like aspect, lacks a crest, has a heavier body with a shorter tail, and leads a solitary and reclusive life in dense forest. Whether or not this species is a rightful member of the Ptilogonatidae remains to be resolved, perhaps by new molecular evidence.

Morphological Aspects

With the exception of the Black-and-yellow Silky-flycatcher, the members of the Ptilogonatidae are slender, long-tailed birds pos-

The silky-flycatchers are a small group of oscine passerines, for the most part with prominent crests, slender bodies and long tails. In all four species males have longer tails and bolder patterning than females, but sexual dichromatism is most pronounced in the ***Phainopepla****, the male of which is jet-black (with white wing-patches visible in flight), and the female grey. Seasonally, this species is one of the most abundant songbirds in the deserts of the south-western USA, especially the Sonoran Desert, where the black plumage of males maximizes their conspicuousness.*

[*Phainopepla nitens lepida*, Santa Rita Mountains, Arizona, USA. Photo: Tom Vezo]

sessing a conspicuous crest, which they can raise and lower expressively. The plumage appears soft and glossy. In colour, they range from the jet-black of the male Phainopepla, the vernacular name of which derives from the Greek and means "shining robe", to the variegated pattern of the colourful Long-tailed Silky-flycatcher, which presents hues varying from pale grey to olive-green and bright yellow. The Black-and-yellow Silky-flycatcher differs in appearance from the others, as it has a relatively stout body, a short tail and no crest, and lacks white patches on the tail and wings.

Phainopeplas have bold white wing patches that flash in flight and are revealed also when the wings are spread. The Grey and Long-tailed Silky-flycatchers have much white on the tail; when they twist and turn in the air in pursuit of insects, they spread the tail, revealing contrasting areas of black and white. The two central rectrices of the Long-tailed Silky-flycatcher extend beyond the others, giving the tail an even greater appearance of length. A. F. Skutch wrote evocatively that "Even in the gales which blow over the high mountains for hours or days together, the silky-flycatchers choose… exposed perches, where they rest while the strong wind ruffles their plumage and twists their tails."

All of the members of the family are sexually dimorphic, the males having a longer tail and bolder or brighter plumage than the females. The contrast in colour between the sexes is most striking in the Phainopepla, the male of which is jet-black whereas the female is grey. A study of the thermal properties of the male's plumage suggests that increased heat gain from the black coloration is small compared with the effects of temperature regulation achieved by behaviour, such as perching posture and selection of micro-habitats. Optical properties indicate that black plumage maximizes visual conspicuousness in the desert, where Phainopeplas maintain winter territories and where they breed in spring.

The plumage of juveniles generally resembles that of females, but the juvenile feathers have a loose texture. After the first moult, in autumn, the plumage of young male Phainopeplas varies from mostly grey to black; some males are pied, with a mixture of black and grey. Young males with some grey in the plumage have fewer protein reserves than do males of the same age that are entirely black.

Silky-flycatchers have a relatively small bill, with which they pick large numbers of small berries. These they swallow whole. The Phainopepla has adaptations in the digestive system that aid in the efficient processing of large quantities of the berries of desert mistletoe (*Phoradendron californicum*), its staple food in the desert during the months of October to April (see Food and Feeding). Most other bird species have difficulty in handling these fruits because, when they break the exocarp, or skin, to expose the pulp, the latter, being sticky, adheres to the bill. Phainopeplas, on the other hand, rapidly swallow the berries whole. The berries collect in the crop, and then pass one at a time into the gizzard. When the gizzard contracts, it extrudes the seed, retains the exocarp, and squirts the pulp into the small intestine. After 12–24 berries have been processed, the gizzard ejects the exocarps all together.

Habitat

The silky-flycatchers inhabit woodlands and deserts in the south-western USA, Mexico and Guatemala, and montane forest and pastures in Costa Rica and Panama. They are most common in areas with numerous berry-producing plants, including mistletoe of the genus *Phoradendron*, redberry (*Rhamnus*), *Schefflera robusta* and *Clusia estenofila*. The Black-and-yellow Silky-flycatcher resides beneath a dense forest canopy, whereas the other three species prefer open spaces with scattered trees.

Black-and-yellow Silky-flycatchers are restricted to the mountain ranges of Costa Rica and western Panama. Usually found above 1200 m, they are most common in evergreen subalpine and elfin forests. On exposed peaks and ridges, the gnarled trees of the elfin forests are 2–10 m in height, and cloaked in bryophytes. Beneath the dense canopy, small trees and bushes form the understorey and the ground is carpeted with a mat of bryophytes and protruding herbs. This species is also found, but to a lesser extent, in upper montane forest where vegetation similar to that of the subalpine forest is present in second-growth areas and natural gaps. Important fruiting plants here include those of the families Araliaceae, Melastomataceae, Rubiaceae and Ericaceae.

Like the previous species, the Long-tailed Silky-flycatcher is found in the mountains of Costa Rica and western Panama. In contrast to it, however, it prefers open habitats, such as secondary forest and pastures with scattered trees at elevations of about 1800–3000 m. Occasionally, Long-tailed Silky-flycatchers perch on the tops of trees of adjacent dense woodland or fly over them. The Grey Silky-flycatcher, too, is an inhabitant of montane woodland with scattered trees. It lives among pine (*Pinus*), oak (*Quercus*) and juniper (*Juniperus*) at elevations of 1000–3500 m in Mexico and Guatemala.

In the south-western USA, Phainopeplas are found in deserts and riparian woodland at different times of the year. During Oc-

tober and through to mid-April, they maintain territories in deserts, especially the Sonoran Desert, in Arizona, where they reach their highest densities in the country. This species is one of the most conspicuous and abundant winter songbirds in desert washes where leguminous trees and shrubs, such as palo verde (*Cercidium*), mesquite (*Prosopis*) and acacia (*Acacia*), have been parasitized by the desert mistletoe, the fruits of which are avidly consumed by this ptilogonatid. By the end of April, most Phainopeplas have departed from the desert. By June and July, nearly all are found in riparian-woodland habitats dominated by oaks and sycamore (*Platanus racemosa*), with an abundance of such fruiting shrubs as redberry and elderberry (*Malosma laurina*). They breed in the desert during the spring and in riparian woodland during the summer. In Mexico, this species is found in arid to semi-arid habitats with scattered trees and bushes and along riparian washes.

General Habits

In their fondness for open spaces, their conspicuous presence on the highest perches, and their social behaviour, the Phainopepla and the Grey and Long-tailed Silky-flycatchers share similar habits. Either one of the the first two species could, for example, easily fit Skutch's description of the Long-tailed Silky-flycatcher: "A far-ranging, restless bird of open spaces... This silky-flycatcher alights by preference on the topmost, exposed twigs of tall trees, where it perches very upright, with its high crest and long tail making it appear elegantly tall and slender and presenting an unmistakable profile against the sky."

When travelling, these three species typically fly above the tops of the trees. During the non-breeding season, they move from treetop to treetop in loose, straggling flocks. The Phainopepla and the Long-tailed Silky-flycatcher sometimes zigzag erratically in flight, especially when descending from the air to alight on a perch.

Whether atop a high lookout or in buoyant flight above the trees, Phainopeplas and Grey and Long-tailed Silky-flycatchers often announce their presence with loud contact calls, flight calls, and aggressive warnings. They rarely land on the ground. The Phainopepla, when nest-building, does descend to collect plant fibres, spider silk and twigs from the ground, but the Long-tailed Silky-flycatcher gathers material, primarily lichens, directly from vegetation.

Silky-flycatchers often flutter buoyantly, sometimes changing direction erratically at the last moment. B. Torrey, writing about the Phainopepla, commented that "No matter where they might be going, though the flight were only a matter of a hundred yards, they progressed always in pretty zigzags, making so many little, unexpected, indecisive tacks and turns by the way, butterfly fashion, that you began to wonder where they would finally come to rest."

Neither solitary nor excessively gregarious, the Phainopepla and the Grey and Long-tailed Silky-flycatchers are characterized by loose sociality during both the breeding season and the non-breeding season. Skutch remarked that, although they seek the company of their own kind, they do not perform any co-ordinated group movements but, instead, remain independent. He was of the opinion that an observer, watching these birds, would quickly conclude that their life is "a continual compromise between gregarious and individualistic impulses".

Phainopeplas, for example, defend breeding territories in the desert during the spring, but both before and after this period, during courtship and soon after nesting, they gather in loose groups, perching and flitting about in the same set of trees. They leave the desert in loose flocks and arrive in May in riparian woodlands, where they settle in loose colonies to breed during the summer. After the nesting season ends, this species and the Grey and Long-tailed Silky-flycatchers move about in loose, straggling flocks.

In general habits, as in appearance, the Black-and-yellow Silky-flycatcher differs significantly from the three other members of the family. Rather than exploiting open spaces with scattered trees, it prefers the dense cover of forest, where it is secretive, less active, and quieter. It is usually encountered singly or in solitary pairs during the breeding season, and when flycatching it tends to travel from perch to perch, rather than sallying back and forth (see Food and Feeding). Skutch's description of the Black-and-yellow Silky-flycatcher, although brief, remained the most detailed account of the species for more than three decades. He wrote that it was regrettable that so little was known about this species, and that his field observations led him to feel the strength of Ridgway's remark that the genus *Phainoptila* is doubtfully a member of the Ptilogonatidae (see Systematics).

Voice

Although they are not renowned for their musicianship, most of the silky-flycatchers are loud and voluble. The Phainopepla and the Long-tailed Silky-flycatcher are also accomplished mimics, capable of imitating other bird species. As Skutch wrote, "It is evident that the silky-flycatchers, although vocally poorly endowed, are capable of producing a wide variety of utterances to meet the various contingencies of their lives."

The Black-and-yellow Silky-flycatcher has the weakest voice, and apparently it does not sing. It utters a slight "tsip" note, reminiscent of the calls of some New World warblers (Parulidae), and it also twitters softly. The loudness and tempo of calls increase before the birds take flight. Skutch overheard low, soft notes exchanged by the two members of a pair that was foraging in the rain.

The other three ptilogonatids use loud call notes while perched at the top of a tall tree or shrub. They also employ the call note to express alarm. The Phainopepla often turns from side to side, flicking the tail as it calls. Long-tailed Silky-flycatchers use three kinds of vocalization in flight; in addition to emitting the same call as that used while perched, they utter a drawn-out clicking, likened to the sound of pebbles being rattled in a box, and a bell-like tinkling noise. Phainopeplas, when chasing one another in flight, give a harsh "churr".

During the nest-building stage of the year, Phainopeplas utter distinctive calls when partners exchange places on the nest. While constructing the nest, they also snap the mandibles together to produce a series of rapid clicking sounds. This species is the only member of the family reported as having a loud song, which is usually given only in the courtship period, before egg-laying. Phainopeplas sing at least 14 different short elements, repeated and mixed in variations, including a loudly whistled "wheedle-ah", a thin downslurred note, a harsh buzz,

*The **Long-tailed Silky-flycatcher** is an elegant Central American form in which the tail is dramatically modified in pattern and shape, having a sharply demarcated white bar and greatly elongated central rectrices. Its bill is short and stubby, and its plumage soft and dense, recalling waxwings (Bombycillidae). Like that family, it is essentially frugivorous and seasonally gregarious. It is found in the mountains of Costa Rica and western Panama, where it prefers open habitats, including the upper canopy of secondary forest and pastures with scattered trees.*

[*Ptilogonys caudatus*, Cerro de la Muerte, Costa Rica. Photo: Michael & Patricia Fogden]

*The **Black-and-yellow Silky-flycatcher** is restricted to the volcanic mountain ranges of Costa Rica and western Panama, where it is usually found above 1200 m in the undergrowth of humid evergreen forests, including stunted, epiphyte-laden elfin forests. Apart from its predilection for lower growth, it is anomalous within the family in lacking a prominent crest, as well as white patches in the remiges or rectrices. Further, its heavy body and short tail give it a thrush-like aspect, which is bolstered by its solitary nature. As such, and despite resembling* Ptilogonys *in overall colour and pattern, the allocation of* Phainoptila *to Ptilogonatidae remains a topic of disagreement, with some authorities claiming that it sits more comfortably in Turdidae. Further details of its evolutionary history should be sought, and a thorough biomolecular analysis undertaken.*

[*Phainoptila melanoxantha*, Cerro de la Muerte, Costa Rica. Photo: Michael & Patricia Fogden]

and an utterance reminiscent of the ring of a telephone. In addition, both this species and the Long-tailed Silky-flycatcher produce quiet songs composed of low lisping notes, whistles, warbles and other sounds that are barely audible even from close range.

In response to predatory threats at the nest, the two above-mentioned species sometimes imitate the calls of other bird species. Either sex utters these quiet vocalizations while fluttering among nearby branches, or while worriedly watching from a perch as a human being inspects the nest. The calls of one Long-tailed Silky-flycatcher reminded Skutch of the alarm notes of the American Mountain Thrush (*Turdus plebejus*); this individual also uttered other, varied sounds that were too soft to be identified. Phainopeplas quietly imitate calls of the Red-tailed Hawk (*Buteo jamaicensis*), the Northern Mockingbird (*Mimus polyglottos*), the Northern Flicker (*Colaptes auratus*) and others.

When Phainopeplas are captured and handled, they imitate other species loudly, sometimes stringing together different vocalizations in rapid succession, and continuing to do so for minutes on end. During handling, they have been recorded as imitating the sounds of at least twelve species, including the Red-tailed Hawk, the Northern Flicker, Gambel's Quail (*Callipepla gambelii*), and the sound made by American Mourning Doves (*Zenaida macroura*) when flapping their wings in flight. Some Phainopeplas captured in the desert imitate species found only in coastal woodlands, and the reverse has also been

reported; these observations suggest that the birds retained what they had learnt in one habitat after they moved to a different region. They will also at times punctuate these imitations with loud, harsh distress calls.

The purpose of the imitations is unknown. In the only reported instance of a Phainopepla using mimicry in a natural context, an individual, as it fled from a Loggerhead Shrike (*Lanius ludovicianus*), imitated the cry of a Red-tailed Hawk. The shrike, undistracted, killed the Phainopepla. Results of playback experiments reveal that Phainopeplas and other species often respond to scream calls and imitations by approaching and mobbing a predator decoy, regardless of whether their own species' calls were imitated. The broadcasting of harsh distress calls alone elicited strong mobbing responses by Phainopeplas and others, and imitations appear to play only a minor role, if any, in escalating mobbing behaviour.

Adult Phainopeplas and Long-tailed Silky-flycatchers sometimes emit loud harsh distress calls when their chicks are removed from a nest. Phainopeplas breeding in loose colonies use these calls when Western Scrub-jays (*Aphelocoma californica*) approach a nest; nearby pairs respond to the calls by approaching rapidly, mobbing the jay, and adding their own cries to the ruckus. Nestlings also utter distress calls when captured and handled by humans.

Food and Feeding

Silky-flycatchers feed primarily on fruit and insects. During the non-breeding season, when insects are much scarcer or absent, the diet consists exclusively of fruit. The distribution, social behaviour, timing of breeding and movements of these species are all strongly influenced by the availability of berries. In turn, the silky-flycatchers, by dispersing the seeds of berry-producing plants, play an important role in the shaping of the plant communities of the habitats in which they live.

All four ptilogonatids typically pluck berries and swallow them whole while clinging to clusters of the fruits or perched on a stem or branch. The Phainopepla and the Grey and Long-tailed Silky-flycatchers are relatively active as they forage, but Skutch described the Black-and-yellow Silky-flycatcher as sluggish. One pair that he watched remained in a chili tree (*Drimys winteri*) for almost an hour, during which time the two birds fed avidly on the highly flavoured fruits, alternating this with periods during which they rested motionless within the shelter of the glaucous foliage, the head drawn in and the plumage puffed out, while they digested their meal.

Berries from a variety of plants are eaten, depending on the availability of each. For example, Phainopeplas consume berries exclusively of desert mistletoe during the winter months in the desert, but in the summertime, in coastal woodlands, they eat the fruits of redberry, blue elderberry (*Sambucus mexicanus*) and sumac (*Rhus*). Black-and-yellow Silky-flycatchers take fruits of at least 40 different plants from 36 genera. In Costa Rica, they consume fruits of more species in the Talamanca and Tilarán mountain ranges than they do in the Volcánic Central and Guanacaste mountains, reflecting the patterns of plant-species richness.

The members of this family capture aerial insects by hawking them from a perch. Black-and-yellow Silky-flycatchers often travel through the air in pursuit of insects, and land on a perch different from the one where they began. In contrast, the other ptilogonatids usually sally back and forth from the same perch. Once airborne, they often twist and dive gracefully to intercept a flying insect before returning to the perch, flashing white patches on the tail or wings as they flutter. When insects swarm in coastal woodlands, Phainopeplas flycatch in groups on the wing in the manner of swallows (Hirundinidae), especially in the evening when the angle of the sun's light illuminates the swarms.

The timing of overlap in availability of fruits with that of insects probably determines when and where silky-flycatchers will breed (see Breeding). This is because the parents feed their nestlings initially with insects, and with increasing proportions of berries as the young grow. In January, Phainopeplas devote about 11·5% of the daytime activity to fruit-eating; this compares with 4·7% in March, when they also feed on insects. In one study, pairs with young engaged in extensive flycatching for about 11·6% of the day, this being approximately 20 times greater than the figure for Phainopeplas without young.

Foraging patterns are often determined by the spatial distribution of fruit. In one study, radiotracked Black-and-yellow Silky-flycatchers spent 9–12 minutes at one location before moving distances of 39–100 m to a new patch of fruit, without feeding along the way. Long-tailed Silky-flycatchers and Phainopeplas in riparian woodland sometimes fly several hundred metres and out of sight of the human observer, apparently in search of fruiting shrubs.

The distribution of fruits appears also to be an important determinant of sociality among ptilogonatids during the breeding season. Long-tailed Silky-flycatchers and Phainopeplas breed-

With the exception of Phainoptila, *members of this family prefer high bare treetops and open spaces. They prefer to perch upright in the topmost branches of trees, on which their elegant outlines and pied tails are noticeable, and from which they launch aerial pursuits of flying insects. During the non-breeding season, they move about in loose, straggling, noisy flocks. Typical in all these respects, the* ***Grey Silky-flycatcher*** *is an inhabitant of open montane pine* (Pinus), *oak* (Quercus) *and juniper* (Juniperus) *woodland in Mexico and Guatemala. This individual was photographed as a vagrant to the USA.*

[*Ptilogonys cinereus*, San Diego County, California, USA. Left, photo: Brian E. Small. Right, photo: Herbert Clarke]

Although it may engage in prolonged bouts of flycatching during the breeding season, even foraging on swarms of insects in continuous flight like swallows, the ***Long-tailed Silky-flycatcher*** *is essentially frugivorous. It eats fruit and berries throughout the year, plucking them in large numbers from trees with its relatively small bill, and swallowing them whole.*

[*Ptilogonys caudatus*, Cerro de la Muerte, Costa Rica. Photo: Marco Saborío]

ing in riparian woodlands are loosely colonial. In these habitats, fruiting plants thrive in sunny areas away from nest trees and are not easy to defend from competitors. In contrast, Phainopeplas breeding in the desert are territorial; here, the primary source of fruit, desert mistletoe, grows on trees used for nesting, and is distributed relatively uniformly throughout the available habitat.

Silky-flycatchers are important dispersers of the seeds of berry-producing plants. In the Monteverde Forest Reserve, in Costa Rica, the Black-and-yellow Silky-flycatcher has been found to be one of three major dispersers for three plant species growing in treefall areas, even though the fruits of these make up a relatively minor proportion of its diet. It disperses the seeds typically within 30 m of the parent plant, but sometimes as much as 500 m or more from it. Seeds deposited by Black-and-yellow Silky-flycatchers germinate more effectively than do the seeds of unconsumed fruits.

Similarly, the Grey Silky-flycatcher is an important disperser of the mistletoe *Psittacanthus schiedeanus* in a cloudforest remnant near Xalapa, in the Mexican state of Veracruz. Here, the abundance of this ptilogonatid varies with the abundance of ripe mistletoe fruits. The Phainopepla, too, is an important disperser of mistletoe. It defecates the seeds of the parasitic desert mistletoe on appropriate host plants, demonstrating a preference for perching on the leguminous trees and shrubs that the parasite requires. Expelled seeds typically pile up as reddish towers beneath favoured perches. Experiments involving the removal of mistletoe revealed that the Phainopeplas deposit seeds disproportionately on tall trees already infested with mistletoe, presumably because they are attracted to tall perches and sources of fruit. Phainopeplas thus influence the distribution of mistletoes, and thereby that of other species of bird, mammal, insect and fungus that consume mistletoe leaves or berries, use mistletoe clumps as shelter, or take advantage of weakened trees.

Breeding

The Ptilogonatidae apparently rear just a single brood in each breeding season, as they are restricted by the brief period when both insects and fruit are abundant. The Phainopepla, however, is unusual among songbirds in that it breeds in two distinct types of habitat at different times of the year. Although it is unknown whether the same individuals breed in both habitats, the respective timings of movement and of breeding suggest that this species may be able to raise two broods annually by moving between habitats where food resources reach a peak at different times of the year. These birds also exhibit striking differences in their social behaviour in these two habitats, this being influenced by the spatial distribution of fruit and nest-sites.

Phainopeplas spend the winter months in the desert, where desert mistletoe, their sole source of winter food (see Food and Feeding), generally bears fruit from November to April. Males and females defend separate territories until late January or February, just prior to the insect bloom, at which point they begin to defend territories as pairs. The insect biomass doubles from the time of egg-laying, in mid-March, to the incubation and nestling stages, in late March and April. Berry abundance, however, declines during this period, and nearly all adults and juveniles depart by the time the mistletoe berries are depleted, in May.

In April and May, meanwhile, Phainopeplas start to arrive in riparian woodlands, in localities ranging from several kilometres to hundreds of kilometres from the desert. Rather than defending territories here, they cluster in loose colonies of 3–15 pairs. In southern California, redberry bushes begin to produce ripe fruits in late May. Although insect mass decreases from the pre-laying period to the post-laying period, berry abundance increases dramatically at this time. In this habitat, the Phainopeplas lay eggs primarily during the first weeks of June. By August, few *Rhamnus* berries remain, thus bringing the summer breeding season to a close.

There are notable similarities in social behaviour between the Long-tailed Silky-flycatcher and Phainopeplas nesting in riparian woodlands. Both species breed in loose colonies, which are separated from each other by a distance of 400 m or more. Within these colonies, the nests are 25–200 m apart. Although the breeding pair defends a small area around the nest, individual pairs forage without aggression at nearby fruiting shrubs clustered in open areas away from the trees where they nest.

Silky-flycatchers are socially monogamous. Little is known about the courtship and breeding habits of the Grey Silky-flycatcher and the Black-and-yellow Silky-flycatcher. The behaviour of the Phainopepla, on the other hand, is better known. In the desert, this species engages in courtship flights in which one or two males fly over their respective territories, in a circling or zigzagging pattern, for periods ranging from 15 seconds to as long as seven minutes, and as many as nine Phainopeplas may join the flight. Courting individuals will also gather in a large

tree and remain there for up to 20 minutes; 14 Phainopeplas have been recorded at such assemblies.

During the courtship and nest-building stages, the male Phainopepla offers gifts of berries or insects to his mate, as also does the male Long-tailed Silky-flycatcher. The males of these two species initiate nest-building, but both sexes contribute in later stages of the construction work. Male Phainopeplas display by descending to the nest-site with exaggerated fluttering wingbeats. During the nest-building process, the partners take turns in shaping the nest. From time to time they exchange soft vocalizations, and make rapid clicking sounds with the bill.

The members of this family build open cup-nests in shrubs, trees or cacti. The Phainopepla and the Grey and Long-tailed Silky-flycatchers often place their nests in a shrub, in the fork of a tree, or on a horizontal branch. They sometimes build nests in locations that blend in with the surroundings, but in sites that may not be well concealed by foliage. Grey and Long-tailed Silky-flycatchers use lichens in the construction of their nests, perhaps as a means of camouflage.

Almost all known nests of ptilogonatids have contained two eggs, the sole exception being the nests of Phainopeplas, which may contain two, three or, rarely, four eggs. The average clutch size of the last-mentioned species is greater in years with heavier rainfall, and is higher in riparian woodland than it is in the desert. The eggs of all four species are pale grey or greyish-white, with a sprinkling of brown and lilac spots over the surface; those of the Phainopepla and the Grey and Long-tailed Silky-flycatchers sometimes have a band of markings near the large end. The eggs of Black-and-yellow Silky-flycatchers are relatively blunt and larger than those of the other members of the family, but are otherwise similar in appearance.

Little else is known about the breeding behaviour of this family, and details are available for only two species. In the case of the Phainopepla, both sexes contribute about equally to the duty of incubation, which lasts for 14 days. The incubation period for the Long-tailed Silky-flycatcher is 16–17 days, and the female does all of the work. On hatching, the chick of the latter species has compact tufts of whitish down in neat rows, separated by larger areas of dark bare skin, whereas the Phainopepla hatchling has scant white down and greyish-black skin; the bill is black, the edges of the mouth are yellow, and the eyes are closed. Both parents feed the young, and both also keep the nest clean by consuming the nestlings' faecal sacs. The nestling stage is long for songbirds, 20 days in the case of the Phainopepla and 24–25 days in the Long-tailed Silky-flycatcher. The chicks of these two species, as they approach the time of fledging, usually sidle out from the nest on to nearby branches, but they then return to the nest for a further day or two before leaving for good.

Recorded nest predators of Long-tailed Silky-flycatchers include the Prong-billed Barbet (*Semnornis frantzii*), the Emerald Toucanet (*Aulacorhynchus prasinus*) of the blue-throated subspecies *caeruleogularis*, and the Brown Jay (*Cyanocorax morio*). Nests of Phainopeplas are preyed on by snakes, by the Loggerhead Shrike, by the Western Scrub-jay and by the Common Raven (*Corvus corax*). Brown Jays and Common Ravens may be coming into greater contact with silky-flycatchers as a result of deforestation and development.

The breeding success of Phainopeplas varies with annual rainfall. The number of individuals that do not attempt to breed increases in years with low or sparse rainfall, as it does also when the mistletoe crop fails because of drought or freezing temperatures. Low total productivity in the desert is accounted for mainly by high numbers of non-breeders, whereas predation is the primary cause of poor breeding success in coastal riparian woodlands. It is possible that, in southern California, brief nesting periods and unpredictable events such as drought have selected for opportunistic breeding in response to regionally and temporally shifting food supplies.

Movements

Ptilogonatids do not undertake any long movements. All are either residents or short-distance migrants. The Black-and-yellow Silky-flycatcher remains throughout the year in the forests of Costa Rica and Panama. During the non-breeding season, it associates in small, loose flocks, some of which occasionally descend to lower elevations during the winter months. Similarly, the Grey and Long-tailed Silky-flycatchers are resident, but they, too, leave their nesting sites after the breeding season and roam adjacent areas in loosely integrated groups. Both breed in montane habitats in Middle America, and, as the previous species, they sometimes make post-breeding movements downslope in some regions. This applies particularly to the Grey Silky-flycatcher, which may vacate the north-west part of its Mexican range during the winter months.

The Phainopepla is the only species that regularly undertakes migrations, moving between desert and woodland habitats that may be separated by only a few kilometres or by hundreds of kilometres. In Mexico, these migratory movements are poorly understood, but at least some populations appear to move southwards to spend the winter in central Mexico.

Straggling flocks of ptilogonatids can contain dozens of individuals. Often, several will perch in the same tree or group of trees, and then the flock departs in small groups, all heading in the same general direction. Rarely, flocks of as many as 200 Phainopeplas or Grey Silky-flycatchers have been reported.

Relationship with Man

Silky-flycatchers are often found in remote areas, such as deserts and wind-swept mountains, but they sometimes settle close to human habitation where food and nest-sites are available. In Costa Rica, for example, Long-tailed Silky-flycatchers can be abundant on highland farms, where they forage and breed in pastures with scattered trees. In the south-western USA, Phainopeplas sometimes nest in orchards or in suburban backyards where fruiting trees and shrubs have been planted. If they are responsible for any damage to these plants, this seems not to have brought them into any conflict with man's interests.

With the exception of the Black-and-yellow Silky-flycatcher, the ptilogonatids are bold and conspicuous birds, usually showing little fear of humans. They are often considered pleasing because of their elegant plumage, their fluttering flight in pursuit of insects, and their expressive vocalizations and body postures, including the raising and lowering of the crest.

*The **Phainopepla** spends much of its time eating berries, specializing at some sites on the desert mistletoe* Phoradendron californicum, *so much so that its digestive system has adapted to process large quantities of this item efficiently. As with other mistletoes, the seeds are extremely sticky, forcing Phainopeplas to regurgitate them and wipe them on nearby branches, where they germinate. Thus the behavioural pattern of the birds determines the distribution of the plants, and vice-versa: Phainopeplas typically perch in the canopies of tall desert trees, the crowns of which become festooned with mistletoes.*

[*Phainopepla nitens lepida*, California, USA. Photo: Herbert Clarke]

*Like other silky-flycatchers, the **Long-tailed Silky-flycatcher** builds an open cup-shaped nest, usually in an upright tree fork or balanced on top of a branch, as seen here. These nests are often ill-concealed by foliage, but profusely covered in lichen, presumably as camouflage. They are frequently clustered in loose colonies, with gaps of 25–200 m between each nest, and only a relatively circumscribed area defended by each individual pair. The usual clutch is of two eggs.*

[*Ptilogonys caudatus*, San Gerardo de Dota, Cordillera de Talamanca, Costa Rica. Photo: Marco Saborío]

As mentioned previously (see Food and Feeding), silky-flycatchers are important seed-dispersers. It is very likely that they play a significant role in the distribution of certain berry-producing plants, especially mistletoes, in the habitats that they occupy and, as a consequence, influence the distribution not only of such plants, but also of other animals dependent on the flora in question.

Status and Conservation

Silky-flycatchers are often abundant in appropriate habitats, and none of the four species is globally threatened. Nevertheless, because their global populations are small and their ecological requirements specific, the destruction of their habitats is a matter of long-term concern.

Black-and-yellow Silky-flycatchers are perhaps the most vulnerable. This species is fairly common to rather uncommon, and is restricted to high elevations on isolated mountain ranges disturbed by periodic volcanic activity. The three subspecies of the Black-and-yellow Silky-flycatcher inhabit mountain ranges separated by deep valleys. The north Costa Rican subspecies, *parkeri*, is found only in the cordilleras of Tilarán and Guanacaste, where it is confined to the upper levels above 1550 m. These mountain ranges are no more than 40 km long and 80 km long, respectively. An estimated 5820 hectares of suitable habitat are available for this taxon in the Cordillera de Guanacaste, where it is absent, rare or uncommon on five volcanoes and abundant only in the subalpine habitat of the Miravalles Volcano. In the Tilarán Range, there are 11,970 hectares of suitable habitat, and on Monteverde the silky-flycatchers are rare in upper montane forest and abundant in the subalpine zone. It is worth pointing out that, in this context, "rare" indicates that just one individual is likely to be recorded in a period of two days; "uncommon" means that 1–4 individuals would be seen in six hours, and "common" means that 5–10 can be expected in that same timespan. A taxon is considered "abundant" if the observer can reckon on finding more than ten individuals in six hours of observation.

Farther south in Costa Rica, the nominate race of the Black-and-yellow Silky-flycatcher is found on the larger Talamanca and Volcánica Central mountain ranges, where it is absent to abundant on various volcanoes in the upper montane forest and rare to abundant in subalpine forest. The estimated area of suitable habitat in the Talamanca Range is 153,750 hectares, with a further 37,705 hectares in the Cordillera Volcánica Central. There is little information on the population status of the third subspecies, *minor*, which occurs in western Panama, but it appears to be rare to uncommon in west Chiriquí.

Population levels of the Black-and-yellow Silky-flycatcher are influenced by volcanic activity, which destroys vegetation, and by windstorms and past deforestation, which create second-growth habitat suitable for nesting. This species occurs in low numbers on massifs that have experienced frequent and widespread volcanic disturbance. It is rare on the Irázu Volcano, which erupted in 1963, destroying vegetation at high elevations, but it is abundant on the Turrialba Volcano, which has been inactive since 1866. Black-and-yellow Silky-flycatchers may reside on active volcanoes, such as that of Poás, where mountain passes facilitate recolonization from nearby areas and where patterns of volcanic eruption have allowed areas with appropriate vegetation to persist.

The Grey Silky-flycatcher, while not considered globally threatened, is included on the "Partners in Flight Watchlist" as a species of medium conservation concern. Grey Silky-flycatchers are sometimes exported from Mexico to Europe for the cagebird trade, although the demand is lower than that for parrots (Psittacidae), and is also not so high as that for other songbirds, such as *Passerina* buntings (Cardinalidae). In 2003/04, trappers were authorized to harvest a total of 4130 Grey Silky-flycatchers. Estimates suggest that, during 21 years of legal trade, at least 92,140 individuals of this species have been taken from the wild.

Current threats faced by the Long-tailed Silky-flycatcher include loss of highland forest in Costa Rica and Panama. The main causes of this are burning, logging and agricultural expansion. Of particular concern is the fact that Panama's highland forests are largely unprotected. This species is still reasonably common, but acceleration of habitat destruction within its restricted range could render it vulnerable in the long term.

"Partners in Flight" lists the Phainopepla as a species in need of stewardship. In the south-west USA, Phainopeplas in southern California and Arizona inhabit deserts and riparian woodlands that are increasingly threatened by housing development and agricultural expansion. As they depend on both habitats for breeding (see Habitat, Breeding), the protection of both is important for the future survival of the species.

Genus *PHAINOPTILA* Salvin, 1877

1. Black-and-yellow Silky-flycatcher

Phainoptila melanoxantha

French: Phénoptile noir et jaune **Spanish**: Capulinero Negrigualdo
German: Gelbflanken-Seidenschnäpper
Other common names: Salvin's Silky-flycatcher, Phainoptila

Taxonomy. *Phainoptila melanoxantha* Salvin, 1877, San Francisco, Costa Rica.

Inclusion in present family questioned by some authors, who have pointed out this species' similarity to members of Turdidae and dissimilarities between it and other ptilogonatids in morphology and habits; further research, including DNA analyses, required. Three subspecies recognized.

Subspecies and Distribution.

P. m. parkeri Barrantes & Sánchez, 2000 – cordilleras of Tilarán and Guanacaste, in N Costa Rica.
P. m. melanoxantha Salvin, 1877 – cordilleras of Talamanca and Volcánica Central, in C & S Costa Rica.
P. m. minor Griscom, 1924 – W Panama (E to Veraguas).

Descriptive notes. 20·5–21·9 cm; 56–60 g. Unusual ptilogonatid, appearance like that of thrush (Turdidae), with tail shorter than wing, bill relatively large compared with that of others in family, no crest. Male nominate race is black on head, neck, back, uppertail-coverts, wings and tail, bright yellow on rump; below, black upper chest and thighs, yellowish olive-green upper breast and undertail-coverts, lower breast and belly grey, bright yellow sides and flanks; iris dark brown or dull red; bill and legs black or brownish-black. Female is black on top of head from bill to nape, grey on hindneck, face and throat, otherwise olive-green instead of black, rump duller than male.

Juvenile is generally duller than female, top of head to nape sooty grey, little or no yellow on flanks, plumage looser in texture. Race *parkeri* has shorter wing and tail than nominate, male completely yellow belly (rather than grey) and yellow undertail-coverts, female faint yellowish streaks on greenish-olive breast; *minor* is similar to nominate but slightly smaller, with longer bill, female has darker, more extensive grey on hindneck, greener (less yellow) rump, uppertail-coverts, and edgings of tail feathers. Voice. Thin, high-pitched "tsip" call, sometimes uttered in twitters. Not known to sing.

Habitat. Evergreen subalpine and elfin forests, with fruiting plants such as Araliaceae, Melastomataceae, Rubiaceae and Ericaceae; also, to lesser extent, montane forest with natural gaps and second-growth areas with vegetation similar to that of subalpine forest. 1000–3400 m.

Food and Feeding. Primarily frugivorous; eats small fruits of at least 40 plant species from 36 genera, including *Schefflera*, *Clusia*, *Erythroxylum*, *Myrsine*, *Psychotria*; fruit fed to fledglings. Some insects also taken, but few details. Forages sluggishly in trees, shrubs and epiphytes, from lowest levels of forest understorey up to canopy. Plucks berries while perched; swallows berries whole, voids seeds intact. During breeding season, observed to pluck "small creatures" from foliage and to capture aerial insects by flying out from exposed branches.

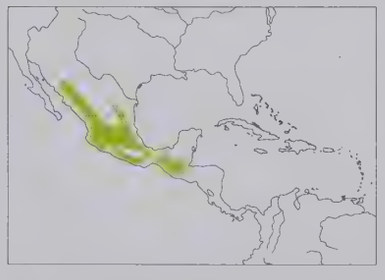
Breeding. Peak Mar–May; empty nests found in Apr, eggs in May, fledglings in Jun; adult moult late Jun. Monogamous; solitary nester. Open cup-nest mostly of green moss interspersed with slender stems and fern fronds, lined with fine rootlets and plant stems, outer diameter 22 × 16 cm, height 12 cm, inner cup 7 cm across and 5 cm deep, typically placed within 2–4 m of ground in crotch of sapling. Clutch 2 eggs; no information on incubation and fledging periods, nor on respective roles of sexes.

Movements. Resident. Moves between patchily distributed fruit sources; in small, loose flocks during non-breeding season, when occasionally moves downslope.

Status and Conservation. Not globally threatened. Restricted-range species: present in Costa Rica and Panama Highlands EBA. Uncommon to fairly common in Costa Rica above 1200 m (in N cordilleras) and 1800 m (in C & S ranges); race *parkeri* restricted to Cordilleras de Tilarán and Guanacaste, where fewer than 18,000 ha of suitable habitat remain. Abundance low on massifs with frequent, widespread volcanic disturbance. In Panama, rare to uncommon above 1650 m in W Chiriquí; local in C & E Chiriquí and Veraguas. Considered vulnerable over the long term because of restricted range in mountains of S Central America; burning of forests, logging, and agriculture have contributed to widespread habitat destruction in this region. A major disperser for fruiting plant species in treefall areas.

Bibliography. Angehr (2003), Anon. (1998b), Barrantes & Loiselle (2002), Barrantes & Sánchez (2000), Blake (1958), Hellmayr (1935), Kiff (1979), Murray (1988), Ridgely & Gwynne (1989), Ridgway (1904), Skutch (1965a), Slud (1964), Stiles (1985), Stiles & Skutch (1989), Stotz *et al.* (1996).

Genus *PTILOGONYS* Swainson, 1827



2. Grey Silky-flycatcher

Ptilogonys cinereus

French: Ptilogon cendré **German**: Grauseidenschnäpper **Spanish**: Capulinero Gris
Other common names: Grey Silky

Taxonomy. *Ptiliogonys* [*sic*] *cinereus* Swainson, 1827, Real del Monte, Hidalgo, Mexico.
Generic name in original description spelt as "*Ptiliogonys*", apparently in error by author, who had earlier described the genus by its current name (which he subsequently used) in what seems to have been an unpublished manuscript. This species may form a superspecies with *P. caudatus*. Four subspecies recognized.

Subspecies and Distribution.
P. c. otofuscus R. T. Moore, 1935 – NW Mexico.
P. c. cinereus Swainson, 1827 – C & E Mexico.
P. c. pallescens Griscom, 1934 – SW Mexico.
P. c. molybdophanes Ridgway, 1887 – S Mexico (Chiapas) and W Guatemala.

Descriptive notes. 18·5–21 cm. Slender, with prominent crest and long tail. Male nominate race has blue-grey head (including crest) and upperparts, dusky lores; flight-feathers and tail black, white band across base of tail extending about halfway down length of feathers (except for central pair); dull white or brownish-white chin and supraloral and malar regions, grey throat and chest, whitish belly, golden-olive or yellow flanks, bright yellow undertail-coverts; iris dark, narrow white eyering; bill and legs black. Female has grey head and crest, greyish-brown upperparts, brown sides and flanks, belly white. Juvenile resembles female, but paler below. Race *molybdophanes* is darker than nominate, male deeper bluish-grey above, olive colour on flanks more restricted and olive-green (instead of golden-olive), female also darker except for yellow of undertail-coverts; *otofuscus* is most similar in colour to previous, but with lighter upperparts, darker auriculars, grey of underparts not extending so far on belly, female with greyer back, lighter rump and uppertail-coverts and darker breast than nominate; *pallescens* is similar to nominate but paler and greyer, male chin, throat and supraloral greyish-white (rather than brownish-white), auriculars greyer and less brown, female also paler and less brown, with grey cap and throat contrasting more sharply with back and breast. Voice. Loud "tu whip, tu whip", second note higher in pitch and more emphatic; dry "chi-che-rup che-chep", and nasal "k-lik"; rattling note in flight. Quiet song a warbled series of "chuck" notes, high "seep" notes and quiet whistles.

Habitat. Montane pine (*Pinus*), oak (*Quercus*) and juniper (*Juniperus*) forests, ranging into open areas with scattered trees; 1000–3500 m, lower in winter.

Food and Feeding. Insects and berries. Berries of mistletoes (Loranthaceae) especially important; numbers of present species vary with abundance of ripe fruits of the mistletoe *Psittacanthus schiedeanus*. Other fruits consumed include *Monnina xalapensis* and *Eurya theoides*. Captures aerial insects by sallying from a perch.

Breeding. In Mexico, two nests under construction in late May in Tamaulipas and nest with chicks in Jun in Morelos. Open cup-nest of oak catkins, coarse black hairs and vegetation, interior padded with stiff *Usnea* lichens (lining lacks grasses or long plant stems), large pieces of foliose lichen attached with cobwebs to exterior, placed 9 m up in oak tree. Clutch 2 eggs; no information on incubation and fledging periods.

Movements. Generally resident. Some downslope movement in winter, when also wanders into adjacent habitat; may vacate NW Mexico, recorded as visitor near Alamos (S Sonora) and San Blas (Nayarit). In cloudforest near Xalapa, in Veracruz (E Mexico), common at 1300 m, in pairs or groups of 3–6 individuals, during Nov–Mar. Vagrant to USA.

Status and Conservation. Not globally threatened. Common to fairly common in much of range; uncommon in NW Mexico (Sonora). Found in 32 Important Bird Areas, including seven protected areas, in Mexico. Not at any apparent risk, but cause for long-term concern because of globally restricted range. Listed on "Partners in Flight Watchlist", considered of medium conservation concern. Legal harvest for cagebird trade surpasses 4000 individuals annually. An important disperser of mistletoe in cloudforest remnant near Xalapa (Veracruz), in Mexico.

Bibliography. Anon. (1998b), Binford (1989), Blake (1953), Browning (1989), Cota-Campbell & Ruiz-Campos (1995), Dearborn (1907), Forcey (2002), Gómez de Silva *et al.* (1999), Hellmayr (1935), Howell & Webb (1995), Kaufman (1996a), Land (1970), Lasley & Pincelli (1986), López & Ornelas (1999, 2001), Lowery & Dalquest (1951), Newman (1950), Ridgway (1904), Rowley (1966), Skutch (1965a), Stotz *et al.* (1996), Yanega (1996).

3. Long-tailed Silky-flycatcher

Ptilogonys caudatus

French: Ptilogon à longue queue **Spanish**: Capulinero Colilargo
German: Langschwanz-Seidenschnäpper

Taxonomy. *Ptilogonys caudatus* Cabanis, 1861, Irazú, Costa Rica.
May form a superspecies with *P. cinereus*. Monotypic.

Distribution. Costa Rica and W Panama (E to Veraguas).

Descriptive notes. Male 23·7–24·4 cm, female 20–21 cm; 37 g. Slender, with prominent crest and long tail, central pair of rectrices extending beyond the rest. Male has forehead and crown grey, rest of head, crest and neck yellowish olive-green, throat tinged with grey; back, rump, uppertail-coverts and upperwing-coverts bluish-grey; flight-feathers and tail black, inner webs of tail feathers (except two central pairs) with large white patch on middle portion; breast and upper belly slightly paler grey than back, sides, flanks and lower belly yellowish olive-green, undertail-coverts bright yellow; iris dark, narrow yellow eyering; bill and legs black. Female is duller than male, with head, neck and crest paler yellowish olive-green, back, rump, uppertail-coverts, wing-coverts, breast and upper belly olivaceous grey (instead of bluish-grey), duller greenish-yellow on flanks, lower belly yellowish-white, undertail-coverts dullish yellow, shorter and duller tail. Juvenile is light greyish-brown with brownish bill and feet, whitish eyering; uppertail-coverts darker brown, underparts paler, undertail-coverts pale yellow with greyish bases. Voice. Call a sharp, dry "che chip, che chip", likened to sound of loose pebbles in a box when uttered by a flock; in flight, a rattling "che-e-e-e-e" or bell-like tinkling note. When threatened at nest, sometimes imitates calls of other bird species, e.g. American Mountain Thrush (*Turdus plebejus*). Sings with low lisping notes punctuated by louder "che chip" notes.

Habitat. Open montane habitats, such as secondary forest and pasture with scattered trees bordered by wooded ravines; 1800–3000 m.

Food and Feeding. Insects and small fruits; fruits include berries of fiddlewood (*Citharexylum*), the fuchsia *Fuchsia arborescens*, and the mistletoe *Eurya theoides*. Both insects and berries fed also to nestlings. Plucks berries while perched, and swallows them whole. Catches insects in air, often in long sallies from a high perch; when collecting food for nestlings, may twist and turn in air, capturing numerous insects before returning to nest.

Breeding. Apr–Jun. Monogamous; solitary or loosely colonial, may nest in groups of 2–5 pairs, defends small area around nest. Male begins construction of nest, both sexes contribute later, male feeds mate during building; nest a broad bulky open cup constructed primarily of pale grey beard-lichen (*Usnea*), bound with caterpillar silk or cobwebs, unlined interior smooth and hard (as though coated with plaster), outer diameter 11·4–12·7 cm, height 5–6·4 cm, inner cup 5·7–6·4 cm across and 4·1 cm deep; placed 2–18 m (average 7 m) up in fork or on stout horizontal branch of tree, sometimes in exposed location. Clutch 2 eggs; incubation by female, fed by male on or near nest, period 16–17 days; nestlings brooded by female, fed by both sexes with insects, also with increasing proportion of fruit as they grow older; chicks leave nest 24–25 days after hatching, by sidling out on branch, but may return to it for a day or two. Fledging success at 15 nests 27%; predators include Brown Jay (*Cyanocorax morio*).

Movements. Resident. During non-breeding season, ranges through forests and pastures in widely straggling flocks; occasionally wanders to lower elevations.

Status and Conservation. Not globally threatened. Restricted-range species: present in Costa Rica and Panama Highlands EBA. Common in appropriate habitats in mountain ranges of Volcánica Central and Talamanca. Not at any risk in most of range, but cause for long-term concern because of restricted distribution and small global population. Highland forests in Costa Rica and Panama have suffered widespread destruction as a result of burning, logging and agricultural expansion.

French: Phénopèple luisant **German**: Trauerseidenschnäpper **Spanish**: Capulinero Negro

Taxonomy. *Ptilogonys nitens* Swainson, 1838, Mexico.
Earlier suggestion of relationship with the turdine genus *Myadestes* contradicted by DNA–DNA hybridization data. Two subspecies recognized.
Subspecies and Distribution.
P. n. lepida Van Tyne, 1925 – SW USA and NW Mexico.
P. n. nitens (Swainson, 1838) – S USA (S Texas) S to S Mexican plateau.

Descriptive notes. 18–21 cm; 22 g. Slender, with prominent crest and long tail. Male is glossy black, with white wing patches (visible in flight or when wing extended); iris red; bill and legs black. Female has plumage grey, wing patch pale grey. Juvenile is similar to female but more brownish, with brownish iris; immature male varies from nearly entirely grey, as female, to black, as adult male, with intermediate plumages a mottled mix of grey and black. Race *lepida* has slightly shorter wing and tail than nominate. Voice. Contact call a mellow rising "wurp"; harsh "churr" note during chases and aggressive encounters. Song multisyllabic, with at least 14 different elements, including loudly whistled "wheedle-ah"; rambling quieter song with warbles, chucks and high-pitched whistles. When threatened at nest, imitates vocalizations of other bird species, including e.g. Red-tailed Hawk (*Buteo jamaicensis*), Northern Mockingbird (*Mimus polyglottos*), Northern Flicker (*Colaptes auratus*); when handled, loud distress calls and mimicry, recorded as imitating at least twelve species.
Habitat. In SW USA, occupies deserts in Oct–Apr and riparian woodland in May–Sept; highest densities in Sonoran Desert (Arizona) during winter. Abundant in desert washes with leguminous trees and shrubs such as palo verde (*Cercidium*), mesquite (*Prosopis*) and acacia (*Acacia greggii*) parasitized by desert mistletoe (*Phoradendron californicum*); summer riparian-woodland habitat dominated by oak (*Quercus*) and sycamore (*Platanus racemosa*), with fruiting shrubs such as redberry (*Rhamnus*) and elderberry (*Malosma laurina*). In Mexico, inhabits arid to semi-arid habitats with scattered trees and bushes, and riparian washes.
Food and Feeding. Small berries and flying insects. Nestling diet as adult's. Forages at variety of fruiting shrubs with small berries (less than 5 mm in diameter). Berries of desert mistletoe usually the single major food source from Oct to end Apr in desert; behaviourally and morphologically adapted to handle and digest these sticky berries, which are swallowed whole, then passed one by one from crop to gizzard, where skin removed; after 12-24 berries processed, all skins are ejected together. Fruits of redberry, blue elderberry (*Sambucus mexicanus*) and sumac (*Rhus*) eaten in coastal woodlands. Sallies from perch to capture insects, sometimes fluttering or changing direction erratically in pursuit of prey; sometimes flycatches aerially in groups. Rarely observed to drink water, even in desert.
Breeding. Nesting seasons in USA brief, coinciding with availability of fruit and insects, Feb–Apr in desert and May–Jul in riparian woodland (unknown whether same individuals breed in both habitats, but timing of movements consistent with this possibility); breeds Apr–Aug in Mexico. Monogamous, but mates usually not retained in successive years. In SW USA, territorial in desert (mistletoe berries and nest-sites simultaneously defensible), but loosely colonial, and defending only area immediately around nest, in riparian woodland (fruiting bushes and nesting sites spatially separated). Male presents female with berries or insects during courtship, also initiates nest construction at this time, and displays by approaching nest-site with fluttering flight; both sexes make rapid snapping noises with bill while shaping nest. Nest an open cup made of stems, small twigs, plant fibres and spider silk, placed 2–5 m above ground in fork of branches, on horizontal branch, or within clump of mistletoe, in palo verde, mesquite, acacia, willow (*Salix*), oak, sycamore, rarely in cactus. Clutch 2–3 eggs, rarely 4, typically 2 in desert but sometimes 3 in wet years, average clutch size slightly larger in woodland than in desert; may renest if first nest fails; incubation by both sexes, period 14 days; nestlings fed by both parents, contribution of male variable, chicks leave nest 20 days after hatching, may initially hop through vegetation and return to nest. Success highly variable, associated with differences in rainfall; some pairs in desert do not breed in drought years or when mistletoe crop fails. First breeding when at least 9 months old. Twenty-five percent of ringed breeders returned to study site within 2 years.
Movements. Short-distance migrant in USA; leaves desert late Mar to early May (timing dependent on food supply), arrives in riparian woodland from a few kilometres to 1200 km away in Apr and May, returns to desert in Oct; occasional stragglers remain in summer breeding range during winter. In Mexico, migratory in some regions; non-breeding grounds in C Mexico.
Status and Conservation. Not globally threatened. Fairly common. Estimates of numbers suggest that population declines have occurred, in USA at least, as a result of habitat loss associated with agriculture and development. Extensive areas of honey mesquite were abundant in lower Colorado Valley (California–Arizona border) during early 1900s, and were probably among the most important wintering and breeding areas for this species; only a single large stand now remains between Ehrenberg and Parker, in Arizona. In Mexico, occurs in 32 Important Bird Areas, including seven protected areas. Listed by "Partners in Flight" as a species in need of stewardship. An important disperser of mistletoe, influencing patchy distribution of plant parasite on host plants.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family BOMBYCILLIDAE (WAXWINGS)

- Medium-sized songbirds with soft dense plumage, short broad bill, pronounced crest, black mask and coloured band on tail.
- 15–23 cm.

- Holarctic, ranging south into northern Neotropical.
- Deciduous and coniferous forests, mainly in broken or edge habitats.
- 1 genus, 3 species, 6 taxa.
- No species threatened, none extinct since 1600.

Systematics

The waxwings make up a small group of three closely related species. The major taxonomic debate surrounding this family has centred on the question of which, if any, of their presumed relatives should be included within its boundaries. Most authors have agreed that the waxwings are closely related to the silky-flycatchers (Ptilogonatidae), and the two groups have often been treated as subfamilies within the Bombycillidae. The Palmchat (*Dulus dominicus*) has also been regarded as a relative, and is sometimes included in the waxwing family. More tentatively, the Hypocolius (*Hypocolius ampelinus*) has been treated by some as another subfamily within Bombycillidae. Finally, some taxonomists have associated the wood-swallows (Artamidae) with the waxwings, but this association has not been generally accepted. There are few paleontological data on which to base conclusions. Specimens of *Bombycilla* are known, however, from Pleistocene deposits in California and Holocene deposits in Illinois, both in the USA.

DNA–DNA hybridization studies by C. G. Sibley and J. E. Ahlquist indicated that the silky-flycatchers and the Palmchat are rather closely related to the waxwings, and that they deserve separation only into tribes and not as distinct subfamilies. The silky-flycatchers appeared to be closer to the waxwings than is the Palmchat. Unfortunately, it was not possible to test whether the Hypocolius is genetically similar to this group, as DNA material of this species was not available. Sibley and Ahlquist's work also suggests that the waxwings are part of a larger group that includes the dippers (Cinclidae), the thrushes (Turdidae), the starlings (Sturnidae) and the mockingbirds, thrashers and allies (Mimidae), but that they are not particularly closely related to any of these families. Their data contradict the idea of an association with the wood-swallows, or any particular relationship with the solitaires of the genus *Myadestes*, an association suggested by their earlier studies of egg-white proteins. Recent analyses of gene sequence data from nuclear and mitochondrial genes have tended to support the pattern of relationships suggested by the DNA-DNA hybridization studies. The most detailed phylogenetic information available from this research confirms the close relationship of at least the silky-flycatchers to the waxwings, and suggests that the expanded waxwing family forms a sister group to a larger assemblage comprising the thrushes and dippers, as well as the closely related starlings and mockingbirds.

Among the three waxwings, there is one principal question with regard to systematics. Which two of the species are the most closely related? On the basis of a number of shared traits, such as similar body size, the markings on the primaries, a greyish belly and contrastingly coloured undertail-coverts, it appears likely that the Japanese Waxwing (*Bombycilla japonica*) and the Bohemian Waxwing (*Bombycilla garrulus*) share a more recent ancestor, while the Cedar Waxwing (*Bombycilla cedrorum*) is somewhat more distantly related. The possession of wax-like red tips on the secondaries of adults by the Cedar and Bohemian Waxwings (see Morphological Aspects) may appear to indicate a relationship between these two species, but Japanese Waxwings may, rarely, have small tips of this sort, suggesting that this trait has been secondarily lost in this species.

Three subspecies have been named for the Bohemian Waxwing and three for the Cedar Waxwing, all of them distinguished by subtle colour differences. These differences do, however, appear to be clinal in nature, at least in cases where the breeding ranges of the forms can be identified with a degree of accuracy. Indeed, it is often difficult to assign specimens to a particular subspecies with any confidence. Geographical variation within the Bohemian Waxwing involves only minor plumage differences. Furthermore, although the race described from central and eastern Siberia, *centralasiae*, is often noticeably paler, individuals from the eastern part of this range are often as dark as those of the nominate race, which breeds in Europe. In addition, the description of one of the races of the Cedar Waxwing, *aquilonia*, was based on wintering individuals of uncertain origin, and the slight colour differences ascribed to it do not seem reliable. While a total of five subspecies is currently recognized, three for the Bohemian Waxwing and two for the Cedar Waxwing, it could certainly be argued that none of these is worthy of recognition.

Morphological Aspects

Waxwings are medium-sized, slightly stocky songbirds, an appearance accentuated by the relatively short tail. They are nonetheless widely regarded as elegant birds in account of their upright posture, distinctive crest and sleek silhouette, the last due largely to the soft, dense and blended plumage.

The three species are similar in size. The Cedar Waxwing, at 15–18 cm, is the smallest, and the Bohemian Waxwing, with some birds as large as 23 cm, is the biggest. The Japanese Waxwing is perhaps slightly smaller than the Bohemian Waxwing, but closer in size to it than it is to the Cedar Waxwing. The sexes apparently

do not differ in size, although females may tend to be slightly heavier than males during the breeding season. Cedar Waxwings weigh on average about 33–34 g, while Bohemian and Japanese Waxwings typically weigh around 55 g.

Waxwings are short-necked and look somewhat plump, but they have fairly long and pointed wings which, when closed, extend about half-way down the rather short tail. The latter comprises twelve feathers of nearly equal length, although the folded tail may show a slight notch. The bill is short but fairly stout, with a convex culmen and gonys, and it has a slight hook and notch at the tip. Rictal bristles are rudimentary, even though it is not unusual for waxwings to engage in flycatching (see Food and Feeding). The gape is wide and deeply cleft to accommodate the larger fruits, such as cherries (*Prunus*), that are swallowed intact. The nostrils are almost concealed by short velvety feathers. The legs are short and are often not visible when the bird is perched, but the toes are strong. This arrangement is presumably useful in providing a secure grip when the bird stretches out, or even hangs upside-down, to reach fruit at the tip of a branch.

All three members of the family have a plumage that is predominantly of a soft vinous-brown colour, shading to grey in some areas, particularly on the flight-feathers. There is a black mask which begins in the velvety feathers near the nostrils and on the lores, continues back broadly to the eyes, and passes more narrowly over the eye and under the base of the crest. The throat is also marked by a black patch, and the larger size of this patch on the male Cedar Waxwing is perhaps the most reliable plumage difference between the sexes, although there may still be some overlap between them. Fine white lines set off the mask and throat patch to varying extents. All three species have a coloured band, bordered by black, across the tip of the tail. That of the Cedar and Bohemian Waxwings is bright yellow, whereas the tailband of the Japanese Waxwing is red. This band is apparently on average wider in older individuals, but it is subject to the effects of wear.

Both Bohemian and Japanese Waxwings have contrastingly coloured undertail-coverts, those of the former being cinammon-brown and those of the latter being of a brighter red. This area of the plumage is more weakly coloured on females, particularly in the case of the Japanese Waxwing. These two species also exhibit complex markings on their wings, although the details differ to some extent. Bohemian Waxwings have white tips on the primary coverts and on the outer webs of the secondaries, while the primaries have a yellow or yellow-and-white stripe along the outer webs and a white edge at the tip of the inner webs. Individuals in first-year plumage lack the white tips on the inner webs of the primaries, and the stripe on the outer web is usually paler or white. In the Japanese Waxwing, birds in the adult non-breeding plumage have only white or white-and-pink edging at the tips of the primaries, and lack a lengthwise stripe; immatures, however, have a bold white stripe along the primaries and no edging at the tip. In contrast to these two species, the wings of the Cedar Waxwing are mostly plain.

Juvenile waxwings differ from adults in a number of ways. They have a shorter crest, they lack the black throat patch, and the facial mask is less extensive. Their underparts are whitish with broad, blurry brownish streaks. Typically, they have no wax-like tips on the secondaries or, in the case of the Cedar Waxwing, only a few small ones, while the juvenile Bohemian Waxwing has a smaller number of such tips than do full adults.

Perhaps the most distinctive feature of the waxwings, and the one from which they have acquired their English name, is the red wax-like appendages that adorn the secondaries. These appendages are extensions of the feather shaft. They are flattened and are like an elongated teardrop in shape, with the pointed basal end inserted into the vane at the tip of the feather. The red coloration is due to astaxanthin, a carotenoid pigment. The frequency of these red tips varies among the three species. Almost all adult-plumaged Bohemian Waxwings have at least some wax-like tips on their secondaries, whereas about half of all adult-plumaged Cedar Waxwings lack these tips. In the case of the Japanese Waxwing, examination of specimens suggests that waxy tips are rare and occur only as small rudiments; instead, they are replaced by spots of bright red or pink on the tip of the outer vane of the secondaries, although these spots appear to be present primarily on males.

Much as waxwings are plump and stocky, their sleek plumage and debonair crests give them an air of elegance. This impression is accentuated by a neat black bib and mask, the latter swept upward behind the eye. Their wings are also crisply patterned, perhaps most impressively in the ***Bohemian Waxwing****, whose black flight-feathers are offset by yellow and white fringes. In adults, the secondaries are further adorned with elongated and flattened tips extending from the feather shaft. These unique appendages are bright red and appear waxy, giving the family its name.*

All waxwings have a stubby bill, stocky body and short tail, making their wings seem incongruously long and powerful. This trait no doubt equips them for rapid and sustained flight, a useful adaptation for their relatively long foraging trips, as well as migrations, and the longer irruptive flights they occasionally make. In the ***Bohemian Waxwing****, the tail is tipped with golden yellow and the vent is rich chestnut. In all members of the family, the legs are so short and sturdy as to be almost invisible when the bird is perched. Again, this design is perfectly suited to an arboreal lifestyle, and provides the strong grip necessary when stretching or dangling from branches in pursuit of berries.*

[*Bombycilla garrulus garrulus*, Helsinki, Finland. Photo: Markus Varesvuo]

The wax-like tips appear to function as indicators of age and perhaps also, in the case of the Bohemian Waxwing, sex. Adult male Bohemians usually have 6–8 tips on the secondaries of each wing, the longest ranging from 6 mm to 9·5 mm, whereas adult females normally have 5–7, with the maximum length 3–7·5 mm. Similarly, in the first-winter plumage, males typically have 4–7 tips per wing, while females usually have 2–5. With the Cedar Waxwing, the age differences seem more pronounced, perhaps because this species, in contrast to its two congeners, lacks the primary pattern that distinguishes young and older individuals; the sex differences, however, are less clear-cut. The overall pattern is for adult-plumaged Cedar Waxwings to fall into one of two categories: those having no tips or occasionally a very few small appendages, and those having a substantial number of larger tips, usually 7–8 on each wing. There are no obvious sexual differences in the distribution of waxes. Both males and females typically have no wax-like tips in their first-winter plumage and usually have 7–8 tips as full adults. With Cedar Waxwings, at least, individuals tend to pair up with others of similar age, as indicated by the number of waxy tips that they possess. The appendages may function in facilitating this assortative mating, or it may come about through other means. In any case, pairs in which individuals possess a larger number of wax-like tips tend to have greater reproductive success than do those with fewer such tips (see Breeding).

Rarely, waxwings may have wax-like tips on the tail feathers, or even on the primaries. The possession of wax-like tips on the tail feathers appears to be more frequent among Bohemian Waxwings than it is among Cedar Waxwings, and may be most likely to occur in older males. Another abnormal plumage condition is the occurrence of an unusually coloured tailband. Cedar Waxwings exhibiting a bright orange tailband have been noted since the 1960s. This coloration is apparently due to the consumption of the fruits of Morrow's honeysuckle (*Lonicera morrowii*), which contains the red carotenoid pigment rhodoxanthin. This pigment is deposited along with the normal yellow carotenoids, but only if the fruit is consumed around the time of tail moult. In some areas, this is more likely to occur while nestlings are developing the tail feathers than it is during adult tail moult, so that individuals with an orange tailband tend to be in juvenile or first-winter plumage.

Adult bombycillids undergo one complete moult each year, this taking place between August and December or January. Juveniles moult at the same time, but they retain their flight-feathers and some of their wing-coverts during this moult. Individuals in first-winter plumage, therefore, have a reduced number of wax-like tips on the secondaries, as in the juvenile plumage.

Habitat

Although waxwings are often described as being birds of forested habitats, they are certainly not typical of large unbroken tracts of wooded land. Rather, they are found in clearings or open woodland, at forest edges and in successional habitats, areas where the fruits on which they depend are most abundant. While trees are important for nesting sites and as perches, most of the fruits consumed by waxwings are produced on shrubs and bushes, or on small trees. For the Cedar Waxwing, these requirements may sometimes be met by small patches of riparian trees and shrubs in otherwise arid habitats, by orchards or by suburban gardens.

The Cedar Waxwing is a more southerly breeder and is generally associated with deciduous forest, while the Bohemian and Japanese Waxwings are typically found in coniferous forest during the summer season. These associations are not strict, however, and are probably a consequence of the species' breeding ranges and the predominant forest types found there, rather than indicating any strong preference for particular tree species. Bohemian Waxwings usually nest in conifers such as spruces (*Picea*), firs (*Abies*) or pines (*Pinus*), but they may breed instead in birch (*Betula*) forest. Cedar Waxwings most often place their nest in a deciduous tree or shrub of some sort, but also frequently use small pines, junipers (*Juniperus*), white cedars (*Thuja*) and spruces as nest-sites. Little is known about the specific breeding habitat of the Japanese Waxwing, other than that this species is typically found in coniferous forest including cedars and larch (*Larix*), and that berries are generally plentiful in the area. While foraging, waxwings will at times travel some distance from trees in search of strawberries (*Fragaria*), blueberries (*Vaccinium*) or other fruits that occur in open areas (see also Food and Feeding).

In the winter months, waxwings will exploit an even broader range of habitats. During this season, Bohemian and Japanese

Outside the breeding season waxwings are usually found in closely knit flocks, containing anything from a handful of birds up to 3000, in the ***Bohemian Waxwing****. In much of Europe and North America, this species is an irregular winter visitor, sometimes arriving in considerable numbers. During invasion years, flocks descend on ornamental fruit-bearing trees and shrubs in suburbs and city centres. Oddly tame and dramatically patterned, they make an unfamiliar sight, and small crowds of onlookers often gather to watch them feed. This they do voraciously, consuming vast quantities of fruit, before adjourning to a nearby treetop to digest.*

[*Bombycilla garrulus garrulus*, Kuusamo, Finland. Photo: Markus Varesvuo]

Waxwings can frequently be found in mixed or deciduous forests, as well as in coniferous ones. All three species often occur in suburban and even urban settings when there are fruits available on ornamental trees, especially in parks and gardens. In some areas, Cedar and Bohemian Waxwings rely heavily on the berries of junipers during the winter, and Cedar Waxwings reach high densities in portions of the south-eastern USA where junipers are abundant. Cedar Waxwings can also be found at this season in arid habitats dominated by such plants as California sagebrush (*Artemesia californica*). They also regularly winter well into the tropics, although they become less numerous as one proceeds south from the USA (see Movements). In the tropics, they occupy a variety of edge or semi-open habitats but seem to favour highlands, especially at the southern extremes of the non-breeding range.

Little has been written about the roosting sites used by this family. Bohemian Waxwings have been noted in flocks in pines during winter, and Cedar Waxwings, after they have finished nesting, apparently gather in flocks to roost in dense trees. During the late summer, Cedar Waxwings sometimes join large mixed-species roosts in deciduous woods. In spring and early summer a tendency to prefer sites near water may be particularly evident, as they rely more heavily on insects at this time of the year and may be observed as they make flycatching sallies for emergent insects (see Food and Feeding).

General Habits

The Bombycillidae are well known for their habit of displaying a high degree of gregariousness throughout most of the year. Outside the breeding season they are almost always found in flocks. These vary in size, but are often quite large. Those of the Bohemian Waxwing are probably the greatest in size. Winter flocks of this species in western Canada, for example, contain, on average, around 200 individuals, but flocks of over 1000 are regularly reported and gatherings of up to 3000 have been observed. Cedar Waxwings also form very large flocks on occasion, but parties of this species more often include fewer than 100 individuals. Japanese Waxwings are more likely to be seen in small groups, occasionally numbering up to 50 birds in non-breeding flocks. Where different species overlap in range, each tends to flock with members of its own species, but smaller numbers of the less common species are often found within flocks of the more numerous species.

Waxwings are fairly agile when clinging to twigs and branches, but they are restricted to short hops when on the ground. They do not spend much time on the ground, but they do visit it in order to bathe, drink, or eat snow, or occasionally to pick up fallen fruit.

The long, pointed wings make waxwings capable of relatively fast flight. The flight speeds of Cedar Waxwings carrying food to the nest have been estimated at 34–50 km/h. Short flights are relatively direct, with steady flapping. Over longer distances flaps are alternated with glides, but without any pronounced dips in the flightpath. Because of the waxwings' pointed wings and short tail, flocks in flight often resemble those of Common Starlings (*Sturnus vulgaris*) at a distance.

Except during the courtship or nesting periods (see Breeding), intraspecific aggression appears to be very subdued or non-existent in waxwing flocks. Captive Bohemian Waxwings have been noted as maintaining individual distances of 2·5–5 cm, and this seems to accord with observations of wild-living individuals in most circumstances. Although waxwings sometimes feed alongside other frugivores, such as American Robins (*Turdus migratorius*), without any obvious aggression, at other times there are conflicts. Waxwings are more often chased by larger thrushes and other species, but they may occasionally initiate chases themselves. Bohemian Waxwings have been observed to chase smaller species, such as the Eurasian Bullfinch (*Pyrrhula pyrrhula*) and tits (Paridae).

The large flock sizes of waxwings apparently allow them to overwhelm the defences of other birds that attempt to defend fruiting trees. An individual waxwing that has been chased can settle and return to foraging a short distance away, while the aggressor turns its attention to other members of the flock. This strategy may fail, however, and a Northern Mockingbird (*Mimus polyglottos*) has been known to kill a Cedar Waxwing that was part of a flock attempting to feed at a defended tree.

Outside the breeding season, waxwings gather at communal roosts. These are usually in trees with dense foliage, but other sites, such as hedges, may be used, and Bohemian Waxwings have been noted to roost in the sheltered spaces of buildings, or on the ground beneath dense cover. Roosts are sometimes shared with other bird species, such as Fieldfares (*Turdus pilaris*), Ameri-

Many aspects of waxwing morphology and behaviour are geared to their consumption of fruit. The bill and gullet, for example, are broad enough to accommodate large drupes, which are always swallowed whole, as demonstrated by this ***Cedar Waxwing****. Frugivory places further demands because winter fruits are high in sugars but low in water and nutrients. This intake upsets their osmotic balance, forcing them to drink often. It also means they must eat a tremendous amount to survive, and eating a lot means defecating a lot. A large flock of waxwings produces a constant rain of droppings that can be heard pattering on the ground.*

[*Bombycilla cedrorum cedrorum*, Dryden Lake, New York, USA. Photo: Marie Read]

can Robins and New World blackbirds (Icteridae). In very cold conditions, the birds may roost in contact with each other, or even on top of other individuals.

Maintenance of the soft, dense plumage is achieved by frequent preening. Head-scratching is accomplished by bringing the leg up over the partially extended wing. Captive Cedar Waxwings have been noted to bathe frequently.

Voice

The fact that the Bombycillidae lack a loud advertising song makes them unusual among passerine birds. This lack of a strong song should not be too surprising, however, as the absence of territoriality in these species, together with the fact that males and females are already in close proximity in flocks at the start of courtship, relieves waxwings of the usual reasons for proclaiming their presence. Despite this, waxwings are often quite vocal and utter many subtle variations of their high-pitched whistles and trilled call notes.

The vocal repertoire of the Cedar Waxwing is perhaps the best known of the three species, and can serve as a reference for comparing the calls of the two other members of the family. The most frequent call type is referred to as the "Bzee Call", although this term refers to a broad category of calls that seem all to be variations on a basic structure. This structure is a high-pitched trill, typically of about 7–8 kHz in frequency, consisting of closely spaced notes. One variant of the bzee call, referred to as "Social Call 1" or the "Location Call", is the usual vocalization heard from perched or feeding flocks, and is often given also in interactions between members of a pair. Many of the other call types, although simply variations on the basic structure of the bzee call, are nevertheless recognizable and may provide a clue to the behaviour of the birds. For example, during nest-building or courtship, pairs often give soft buzzing trills, which have been referred to as the "Contact Call" or the "Courtship Note". The food-begging calls given by fledglings, or directed by the female towards her mate during incubation, are particularly loud and intense variants of the bzee call. Soft trills of variable structure, referred to as the "Warbling Call", are occasionally given by waxwings during incubation or while quietly perched.

Other call types of the Cedar Waxwing take the form of high-pitched hissing whistles of relatively constant frequency, and can be collectively referred to as "Seee Calls". The most frequently heard variant in this category is the usual flight call of this species, known as "Social Call 2" or the "Flock Call". As well as being given in flight, it may be heard within perched flocks, and an increase in the frequency and intensity of these calls signals the imminent departure of the flock. The "Distress Call" has a similar structure, but it drops sharply in pitch at the end.

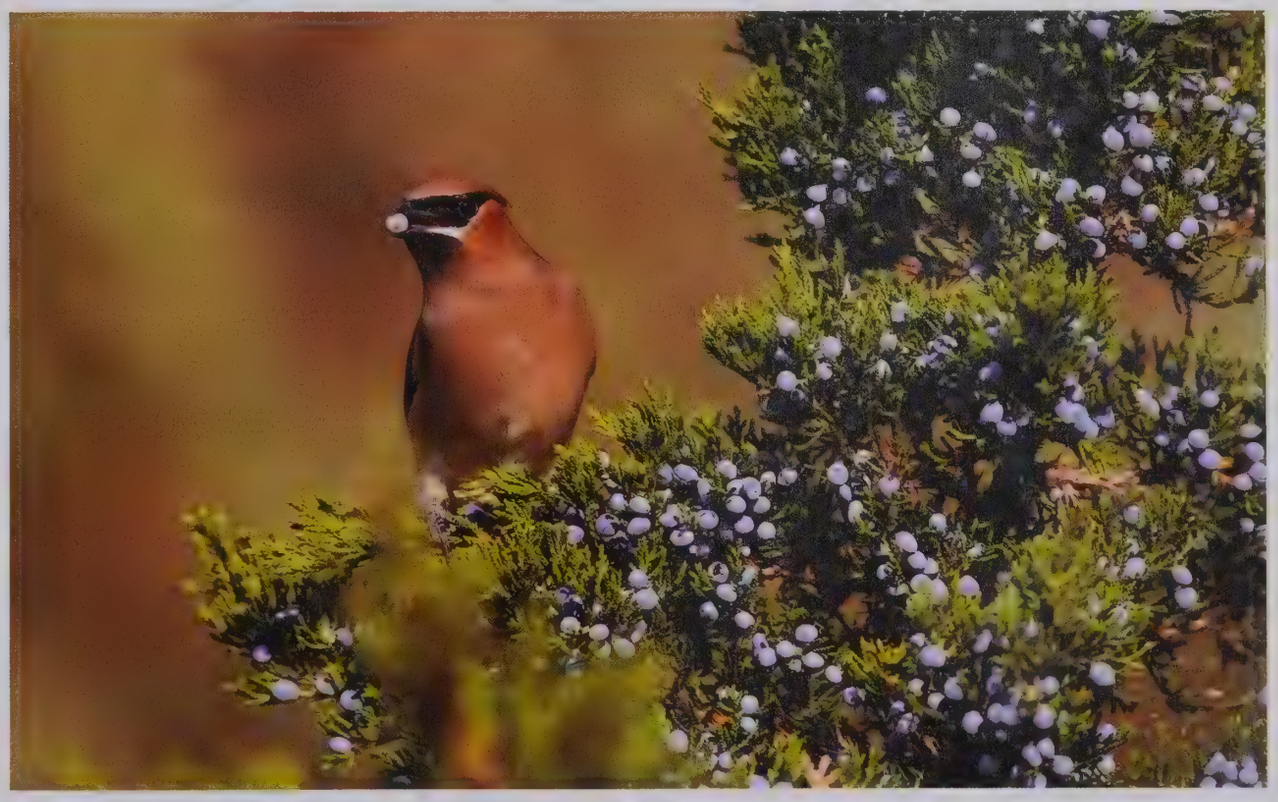
The most common calls of the Bohemian Waxwing are high-pitched trills that are similar in structure to the bzee call of the Cedar Waxwing. These trilled calls seem to dominate the repertoire of Bohemian Waxwings even more than is the case with the Cedar Waxwing, as they are frequently given in flight, as well as by perched individuals. The most familiar variation of these trilled calls has again been named the "Social Call 1". In comparison with the corresponding call of Cedar Waxwings, it is slightly lower-pitched, with a frequency of 6–7 kHz, and the individual notes are longer, with a drop in pitch during each note, producing a "silvery" and somewhat musical trill. Variations on the standard trilled call are used in interactions between mates. Bohemian Waxwings have been described as having a "song", but there is no evidence that it serves the territorial or mate-attraction functions of most passerine songs. It appears to consist of a series of trills resembling social call 1, with varied wheezing or scraping notes interspersed within it. This vocalization may perhaps be similar to the warbling call of the Cedar Waxwing. Pure-toned calls are also occasionally given by Bohemian Waxwings, but the context and function of most of these are unclear.

The vocal repertoire of the Japanese Waxwing is not very well known. This species frequently emits trilled calls similar to those of the Bohemian Waxwing, although these are shorter than the latter's social call 1. Japanese Waxwings also give descending pure-toned "pee" and "peeeh" calls of varying length.

Food and Feeding

The members of this family are among the most strongly frugivorous of birds. This reliance on fruit as a staple food is especially surprising, however, as the fruits that they most fre-

quently consume are high in sugars but low in other nutrients. Sugary fruits appear to be the predominant food item whenever they are available in sufficient quantity, and most aspects of the life history of these birds seem to be adapted to the characteristics of this food source.



The diet of the Cedar Waxwing has been studied in some detail, and it has been found that fruit constitutes about 84% of the food volume consumed throughout the year. During the months of October to April the proportion of fruit in the diet approaches 100%, and the only month in which it was found not to make up the majority of the diet was May. At this time of the year, when fruit is scarce, Cedar Waxwings turn to flowers for a large proportion of their diet; flowers accounted for 44% of their food in May. Both petals and stamens are consumed. At least on some occasions, as, for example, when feeding on apple (*Malus*) blossoms, the petals are clearly targeted and the stamens left untouched. At other times, stamens appear to be deliberately eaten.

Insects, and occasionally other invertebrates, are a significant supplement to the diet of Cedar Waxwings. They make up about 40% of the diet during May, and are only slightly less important in June and July, but their importance decreases in August and September. The flycatching behaviour of waxwings is very conspicuous and is frequently noted in the literature, but the obvious visibility of this activity may lead to incorrect assumptions about its relative importance in the foraging behaviour of these birds. Although Cedar Waxwings do take many flying insects, the largest component of their arthropod consumption is beetles (Coleoptera), especially scarab and leaf beetles (Scarabaeidae and Chrysomelidae), and these are probably often captured by gleaning. Other frequent insect prey include hymenopterans, especially ants (Formicidae), lepidopterans, including many larvae, dipterans such as craneflies (Tipulidae), and homopteran bugs, especially scale insects (Coccoidea) and aphids (Aphididae).

The diets of the two other bombycillids appear to be similar, at least in broad outline. All waxwings feed heavily on sugary fruits, especially in autumn and winter, and also regularly consume arthropods during the summer. There is, however, some uncertainty as to the importance of insects in the diet of Bohemian and Japanese Waxwings. Some published statements intimate that insects make up the bulk of the Bohemian Waxwing's food during the summer months, but the limited quantitative data available suggest that this is incorrect, and it may be that casual observations have been biased by the conspicuousness of flycatching activities. The stomach contents of 26 individuals collected during May–September in southern Kareliya, in extreme north-west Russia, consisted largely of fruits of *Vaccinium*, *Sorbus* and *Rubus*; insects were consumed mainly in June, and beetles made up the majority of these. Leaf buds of aspen (*Populus*) and flower buds of willow (*Salix*) were also recorded in small quantities in this study. Other observations of summer foraging do not establish the relative proportions of plant and animal material in the diet, but the fact that nestlings are fed with fruit, as well as insects, and the apparent importance of fruiting shrubs in descriptions of this species' breeding habitat would appear to indicate that fruit is quite significant at this season.

Even less information is available on the summer diet of Japanese Waxwings, but it is again suggested that this species feeds on flying insects. Juveniles, at least, are known to feed on blueberries, and it seems likely that breeding adults would also utilize fruit during the summer, as do both Cedar and Bohemian Waxwings.

Bearing in mind the extensive range of this family, which breeds across almost the entire northern Holarctic Region and in the winter months is found as far south as the northern Neotropics, it is not surprising that the list of fruit species consumed is very wide. Certain species or genera do, however, seem to be particularly important in waxwing diets. Serviceberries (*Amelanchier*), strawberries and mulberries (*Morus*), being some of the first fruits to become available in early summer, are significant foods. Midsummer fruits that are important to breeding waxwing include raspberries (*Rubus*), blueberries, cherries, and certain species of dogwood (*Cornus*). In the autumn and winter a broader range of fruit is consumed. Juniper berries are eaten by all three waxwings, but they seem to be especially important to the Cedar Waxwing, as they make up half of that species' winter diet. This reliance on juniper berries may have been even more pronounced before the planting of ornamental shrubs provided an abundance of alternative foods, but Cedar Waxwings still tend to spend the winter months preferentially in areas with high densities of juniper. Bohemian Waxwings, especially in Eurasia, are noted for their winter consumption of the berries of rowan, or mountain-ash (*Sorbus*), and these fruits are also popular with Cedar Waxwings. Japanese Waxwings are reported as frequently feeding on mistletoe berries (of the genus *Viscum*). Other important fruits for waxwings include those of hawthorns (*Crataegus*), rose hips (*Rosa*), honeysuckle (*Lonicera*), crabapples (*Malus*), cotoneaster (*Cotoneaster*), holly (*Ilex*) and firethorn (*Pyracantha*).

By measuring the volume of different items in the diet, it has been calculated that 84% of food consumed by the ***Cedar Waxwing*** *is made up of fruit. This figure is an average of monthly intake throughout the year, and conceals some fluctuations in dietary composition. Between October and April the proportion of fruit in the diet approaches 100%, but it drops below 50% in May. Towards the latter part of the spring, buds and flowers rise briefly to prominence, and insects are relatively important from May to July. When waxwings eat flowers they target petals and stamens, while insects are usually caught in flight, or plucked from branches.*

[*Bombycilla cedrorum cedrorum*, Jamaica Bay, New York, USA. Photo: Arthur Morris/ Birds as Art]

Waxwings build bulky cup-nests in trees or bushes, using twigs, grasses and roots to form the structure. Nest construction is carried out by both sexes, often in unison, although females tend to contribute more effort, at least during the first breeding attempt. This ***Cedar Waxwing*** *nest is balanced on the horizontal fork of a branch, a typical location for the species. Positioning varies, however, with nests reported 1-15 m above the ground, sometimes in an upright fork, and placed in a range of trees or shrubs, including pines, junipers, apples, maples and oaks.*

[*Bombycilla cedrorum cedrorum*, near Thunder Bay, Ontario, Canada. Photo: Wayne Lankinen/ DRK]

Aside from the usual food items of fruit, arthropods and flowers, waxwings have been recorded as consuming a variety of other items as occasional supplements. Buds are eaten by Bohemian Waxwings with some regularity, especially during the winter and early spring. This species also consumes a variety of seeds, such as those of birches (*Betulus*), alders (*Alnus*) and spruces (*Picea*), and both it and the Cedar Waxwing sometimes feed on sap dripping from damaged trees. Bohemian Waxwings have also been reported to eat small shoots and leaves, mosses and lichens, and, rarely, to take table scraps from feeding stations.

In the winter months, waxwings frequently drink water or eat snow. It has been suggested that the sugars in dried fruits create a high osmotic load, tending to dehydrate the birds. This is not likely to be a problem in summer, when most of the fresh fruit consumed has a relatively high water content.

The feeding techniques used by bombycillids are fairly straightforward. Fruits are usually obtained while the bird is perched, and it plucks these either by reaching up to another branch or by reaching down to a fruit hanging below. The short but strong legs allow the waxwing to dangle below a branch, occasionally hanging upside-down, to pluck fruits. In addition, these birds will sometimes hover briefly in order to get at dangling fruit. Insects are obtained both by gleaning from vegetation and by flycatching. The aerial sallies made by waxwings are generally slower and less agile than are those of the specialized flycatchers, such as the muscicapids and the tyrannids, but they do manage to capture some strong-flying prey, including dragonflies (Odonata).

Waxwings travel significant distances each day while foraging for fruit, and this mobility seems likely to have substantial consequences in terms of the seed dispersal of the plants upon which they feed. Breeding Cedar Waxwings frequently travel 1 km from the nest when collecting fruit with which to feed the nestlings, and occasionally they carry fruit gathered at sites up to 2 km away. The daily distances travelled by waxwings at other seasons have not been measured, but they appear to be substantial. Thus, it is probable that waxwings disperse seeds into new areas to a greater extent and more effectively than do many other frugivorous birds that are territorial or confine their foraging to a small area.

Breeding

Generally speaking, waxwings breed later in the year than do most passerines, an adaptation which reflects their dependence on fruit during this season, even for the purpose of feeding the young. Cedar Waxwings do not usually begin egg-laying until early June, and laying continues into the first week or so of August. Exceptionally, active nests have been reported as late as early October. The majority of Bohemian Waxwings, too, nest relatively late in the year, with egg-laying typically initiated in mid-June. The forming of pairs, however, can begin much earlier. For example, Cedar Waxwings can be seen "courtship hopping" in winter flocks from March, or even before then, although this activity intensifies in late spring. Bohemian Waxwings have been reported as displaying some courtship behaviour as early as the end of November, but courtship can also last into the second half of June.

Courtship involves a series of exchanges of a food item between the male and the female, with the individual currently holding the food first hopping away and then returning to the side of the other bird. This behaviour has been referred to as "courtship hopping" or the "gift-passing ceremony". It is usually initiated by the male, which brings a small item of food to the female and offers it to her, but sometimes an inedible item is substituted or the passing is merely simulated, with the two birds touching bills but not exchanging any item. After a few exchanges, sometimes twelve or more, the display typically ends when one individual, usually the female, consumes the item. Copulation is normally preceded by courtship hopping. Most such displays, however, are not followed by copulation, as waxwings copulate only infrequently.

Although waxwings are often regarded as gentle and non-aggressive birds, the male does endeavour to keep other males away from his mate as the time of egg-laying approaches. At this stage, threats and short chases are not uncommon. The male threatens rivals either by using an upright posture or by leaning forwards while holding the bill open. Cedar Waxwings have also been observed during the breeding season to engage in what appear to be aggressive chases, in which several individuals fly in a rapid and twisting pattern among trees and shrubs, seemingly chasing the leading bird. Such flights may end with one individual flying at several others and apparently trying to drive them off. The significance of such flights is unknown, but it is possible that they could involve a male that is attempting to defend his mate from the attentions of other males.

Observations indicate that bombycillids are at least seasonally monogamous. In the case of Cedar Waxwings, which are often double-brooded, this usually means that the members of a pair will remain together for both nesting attempts. In fact, in terms of the work required of the parents, there is often substantial temporal

Waxwings are at least socially monogamous during the breeding season, although males invest considerable effort guarding their mates during the fertile period, suggesting that extra-pair copulations do occur. The female takes sole responsibility for incubation of the eggs and brooding the young nestlings, but the male nonetheless plays an important role: he diligently delivers food to his mate during this period, allowing her to remain at the nest for 95% of the daylight hours. In the ***Cedar Waxwing****, the eggs (usually five in a clutch) are incubated for about 12 days before they hatch. At first, the nestlings are blind and naked, with colourful gapes. The mouth-lining is bright red, as can be seen here, with a violet-blue band at either side, and the tongue is purplish. By the time they reach five days of age, the nestlings have all their major feather tracts covered with pin feathers, which break from their sheaths around nine or ten days after hatching. After 14-18 days, the brood fledges.*

[*Bombycilla cedrorum cedrorum*, Adirondack Mountains, New York, USA. Photo: Robert A. Lubeck/ Animals Animals]

overlap between the two attempts, and the male's continuing assistance in feeding both the fledged first-brood young and the incubating female is probably vital in enabling the pair successfully to raise two broods. Insufficient information is available to determine whether pair-members re-mate in subsequent years.

Waxwings seem not to defend a breeding territory, although, as already mentioned, a male will sometimes exhibit mate-guarding behaviour and will drive off other males that approach his mate. There appears also to be a need to defend the nest from conspecifics on occasion, as Cedar Waxwings, and probably the two other bombycillids, frequently steal nest material from active nests of their own species, as well as from nests of other bird species. Apart from these instances, however, waxwings seem to tolerate conspecifics near the nest, and it is not unusual for several pairs to end up nesting in close proximity to one another. For Cedar Waxwings in the USA, for example, 13 nests in Michigan and eight nests in North Carolina were spaced at densities corresponding to, respectively, 14·1 nests/ha and 44·4 nests/ha. Bohemian Waxwings have also been observed to nest in an almost colonial fashion at times, with clusters of 6–12 nests within a small area. Most pairs, however, nest solitarily. Clusters of nests probably result from a local abundance of favourable nesting sites, rather than reflecting a social attraction between breeding pairs.

Nest construction is carried out by both sexes, the two usually travelling together to and from the nest-site. The female may bring more material, and she does more of the actual construction work, but the male does participate in the task. In fact, in the case of second nests, the male may be responsible for the majority of the building work. Waxwings build bulky open cup-nests, most of the structure being typically formed from small twigs, grasses and roots. The limited information available on the nests of the Japanese Waxwing suggests that this species favours larch twigs. Cedar Waxwings sometimes incorporate pieces of string, strands from fishing nets or other artificial material into their nests, and they characteristically "decorate" them with the flowering heads of grasses or catkins, which dangle below the structure. Bohemian Waxwings often use lichens or horsetail (*Equisetum*) stalks in the exterior covering of the nest, and may employ feathers and fur in the lining.

The nest is normally placed in a tree or bush. Cedar Waxwing nests are most often situated in the fork of a horizontal branch, but those of the Bohemian Waxwing are typically saddled on a branch and close to the main trunk. The rather few nests of Japanese Waxwings that have been found have been placed at heights of 8–10 m in larch trees. Similarly, Bohemian Waxwing nests are usually built in conifers, including spruces, firs and pines, at heights ranging from 1 m to 15 m. The Cedar Waxwing seems to be less strictly selective in its nest-site requirements and is known to use a fairly broad range of sites, often choosing a dense young tree or shrub, but also regularly using high branches in more sparsely vegetated trees. The height at which it places its nest varies in accordance with the particular site, and ranges from 1 m to 15 m, although the majority of nests are below 4 m. Tree species that are frequently used by Cedar Waxwings include junipers, apples, maples (*Acer*), oaks (*Quercus*) and pines, and this species will occasionally place its nest in a vine, such as a species of *Vitis*, that is supported by a tree.

For all three waxwings, the normal clutch size appears to be five eggs. Cedar and Bohemian Waxwings regularly lay clutches of between four and six eggs, but they sometimes lay as few as two. The eggs of these two species are very similar in colour. They are pale bluish-grey, with slightly purple tones, and are sparsely marked with grey or blackish blotches of varied size and darkness. The dimensions of Cedar Waxwing eggs are approximately 25 × 15 mm, while the average size of those of Bohemian Waxwings is 25 × 17 mm. No description of the eggs of Japanese Waxwings is available.

The Bohemian and Cedar Waxwings, the breeding behaviour of which has been reasonably well studied, appear to be similar with regard to the respective roles of the sexes in breeding duties. The female alone is responsible for incubation, but the male regularly delivers food to his mate during incubation and for the first few days of nestling care. The male may take food directly to the nest or he may perch near the nest; in the latter situation, the female approaches the male and produces loud begging calls, before being fed. The male Cedar Waxwing feeds his mate at an average rate of more than once per hour. He is able to regurgitate substantial numbers of berries at each visit, and his feeding efforts appear to satisfy most of his sitting partner's requirements, allowing her to remain at the nest for 95% of the daylight hours.

Incubation requires about 12 days in the case of the Cedar Waxwing, while the incubation period of the larger Bohemian Waxwing is usually 13 or 14 days. On hatching, the pink-skinned nestlings are blind and naked. The mouth-lining is bright red, with violet-blue bands laterally, and the tongue is purplish. The young of Cedar Waxwings exhibit pin feathers in all of the major feather tracts by the time they reach five days of age, and these feathers burst out of their sheaths around the ninth and tenth days. There is very little information on the development of Bohemian Waxwing young. The chicks of both species generally remain in the nest for 14–18 days, the duration of the nestling period being influenced to some degree by the weather and by disturbances at the nest.

The nestlings are fed by both parents. During the first few days of their life, while the female is still brooding the young almost constantly, the male provides most of the food for the family. In these early food deliveries the male normally feeds the female first, and she then transfers some of the food to the nestlings. During the first couple of days the young are fed mostly with insects, but after that stage the diet is predominantly fruit. Indeed, Cedar Waxwings have been observed to feed their young with fruit even on the very first day of the nestlings' life. Observations of this species reveal that the female's participation in brood-feeding increases rapidly from about the fifth day to the tenth day, but subsequently declines. It is remarkable that the nestlings manage to sustain rapid growth on a diet that contains only a low percentage of protein.

After fledging, young Cedar Waxwings are fed by the parents for a further 6–10 days, although the fledglings start to obtain significant quantities of food for themselves about three days after leaving the nest. When a pair makes an attempt at producing a second brood, the feeding of the young from the first nest is the task solely of the male. Young Cedar Waxwings often form flocks with juveniles from other nests shortly after reaching independence.

Among Cedar Waxwings, there is a strong tendency for yearling birds to pair up together, while older individuals usually have mates of a similar age to their own. The proportion of yearlings observed in the breeding population is similar to that expected in the population as a whole, indicating that most or all of the waxwings attempt to breed at one year of age. It has been suggested, on the basis of observations of "nomadic" flocks of non-breeding immatures, that some Bohemian Waxwings do not breed at one year, but it is not clear how such flocks could be distinguished from breeding birds. Cedar Waxwings frequently form small flocks during foraging trips away from the nest, and, as mentioned previously (see Food and Feeding), they may travel up to 2 km from the nest-site while gathering food.

Movements

Waxwings are renowned for their winter irruptions, which can take them in large flocks to areas where they do not normally occur. They show low levels of philopatry to their breeding areas, and they wander extensively within their non-breeding ranges. These habits are reflected in the use of the modifier "Bohemian" for one species and the frequent description of all three species as being nomadic. There is also, however, a strong degree of regularity and predictability in their movements, and in the timing of these, that should not be obscured by the use of generalizations such as "erratic" and "nomadic".

All three members of the family engage in annual migrations of short to moderate distance, with either the entire breeding range or a large portion of it being abandoned during the winter period. Migrants typically travel in flocks of varying sizes, and movements are often conspicuous during the daylight hours. The fact that Cedar Waxwings are occasionally found dead after having flown against towers and similar artificial structures during the night-

*Like its congeners, the **Bohemian Waxwing** feeds its nestlings a diet of fruit and insects, most of which is regurgitated. The male provides food during the first days after hatching, delivering items to the incubating female. She takes her share then passes the rest to her brood. At first they are given small insects, but fruit soon makes up the bulk of the diet, even a few days after hatching. This is particularly noteworthy, as most frugivorous birds feed their offspring with invertebrate or vertebrate food until they fledge, thus ensuring all the proteins and minerals necessary for growth and development are supplied.*

[*Bombycilla garrulus garrulus*, Lapland. Photo: R. W. Powell/ Windrush]

time does, however, indicate that some nocturnal migration may also occur. Movement away from breeding sites appears to begin soon after breeding has been completed, although these initial movements may be of shorter distance and not clearly oriented in a particular direction. Cedar Waxwings begin to depart from the northern sections of the breeding range from as early as late August through to October. The departure of Bohemian Waxwings from northern parts of the range, such as interior Alaska and Russian Lapland, usually commences in September, but some individuals may linger, depending on the abundance of berries.

The first of the Cedar Waxwing migrants arrive in some of the northern parts of their wintering range in September, but the species does not normally reach the southern USA until October or November, and may not be seen in the southernmost portions of the non-breeding range, in Central America, until December. Occasionally, however, waxwings move south in more rapid fashion, appearing in Texas by August or in Mexico by September. Similarly, Bohemian Waxwings typically arrive in the wintering areas between October and November, but the numbers at the southern extremes of the range may continue to increase until February, indicating ongoing migration. When large irruptive movements of this species occur, the first individuals sometimes arrive earlier than normal; in Scotland and in southern Saskatchewan, on the Canada–USA border, for example, the vanguard can be observed by late September. Japanese Waxwings, which breed in south-east Russia and adjacent extreme north-east China, usually reach wintering quarters in Japan in late November, but they have been recorded there as early as the beginning of October.

Unlike many migratory birds, waxwings appear not to settle into any one location for an entire winter. Rather, they move on after having depleted local crops of fruit, and they may continue their movements throughout the winter months. Recoveries of Cedar Waxwings ringed during the summer and early autumn demonstrated that the birds did not reach the greatest distances from the ringing location until February. Waxwings may be present throughout the winter in some areas where fruit is available in abundance during this season, but there may still be turnover among the individuals present in the local flocks. Ringing studies in Saskatchewan during the non-breeding season have shown that Bohemian Waxwings ringed in mid-January had mostly departed before March, but those ringed in late February were frequently recaptured into April.

Further, waxwings are known to use wintering areas widely separated geographically from those used in a previous year. For example, two Cedar Waxwings ringed during one winter in California, in the south-west USA, were recovered in subsequent winters in Alabama, about 3100 km away in the south-east USA. Similarly, a Bohemian Waxwing that had been ringed in the non-breeding season in Poland was recovered in the following winter in eastern Siberia, about 5500 km distant, and another individual of this species, ringed in British Columbia, in south-west Canada, was recovered in the next year in South Dakota, about 1200 km to the south-east, in the north-central USA.

Despite having a relatively late breeding season, from June onwards (see Breeding), Bohemian Waxwings usually leave their wintering areas at an early date. Northward migration probably begins in February and intensifies in March in many parts of this species' range, although it can be difficult to distinguish the beginning of return passage from winter wandering. The migrants arrive in northern sections of the breeding range in April and early May, but it is not uncommon for stragglers to be found still far to the south at this time, especially after major irruptions. Japanese Waxwings, too, seem to move north at a relatively early date. They are usually gone from most of Japan by early April, with a few stragglers sometimes lingering until the middle of May.

In contrast to its two congeners, the Cedar Waxwing is a late migrant and does not usually move northwards out of the wintering region until May. In the northern portions of its wintering range in the USA, in Massachusetts, Ohio and Illinois, for example, an increase in numbers is often evident in March and April. This has sometimes been interpreted as reflecting an early migratory surge, but it seems that these birds do not move much farther north at this time. It may be that these sightings represent wandering winter flocks that temporarily move north as the temperature moderates. Large numbers of migrants pass through these areas during the middle and end of May, and the northern parts of the species' breeding range are not fully occupied until some time in June. Stragglers linger as far south as Costa Rica into May, and can still be seen in the southern USA in June.

Cedar Waxwings show little philopatry to the areas where they were hatched or where they previously bred. Only about 4% of ringed individuals return to the precise area where they were captured during a previous breeding season, this being a much lower percentage than those found for most passerine birds. In contrast to their winter wanderings, however, there is no good

*This recently fledged **Bohemian Waxwing** is begging its overworked parent for more food. Fledglings tend to be fed for around 6-10 days after leaving the nest, although they can forage adequately for themselves after about three days. Shortly after reaching independence, different broods of waxwings coalesce to form flocks of juveniles.*

[*Bombycilla garrulus garrulus*, Kuusamo, Finland. Photo: Hannu Hautala/Bios]

evidence that they ever breed in widely separated areas in different years. For individuals ringed and recovered during the months of June to October, the average distance between the original capture site and the recovery location was 222 km. This figure is certainly not a true representation of the distance between breeding areas used by these individuals in different years, as many of these waxwings would already have departed from their breeding areas in October, and others would still be on spring migration in early June. It does suggest, on the other hand, that Cedar Waxwings typically nest within 200 km of previous breeding sites, and probably much closer to them.

Comparable data are not available for the Bohemian and Japanese Waxwings. Although there are indications that the former may occasionally breed farther south than it normally does, and that breeding populations are variable at specific sites, it nevertheless seems that the distribution of breeding birds is relatively constant across the main range, and that the species is not nearly so erratic in its choice of breeding areas as are some other passerines, such as crossbills (*Loxia*).

All three of the Bombycillidae are to some degree erratic in their non-breeding distribution, sometimes occurring well beyond their normal range. This trait seems to be most pronounced in the Bohemian Waxwing, which is famed for its periodic winter irruptions. These invasions are notable both for the numbers of individuals involved and for the distances travelled. Perhaps the best-documented irruption in Europe is that which took place in 1965–66, when large flocks of this species reached western and central parts of the continent and smaller ones were recorded in the Mediterranean region. An idea of the numbers involved in this massive irruption can be gained from observations made in south-west Germany, where an estimated 34,000 individuals were present in the Baden-Württemberg region alone. During a major irruption of this species in North America in 1908, observers in Iowa, in the north-central USA, reported that the waxwings arrived in a dense flock that was 60–90 m wide and passed overhead for 2–3 minutes. During invasion events in North America, Bohemian Waxwings have appeared as far south as southern California, northern Texas, north-west Arkansas and Virginia, and in the winter of 2001–02 a party of five was recorded in Bermuda, in the western Atlantic Ocean. In the Old World, likewise, they have been recorded as far south as northern Algeria, Malta, Cyprus, south-west Iran, southern Pakistan, Nepal and Taiwan.

Irruptions of Bohemian Waxwings appear not to be correlated with weather conditions and are presumed to be caused generally by food shortages, although this has not been rigorously studied. Even so, observations certainly indicate that the large-scale invasion in Europe in the mid-1960s was triggered by the combination of a large waxwing population and an inadequate food supply in northern regions, and a similar coincidence of events has been noted in other irruption years. It has been suggested that irruptions in Eurasia might tend to occur at ten-year intervals, but there seems to be little evidence to support this; following an invasion, the subsequent one may occur much sooner than this, even in the very next winter.

In North America, there is no apparent periodicity in the timing of invasions, but in some regions of south-eastern Canada and the north-eastern USA the frequency of occurrence of Bohemian Waxwings seems to have increased in recent decades. In Wisconsin, Massachusetts and Nova Scotia, for example, winter records of this species have become more frequent over this period. This change may reflect an apparent expansion of this species' breeding range into the north-eastern part of the continent (see Status and Conservation).

The Cedar Waxwing exhibits a far less marked degree of irruptive behaviour, although its appearance in different parts of the non-breeding range can be irregular, being dependent on food availability. It is an annual visitor as far south as Costa Rica, but is less regular in the south of Central America and in the West Indies. Vagrants are reported sporadically in the northern part of South America. Of particular interest is the fact that this species has occurred also on the eastern side of the Atlantic Ocean, where it has been recorded at least twice. The appearance of a vagrant in Iceland in April 1989 followed reports of exceptionally large numbers in north-east North America during the preceding months, and the discovery of a Cedar Waxwing in England in February 1996 coincided with a huge invasion of Bohemian Waxwings in that country.

Relationship with Man

Waxwings are viewed by most people as a particularly attractive component of the avifauna, and the activities of these birds generally result in few conflicts with man. Both Bohemian and Japanese Waxwings breed in areas with low human population densities, which reduces the potential for problems. By the time these birds move into more densely populated areas in the autumn and winter, commercial fruit crops have already been harvested and the waxwings feed mostly on berries and other fruits of no commercial value. Japanese Waxwings have been reported to cause some damage to the buds of kiwifruit (*Actinidia*), but such incidents are probably uncommon.

Cedar Waxwings, however, have a range that overlaps much more extensively with areas of active agricultural activity, and in some situations they can be responsible for significant crop damage. They consume primarily smaller fruits, such as blueberries, grapes and serviceberries (see Food and Feeding). Growers have reported bird damage to their crops of 10–60%, although it is quite possible that American Robins, icterids and other species are responsible for a substantial proportion of these losses. The most effective control method for crops such as blueberries appears to be netting, although this is a relatively costly measure.

Waxwings clearly have some special appeal. In much of Europe and Asia, they are no more than occasional visitors, and in years of irruptions (see Movements), when large numbers of Bohemian Waxwings invade areas farther south than their normal non-breeding quarters, they attract the attention of many birdwatchers and even sometimes of the media. Newspaper and television reports seem to delight in these strange birds that are feeding on berries in suburban and urban gardens and parks.

Status and Conservation

The three species of waxwing vary considerably in their population size and probable conservation status. The Cedar Waxwing is a very common species within its core breeding range, and it has an extensive distribution. In breeding-bird atlas projects undertaken in Ontario, Quebec and the Maritime Provinces of Canada, and in New York, in the USA, this species was in each case found to be among the top 20 bird species with regard to the number of atlas squares in which it was recorded. Roadside counts used in the North American Breeding Bird Survey revealed that Cedar Waxwings increased significantly over the period from 1966 to 2002, the numbers rising at an average annual rate of 1·3%. This increase was evident throughout most of the species' range, with the exception of portions of the Pacific coast, the northern prairies and other isolated pockets. The population as a whole, however, seems to have remained fairly stable since 1980.

Bohemian Waxwings appear to breed at lower population densities than do Cedar Waxwings. Although figures of up to 35·6 birds per square kilometre have been recorded in Russia, a more typical breeding density is of fewer than ten individuals per square kilometre, even in preferred habitats. Despite these low densities, the very extensive breeding range of the Bohemian Waxwing results in a very large population size for the species as a whole. Its population seems to be stable in the European part of its range, and numbers are stable or slightly increasing in North America. In the latter continent, not only has this species become more frequent as a winter visitor in south-east Canada and the north-east USA (see Movements), but there are also indications that it may now be nesting beyond its traditional range. In Canada, evidence of breeding in northern Ontario was first obtained in 1964, individuals in breeding condition were collected in northern Quebec in the 1970s, and there have been a number of recent sightings of summering Bohemian Waxwings in Labrador.

Of the three members of the Bombycillidae, the only one for which there is concern with regard to its conservation status is the Japanese Waxwing. The limited range of this species and its apparently small population raise the possibility that it could become globally threatened if it suffers any major perturbations. As a consequence, it has been placed by the IUCN in the conservation category of Near-threatened. While there is no obvious indication that the Japanese Waxwing population is declining, the clumped and rather sporadic distribution of waxwings, especially in winter, makes it difficult to monitor population trends accurately. More information on this species' precise breeding-habitat requirements, and potential changes in its environment, would be valuable, as also would reliable indications of any trends in its global numbers.

The impact of human beings on waxwings is difficult to assess, but a variety of human activities affect these birds, and in some situations significant mortality has been reported. Waxwings appear to be susceptible to impacts with windows and collisions with cars, often as a result of the planting of ornamental fruit trees close to these hazards. In the USA, for example, over 360 Cedar Waxwings were killed by cars after having been attracted to Russian olive (*Eleagnus angustifolia*) plantings in the central reservations of busy highways near Richmond, in Virginia. In addition, this species is occasionally killed when it crashes into towers during the night, but this is probably a minimal cause of mortality for this largely diurnal migrant (see Movements).

Exposure to pesticides is a potential risk for birds that feed on fruit and insects. For instance, the eggshells of Cedar Waxwings collected in Michigan, USA, in 1968/69 were significantly thinner than those of eggs collected prior to 1920, suggesting that they may have been affected by DDT. In one study, it was also reported that the incidence of hatching failure was higher in orchards than in other habitats, although this may have been due to disturbance rather than pesticide contamination. Direct mortality of adults exposed to pesticides has also been reported. In the Nagano prefecture of Japan, for example, 67 Bohemian Waxwings were reportedly killed in one episode of exposure to EPN.

Despite the various negative influences described in the above two paragraphs, it is possible that the overall impact of humans on waxwings has been a positive one. Certainly, Cedar Waxwings seem to have benefited from the break-up of extensive mature forests, which they eschew, and from the increase of edge habitats and young regenerating forests, which provide their preferred biotopes. Of course, some habitat alterations have also had negative consequences. Examples include extensive urbanization in some areas, the planting of monoculture forests that do not favour an understorey of fruiting shrubs, and possibly fire suppression. Nevertheless, the net effect has probably been favourable for Cedar Waxwings, at least, and possibly also for Bohemian Waxwings. The planting of ornamental trees that provide an abundance of winter fruit is also likely to have had at least some positive impacts on all three species of waxwing.

*Unlike its congeners, the **Japanese Waxwing** occupies a limited range, and its global population is apparently small. While there is no direct indication of any decline, it is difficult to assess trends in numbers because populations are mobile and patchily distributed, especially in winter. Because of these factors, and the possibility that perturbations of habitat could soon lead to a decline, this species is classified as Near-threatened. Surveys and field studies are required to identify more precisely its ecological requirements, in both summer and winter, and to monitor population size as accurately as possible.*

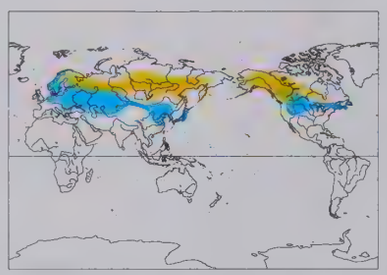
cm 5



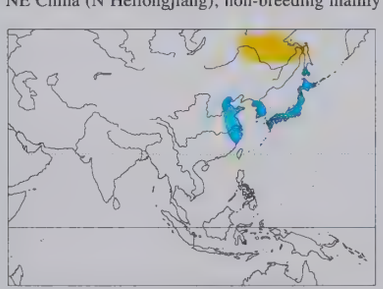
Genus *BOMBYCILLA* Vieillot, 1808

1. **Bohemian Waxwing**

Bombycilla garrulus

French: Jaseur boréal **German**: Seidenschwanz **Spanish**: Ampelis Europeo
Other common names: Waxwing, Greater/Common Waxwing

Taxonomy. *Lanius Garrulus* Linnaeus, 1758, Sweden.
Appears to be most closely related to *B. japonica*. Geographical variation involves only minor plumage differences; individuals from E part of range of *centralasiae* often as dark as nominate. Three subspecies recognized.
Subspecies and Distribution.
B. g. garrulus (Linnaeus, 1758) – breeds N Sweden, far N Norway, N Finland and N Russia (S of tree-line) E to approximately Ural Mts; non-breeding S to Poland, the Balkans, Ukraine, irregularly farther S.
B. g. centralasiae Poliakov, 1915 – breeds C & E Russia S of tree-line from approximately Ural Mts E to Sea of Okhotsk and Kamchatka, S to Altai Mts, L Baikal and lower Amur Valley; non-breeding S to Kazakhstan, N China and Japan, rarely to N Indian Subcontinent, S China and Taiwan.
B. g. pallidiceps Reichenow, 1908 – breeds NW & NC North America; non-breeding E to SE Canada (Newfoundland) and S to C & NE USA, irregularly farther S.
Descriptive notes. 19–23 cm; 34–85 g, average c. 55 g. Medium-sized passerine with prominent backward-pointing crest of moderate length, distinctive wing markings. Male nominate race has black mask from base of bill extending over eye and to rear of head under crest, white arc below eye, white streak below gape, black chin and throat; rest of plumage mostly brownish-grey, with



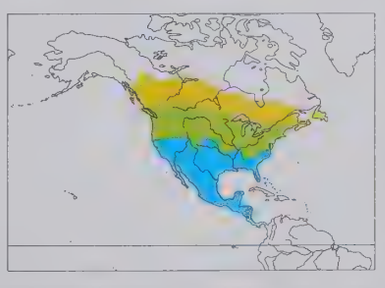
warmer tawny or cinnamon tones on head (especially crown and malar region), paler and greyer rump and underparts, dark chestnut-orange crissum; flight-feathers blackish, tips of primaries edged yellow on outer webs and more narrowly white on inner webs (forming yellow stripe and white fishhook markings on closed wing), broad white tips on primary coverts and secondaries, secondaries also with long wax-like red appendages; tail blackish with broad bright yellow terminal band, sometimes a few small red waxy tips; iris dark brown; bill black with blue-grey to pale horn base; legs dark grey to black. Female is very like male, but yellow tailband narrower, lower edge of black throat less well demarcated, generally fewer or broken white lines on outer webs of primary tips, often fewer or shorter red appendages on secondaries. Juvenile is duller and greyer than adult, has shorter crest, no black throat patch, less extensive black facial mask, no white tips on inner webs of primaries, paler (whitish) tips on outer webs, fewer wax-like tips on secondaries, narrower tailband, whitish underparts with diffuse brownish streaks. Race *centralasiae* differs from nominate in generally greyer and paler coloration, with little cinnamon coloration on malar area; *pallidiceps* is slightly lighter and less brightly coloured than nominate, but with more cinnamon on forehead and malar region than previous.
Voice. Most familiar call a ringing trill, "sirrr", similar to that of *B. cedrorum* but lower-pitched (5·3–6·4 kHz, usually below 6 kHz) and with notes more separated, average duration c. 400 milliseconds; also soft, sustained trilling vocalizations (often described as "song"), similar to typical call but mixed with wheezy notes, twittering and harsh scraping sounds; whistled calls of uncertain function occasionally given, but apparently much less often than by *B. cedrorum* or *B. japonica*.
Habitat. Breeds in boreal forest and muskeg. Prefers relatively open forest or edge, usually coniferous, e.g. spruce (*Picea*), pine (*Pinus*), etc., but occasionally in birch (*Betula*) forest or mixed

forest; favours well-drained areas near major rivers, normally including dense growth of fruiting plants. In non-breeding season found in wide variety of habitats with fruiting plants and at least scattered trees, including roadsides, gardens, farmland and edges of deciduous forest. Mostly lowlands and lower parts of uplands; also breeds in Rocky Mts in W USA.
Food and Feeding. Predominantly fruits and insects. Other foods noted include buds of various trees, flowers, tree sap, bark, shoots and leaves, moss and lichens; also spiders and snails, and varied table scraps from feeders. Strongly dependent on fruit during non-breeding seasons, probably also to large extent during breeding season; sometimes stated to be primarily insectivorous during breeding, but importance of insects in diet possibly exaggerated by conspicuousness of foraging method, and limited data on stomach contents indicate heavy use of fruit in summer. Important summer fruits include *Vaccinium*, *Sorbus aucuparia*, *Rubus*, and *Shepherdia canadensis*; at other seasons, fruits of *Sorbus*, *Juniperus*, *Cotoneaster*, *Crataegus*, *Rosa*, *Loranthus europaeus*, *Sophora japonica*, *Malus*, *Pyrus* and many others commonly eaten. Significant quantities of insects taken, including mosquitoes (Culicidae), midges (Chironomidae and others), beetles (Coleoptera), mayflies (Ephemeroptera), stoneflies (Plecoptera, e.g. of family Perlidae), caddis flies (of family Phryganeidae), dragonflies (Odonata). Insects often taken by aerial flycatching, probably also by gleaning.
Breeding. Relatively late season; some nests with eggs in late May, but laying more often begins mid-Jun and may continue to end Jul. Apparently monogamous. Territorial behaviour restricted to immediate vicinity of nest, and sometimes several pairs rather close together. Nest built by both sexes, an open cup of fine twigs and coarse grasses, lined with finer material including grasses, mosses, plant fibres and feathers or mammal fur, often fine material dangling some distance below cup; usually placed on horizontal branch of tree, often close to trunk, 1·3–15 m above ground. Clutch 3–7 eggs, mostly 5 or, less often, 6; incubation by female, fed on nest by male, period 14–15 days; chicks fed by both parents, fledge at 14–15 days, but up to 17 days if weather conditions poor.
Movements. Partial migrant, withdraws from large portion of breeding range in winter. Main non-breeding range in Old World extends W to E Britain and S to Balkans, Ukraine, Kazakhstan, N China and Japan; in North America movements largely to ESE, regularly wintering in SE Canada and to lesser extent in C & NE USA, well E of major breeding populations. Apparently does not show fidelity to non-breeding sites; one ringed in Poland in winter was recovered in following winter c. 5500 km to E, in E Siberia. Main departure from N parts of range usually in Sept, but some individuals linger, depending on abundance of berries; arrival in wintering areas Oct–Nov, numbers at S extremes of range continuing to increase until Feb; wanders widely during winter months. Return migration starts early, from Feb, passage intensifying in Mar in many regions; arrives in N sections of breeding range in Apr and early May, but some still far to the S at this time. Renowned for periodic irruptive movements, large flocks sometimes reaching areas well outside normal wintering grounds, in Old World e.g. much of W & C Europe and S China, and smaller ones as far S as Mediterranean region (including N Africa), Middle East, N Indian Subcontinent and Taiwan; in America sometimes S to S USA. Numbers involved often massive, e.g. c. 34,000 present in just one region of SW Germany alone during one invasion; during major irruption in North America in 1908, one dense flock 60–90 m wide took 2–3 minutes to pass over the observers' heads. Recent record of flock of five individuals in Bermuda, in W Atlantic Ocean. May show some evidence of approximate 10-year cycle in irruptions in Europe.
Status and Conservation. Not globally threatened. Common. Populations estimated at 25,500–102,000 pairs in Scandinavia and 100,000–1,000,000 pairs in Russia. No estimates for North America, but numbers no doubt substantial, on basis of winter counts that often involve flocks of more than 1000 individuals; numbers wintering in Maritime Provinces of E Canada seem to have increased in recent years. Extensive breeding range mostly to N of dense human populations; this, coupled with the species' utilization of disturbed habitats, suggests that populations not likely to suffer significant declines in the near future.
Bibliography. Ali & Ripley (1987a), Anderson (1909, 1915), Anon. (1998b), Armstrong (1983), Arvey (1951), Baicich & Harrison (1997), Bent (1950), Berthold (2001), Blok (2000), Blyumental (1961), Braeko & Grošelj (1990), Brazil (1991), Cadman (1987), Campbell *et al.* (1997), Cramp (1988), Cyr & Larivée (1995), Dementiev *et al.* (1968), Dobson & Gray (2002), Duncan (2002), Duncan & Church (1992), Erik (1961), Eriksson & Nummi (1982), Étchécopar & Hüe (1964, 1983), Fleming (1968), Godfrey (1986), Grahn (2004), Grimmett *et al.* (1998), Hagemeijer & Blair (1997), Heath *et al.* (2000), Heinroth & Steinbacher (1952), Hellmayr (1935), Howell (1973), Hüe & Étchécopar (1970), Inskipp & Inskipp (1991), Jiang Zhihua & Zhang Yuling (1987), Kaufman (1996b), Keith *et al.* (1992), Kessel (1989), Knapton & Sexton (1978), Knystautas (1993), Koenig (2001), Kulakowski & Polakowski (2003), Lewis (1949), Li Kueiyan (1958), MacKinnon & Phillipps (2000), Meaden & Harrison (1965), Mountjoy & Robertson (1988b), Nankinow (1993), Palmgren (1960), Paz (1987), Peck & James (1987), Phillips (1947), Price *et al.* (1995), Pulliainen (1985a), Pulliainen *et al.* (1981), Ridgway (1904), Ripley (1982), Roberts (1992), Rogacheva (1992), Root (1988), Saari & Pulliainen (1997), Sapetina (1998), Shevarea (1961), Shimeld & Shimeld (1997), Shirihai (1996), Snow & Perrins (1998), Stepanyan (1990), Ulfstrand (1963), Vaurie (1958, 1959), Whitehead (1907), Witmer (2002), Yoshida *et al.* (2001), Zheng Guangmei & Zhang Cizu (2002), Zimin *et al.* (1961).

2. Japanese Waxwing
Bombycilla japonica

French: Jaseur du Japon **German**: Blutseidenschwanz **Spanish**: Ampelis Japonés
Other common names: East Asian Waxwing

Taxonomy. *Bombycivora japonica* Siebold, 1824, Kumamoto and Fukuoka prefectures, Kyushu, Japan.
Appears to be most closely related to *B. garrulus*. Monotypic.
Distribution. Breeds SE Russia (E Yakutia, Khabarovsk and Amur), also irregularly in adjacent NE China (N Heilongjiang); non-breeding mainly E China, Korea and Japan.



Descriptive notes. 15–18 cm; 54–64 g. Medium-sized passerine with prominent backward-pointing crest of moderate length, distinctive wing markings. Male has black mask from base of bill extending over eye and to rear of head under crest, white arc below eye, short white streak below gape, black chin and throat; rest of plumage mostly greyish-brown, with warmer tawny tones on head (especially crown and malar region), grey on rump; greater secondary wing-coverts edged bright chestnut-red on outer webs; flight-feathers bluish-grey to blackish, white tips on both webs of primaries, sometimes a spot of pink on outer web, usually small red spots at tip of outer webs of secondaries, rarely one or more small wax-like shaft tips (waxy tips usually lacking); tail dark grey to blackish, bright pinkish-red band at tip; paler below, lower underparts often yellowish, crissum reddish; iris deep red to dark brown; bill blackish; legs dark brown. Female is very like male, but somewhat paler, small red spots at tips of secondaries lacking or reduced, crissum duller, more ochre. Juvenile mainly grey, darker on crest, whitish on belly with flanks heavily streaked dark grey; first-winter plumage has white line only along outer webs of most of primaries. Voice. Commonest call a high-pitched trill, similar to that of congeners, but shorter (150–380 milliseconds) and slightly higher (5·5–6·4 kHz) than trill of *B. garrulus*; also, frequently gives high (5 kHz) whistled calls, ranging from short (c. 205 milliseconds) to long (c. 540 milliseconds), that may represent two call types.
Habitat. Breeds in forested areas; apparently favours coniferous trees, including larch (*Larix*), spruce (*Picea*) and fir (*Abies*); presence of fruiting plants likely also to be important component of breeding habitat. In winter occurs in deciduous and mixed forest, as well as in more open habitats with scattered trees, including parks and gardens, so long as fruiting trees present.
Food and Feeding. Few data, but diet apparently similar to that of congeners. Summer foods include *Vaccinium* berries and insects. Feeds on variety of fruits in other seasons, including mistletoe berries (*Viscum coloratum*) and Amur grapes (*Vitis amurensis*).
Breeding. Little information available. Probably relatively late breeder; laying from early Jun, female specimen from R Amur in late Jun was apparently in middle of laying; flocks of juveniles observed on R Maya at end Aug. Thought to nest as individual pairs. Few nests found; nest built of larch twigs and lichens, placed at 8–10 m in larch. Clutch 5 eggs, occasionally 4 or 6; incubation by female. In captivity: incubation 15-16 days; fledging 16 days.
Movements. Relatively short-distance migrant. Apparently vacates breeding range almost completely; some may winter in extreme SE Russia (S Primorskiy), but numbers dependent on fruit crop and this may influence winter distribution generally. Main non-breeding range E China (mainly Hebei and Shandong), Korea and Japan; sporadically farther S, to C & SE China (S to N Yunnan and Fujian), Ryukyu Is and Taiwan. Typically arrives in Japan in late Nov, exceptionally in early Oct, and departs early Apr, with stragglers until mid-May; arrival back on breeding grounds in May. In S Primorskiy seen principally on spring migration, and rare in autumn, suggesting that species may take different routes for migration S.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Generally uncommon, but locally common in suitable breeding habitat. Occurs in relatively limited range, and global population thought to be small. Use of human-altered habitats in non-breeding season, at least, suggests that this species may not be greatly affected by human activities, but further study warranted; may have declined as a result of logging and development of forest in its breeding range. Possibly adversely affected by pesticides or other control measures used by commercial fruit-growers. May cause some damage by feeding on buds of kiwifruit (*Actinidia*).
Bibliography. Arvey (1951), Austin (1948), Austin & Kuroda (1953), Brazil (1991), Cheng Tsohsin (2002), Collar, Andreev *et al.* (2001), Collar, Crosby & Stattersfield (1994), Dekker *et al.* (2001), Dementiev *et al.* (1968), Étchécopar & Hüe (1983), Gore & Won Pyongoh (1971), Jerrard (2004), Knystautas (1993), Knystautas & Sibnev (1987), Leonovich (1977), Li Kueiyan (1958), MacKinnon & Phillipps (2000), Meyer de Schauensee (1984), Momiyama (1928), Mountjoy & Robertson (1988b), Moyer (1957), Nakamura & Tsuchiya (2000), Pugachuk (1991), Sonobe (1982), Stattersfield & Capper (2000), Stepanyan (1990), Tomek (2002), Ueda (1998), Vaurie (1959), Won Pyongoh (1993), Lee Woo-Shin *et al.* (2000), Yoon Mooboo (1992), Yoshida *et al.* (2001), Zhang Cizu *et al.* (1997), Zheng Guangmei & Zhang Cizu (2002).

3. Cedar Waxwing
Bombycilla cedrorum

French: Jaseur d'Amérique **German**: Zedernseidenschwanz **Spanish**: Ampelis Americano
Other common names: Cedar Bird

Taxonomy. *Bombycilla cedrorum* Vieillot, 1808, Pennsylvania, USA.
Birds from N of range named as race *aquilonia*, but description based on wintering individuals of uncertain origin, and slight colour differences seem unreliable. Two subspecies recognized.
Subspecies and Distribution.
B. c. cedrorum Viellot, 1808 – breeds extreme S Alaska and S Yukon E across C & S Canada to Newfoundland, S in E USA to N Georgia; non-breeding regularly S to Costa Rica.
B. c. larifuga Burleigh 1963 – breeds SW Canada and W USA S to N California; non-breeding S probably to at least W Mexico.

Descriptive notes. c. 15·5 cm; c. 32 g. Medium-sized passerine with distinctive crest of moderate length pointing rearwards from crown. Male nominate race has black mask extending from base of bill back over eye and to rear of head under the crest, outlined by thin white line from forehead to over eye, white arc below eye and short white streak below gape; chin and throat black; rest of head, and upperparts to back, tawny-brown, rump grey; wings grey-brown, dark grey flight-feathers, secondaries (and rarely other flight-feathers) with red wax-like shaft extensions at tip, white line on inner edge of tertials; tail dark grey with black subterminal band, contrasting bright yellow band at tip (tip sometimes orange); underparts paler, belly usually with strong yellow tone, undertail-coverts whitish; iris dark brown; bill blackish; legs dark brown. Female is very like male, but has throat brown, with black restricted to chin. Juvenile is duller and greyer than adult, has shorter crest, paler throat, diffusely streaked underparts; first-winter differs from adult in having few or no wax-like shaft extensions on secondaries. Race *larifuga* is paler and slightly greyer than nominate. Voice. Calls high-pitched, and most fall into two categories. "Bzeee Call", commonly given when perched, a trill consisting of 5–20 or more closely spaced elements, dominant frequency c. 6–8 kHz, duration 100–400 milliseconds, quite variable in length, repetition rate and volume, perhaps reflecting motivation; some other named calls seem to be variations of this, e.g. contact and courtship calls similar in structure but shorter and are rapid trills, while begging call also similar but given in long, often loud series; also warbling call, soft and variable in structure, function unclear, usually given by relatively inactive birds (perched or incubating), has been described as "song". Second major category is "Seee Call", a high (6–7 kHz) hissy whistle, may rise in pitch at beginning but mostly at constant frequency, often given in flight or just before flock takes off (switch from "Bzeee" to "Seee" usually indicates imminent departure); disturbance call similar, but with strong frequency drop at end.
Habitat. Variety of habitats with trees and shrubs, but generally favours edges or open woods, and avoids dense forest; presence of fruiting plants an important component. Specific habitats include

old fields, riparian areas, deciduous and coniferous woodlands, bogs, orchards and suburban gardens. Winter habitats often include urban areas with ornamental fruiting trees and shrubs, and open woodland with many junipers (*Juniperus*).

Food and Feeding. Relies heavily on fruit (84% of annual diet); insects (12% of annual diet) consumed primarily in spring, when fruit scarce. Also feeds on flower parts (4% of annual diet), mostly in May; often selects petals of e.g. apple (*Malus*) blossoms and ignores reproductive parts. Occasionally feeds on sap in spring, and reported as consuming salt-rich mud. Important fruits in diet include mulberry (*Morus*), serviceberry (*Amelanchier*), cherry (*Prunus*), dogwood (*Cornus*), blueberry (*Vaccinium*) and raspberry (*Rubus*); in winter includes those of mountain ash (*Sorbus*), crabapple (*Malus*), Russian olive (*Elaeagnus*) and juniper. Prefers sugary fruits or those with mix of sugars and lipids; avoids those primarily of lipids. Fruits normally obtained while bird perched or dangling, but sometimes plucked in short flight or during brief hover. Insects consumed are mainly aerial forms, captured during short sallies, or herbivorous species, gleaned from vegetation; include mayflies (Ephemeroptera), dragonflies (Odonata), ants (Hymenoptera), scale insects (Coccoidea), caterpillars (Lepidoptera) and beetles (Coleoptera). Often flycatches from prominent perch near water.

Breeding. Season later than that of most birds: laying usually begins early Jun, but some nests initiated early Aug; rarely, active nests late Sept and early Oct. Apparently monogamous (at least seasonally). Lack of territoriality allows close spacing of nests on occasion, e.g. 8 nests in 0·18 ha, but most nests not clustered; concentrations likely due to density of suitable sites, rather than social attraction. Nest built by both sexes, an open cup of small twigs, grasses and roots, sometimes pieces of string, strands from fishing nets or other artificial material incorporated, and with flowering heads of grasses or catkins dangling below the structure; placed 1–15 m (majority below 4 m) above ground in fork of horizontal branch, often of dense young tree or shrub, also regularly on high branch in more sparsely vegetated tree, frequently in juniper, apple, maple (*Acer*), oak (*Quercus*) or pine, occasionally in vine (e.g. *Vitis*) supported by tree. Clutch 2–6 eggs, usually 4 or 5, yearling females lay smaller clutches; incubation by female, male delivers food to her either at nest or nearby, incubation period 11–13 days, typically 12 days; chicks fed by both parents, male providing more, especially in first 3 days, while female broods for extended periods, nestlings fledge at 14–18 days, usually 15–16 days; fledglings fed by both adults for 6–10 days, only by male if female lays second clutch. Between 50% and 75% of nests produce fledglings, with 2·6–3·8 young per productive nest in various studies. Most birds probably breed in first summer after fledging. Annual mortality c. 55%.

Movements. Complex and not fully understood. Withdrawal and return to N parts of breeding range on predictable schedule, indicating regular migration, but movements apparently continue throughout winter in response to fruit crops. Non-breeding range extends S to Mexico and Costa Rica; irregular in occurrence in S Central America and West Indies, vagrant in N South America. Ringing recoveries indicate that individuals may winter in E or W USA in different winters. Adults move S from late Aug, c. 1 month before juveniles, arrival in S USA normally Oct or Nov and in Central America Dec, occasionally earlier; some leave wintering areas in extreme S in Feb, but generally a late migrant, some lingering in Costa Rica until mid-May, generally departing S USA late May or early Jun. Sometimes becomes more numerous in N sections of wintering range in Feb–Mar, but probably not true migrants. Low philopatry to precise breeding areas, but most probably return to same region; no evidence that individuals breed in different regions in subsequent years. Vagrants recorded in Europe (Iceland, Britain).

Status and Conservation. Not globally threatened. Abundant in much of breeding range. Numbers generally stable or increasing; Breeding Bird Survey shows 1·3% annual increase from 1966 to 2002. Has probably benefited in some areas from successional vegetation changes after abandonment of marginal farmland, and perhaps also from forest fragmentation. Planting of ornamental fruiting trees and shrubs may also have helped this species. Adverse human factors include use of pesticides; some evidence from eggshell-thickness data suggests that it may have been affected by DDT in past. Some mortality caused by collisions with vehicles (especially if ornamental plantings attract flocks to roadways) and with windows and other structures.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family HYPOCOLIIDAE (HYPOCOLIUS)

- Medium-sized, long-tailed passerine with greyish plumage, male with black face mask.
- 23 cm.

- South-west Asia.
- Subtropical riverine forest, date palms, gardens and scrub.
- 1 genus, 1 species, 1 taxon.
- No species threatened; none extinct since 1600.

Systematics

Since being named in 1850 by C. L. Bonaparte, the Hypocolius (*Hypocolius ampelinus*), or Grey Hypocolius, has generally been considered to be most closely related to the waxwings (Bombycillidae). Indeed, it has sometimes been placed within that family, typically being awarded a monotypic subfamily, Hypocoliinae, with the waxwings themselves and the New World silky-flycatchers (Ptilogonatidae) usually treated as two further subfamilies. In contrast to these ideas, C. G. Sibley and J. E. Ahlquist appeared to believe that the Hypocolius was more closely related to the bulbuls (Pycnonotidae), and placed it next to them in a family of its own, but with the caveat that there was no firm evidence for a relationship with the bulbuls.

The Hypocolius does, indeed, bear a close resemblance to the waxwings, particularly in structure, plumage pattern, social patterns and behaviour. In these respects, it does seem to be closer to them than to the bulbuls.

As there are no DNA data which may shed some light on the possible relationships of this species, it is perhaps sensible to adopt a traditional view of its systematic position. Whether the Hypocolius genuinely merits separation in a family of its own is a matter open to question, but such treatment serves to highlight the uncertainty, and may help to draw attention to the species, thus encouraging further study of this interesting bird. Clearly, the Hypocolius is in need of a much more detailed taxonomic investigation.

Morphological Aspects

In structure, this enigmatic, sleek passerine most closely resembles a long-tailed bulbul of the genus *Pycnonotus*, but with certain features, notably the short, stubby bill and the short crest, that are suggestive of waxwings. In addition, it is often likened to the grey shrikes (*Lanius*) and the *Turdoides* babblers. With regard to the plumage, it exhibits patterns that are similar to those found in the waxwings, as it possesses a black facial mask and prominent markings on the tail tip and the flight-feathers.

The sexes differ, and there is no seasonal variation in plumage. The male is a soft bluish-grey above and pale buff or whitish below, with a conspicuous black mask over the eyes and extending on to the nape, isolating a grey-buff crown; this pattern creates a shrike-like appearance. In excitement, the ear-coverts and nape feathers are raised to form a short crest. The male also has extensive white tips on the black primaries and a well-defined black tip on the tail, features that are prominent in flight. The primaries appear all white when the bird is perched. The female is duller, pale grey-brown, with a creamy throat rather well demarcated from the darker cheeks and ear-coverts, but no black mask. As her tail has only an ill-defined terminal band, and there are only narrow white tips on the otherwise grey-brown primaries, the female exhibits little contrast in pattern when in flight. Juveniles are a pale sandy brown in colour, with washed-out blackish tips on the tail feathers.

Adults and juveniles have a mainly blackish bill and straw-coloured to pinkish legs and feet. The bill is short and blunt and the legs and feet short and fairly heavy, very like those of the waxwings, although the claws are a little longer than those of the latter. The toes are rather like those of an Old World warbler (Sylviidae). The sleek body, long tail and rather warbler-like toes assist with the species' mode of feeding among the branches of fruiting trees (see Food and Feeding).

Adults undergo a complete moult after breeding. Although only limited information is available, this appears to take place from early July to October. Juveniles undertake a partial moult, the timing of which is uncertain but probably coincides more or less with that of the adults. This juvenile moult involves the head, most or all of the body feathers, some or most of the upperwing-coverts, and a variable number of the tertials and their coverts; the central pair of tail feathers, too, is occasionally renewed in this moult.

Habitat

The Hypocolius is found throughout the year in the subtropical zone, occupying lowland drainage basins within its restricted south-west Asian and Middle Eastern breeding range. The areas inhabited by this species are characteristically better-vegetated corridors or belts within generally level or gently undulating terrain. River valleys traversing or fringed by desert or semi-desert, and supporting open broadleaf woodland or copses, are favoured for breeding. The landscape is typified by meandering earth-banked rivers, ox-bow lakes and seasonally flooded marshy depressions, with an associated woodland patchwork. The preferred woodland for nesting is often dominated by tamarisk (*Tamarix*), occasionally with the declining riparian poplar *Populus euphraticus*, but in most cases also with extensive stands of an all-important food source, fruiting

*The male **Hypocolius** is a sleek bluish-grey passerine with a dark mask flaring behind the eye, and a sharply contrasting dark tip to the tail. Its general shape and pattern recall a bulbul (Pycnonotidae) or a shrike (Laniidae), but its stubby bill, the texture and pattern of its plumage, and its social behaviour suggest that it is most closely related to the waxwings. It is unique in several respects, however, suggesting that it is best retained in a monotypic family, at least until its true taxonomic affinities are determined.*

[*Hypocolius ampelinus*, Ghantut, United Arab Emirates. Photo: Hanne & Jens Eriksen]

Salvadora persica, as an understorey, or at least in close proximity. In the southern part of the breeding range, tamarisk is still usually present, but acacia (*Acacia*) may be the dominant species in surrounding woodland and the tree in which nests may be located. The presence of ample fruiting *Salvadora persica* in the vicinity, even if across open plains or rivers, appears to be an ecological necessity for this species in summer.

During the winter months the Hypocolius is restricted to the subtropical and arid tropical zones, occurring in abundance to just south of the Tropic of Cancer in the Arabian Peninsula (see Movements). Its non-breeding habitat includes acacia woodland, groves of date palms, overgrown gardens, thorny scrubland and other woodlands. It has also, in recent years, been increasingly recorded at this time of the year in irrigated plantations, particularly those with *Salvadora persica*.

In the non-breeding season, this species typically assembles at communal roosts. The favoured habitat at winter roost-sites is generally neglected or abandoned date gardens, thorny woodland, most often of acacia, and also irrigated mixed plantations.

General Habits

This is a gregarious bird, both during and, especially, outside the breeding season, and it is often conspicuous. When breeding, however, it becomes shy and may quickly abandon its nesting attempt. In non-breeding areas, however, the Hypocolius can be confiding, or even tame, and thick cover can permit the observer to approach closely.

In what appears to be an anti-predator response, the Hypocolius will freeze and remain silent in the centre of a thick, often spiny tree or bush, especially an *Acacia* or *Zizyphus*. This behaviour has been noted during the presence of Common Kestrels (*Falco tinnunculus*), Eurasian Hobbies (*F. subbuteo*), Eurasian Sparrowhawks (*Accipiter nisus*) and human beings. When the Hypocoliuses do flush, they generally fly, sometimes in a low sweep, only a short distance into yet more cover, quickly and nimbly clambering into the interior of the thickest part. On some occasions, they will fly off strongly in a direct line for several hundred metres or circle around at some height for a few minutes.

Although alarm calls are given in response to the presence of predators, such as snakes, near the nest, more animated mobbing has not been reported. Agitated individuals may erect the nuchal feathers to form a small pointed crest, which, in the case of adult males, includes part of the black feathering of the nape.

The species is social at all times, and without demonstrating antagonistic behaviour, even when feeding or collecting food. Moreover, breeding pairs occur at high density in suitable nesting habitat (see Breeding), and family parties and small flocks remain social and highly vocal at such times. The birds are active throughout the day in summer, even though temperatures may reach 49°C, and they make regular trips to nearby rivers and pools in order to drink, when up to a dozen individuals may visit simultaneously. The Hypocolius regularly visits water during the non-breeding season, too, dropping to the ground briefly to drink from pools, tanks, barrels, *falaj*s (irrigation channels) and drainage channels. In the wintering areas, groups have also been observed at lawn sprinklers.

Communal roosts, sometimes containing over 500 individuals, are a typical feature of this species on its wintering grounds. The birds arrive punctually at the roost-site each evening, with a seasonal progression in relation to daylength clearly evident. The first sign of their arrival is often their distinctive calls, heard as they fly high overhead, although it can be difficult to pinpoint the exact position of an arriving flock.

Although individuals sometimes fly in singly, they generally arrive in flocks, in Bahrain of up to one hundred birds at a time. Swirling flocks may circle the roost for several minutes, but if undisturbed they will plunge directly into the roost from some height, quickly and deftly moving into the centre of a thorny bush or suckering date palm, where they remain silent but vigilant. Flocks often break up during descent over the roost, smaller parties then dispersing into different parts of the overall area. One or more individuals may perch openly during the earlier stages of arrival, or move into the open again shortly after reaching the roost. The birds often remain somewhat jittery and will sometimes take to the wing again, circling around while calling, before dropping in once more. Although the arrival at the roost is typically at high level, as with winter roosts of Redwings (*Turdus iliacus*), for example, individuals and flocks sometimes fly in at low level immediately prior to dusk. No further movement or calling is noted after nightfall.

Departure from the roost takes place at first light, generally in small groups of fewer than ten individuals. If the roosting birds are disturbed by humans, however, a mass and rather disordered exodus may be provoked.

This species exhibits strong fidelity to roost-sites from year to year, even when apparently similar sites are present in abundance in the surrounding habitat. In Bahrain, subsidiary pre-roost assembly points have been identified where, although some indi-

Unlike its presumed relatives the waxwings (Bombycillidae), the ***Hypocolius*** *is characterized by distinct sexual dimorphism. In all seasons, females are pallid, poorly marked versions of males, with pale throat patches. The ill-defined dark mask and the prominent pale base to the lower mandible imply that this is a young bird. As in females, the dark patch at the tip of the tail is much more restricted and diffuse in juveniles, and they lack the black and white effect so conspicuous on the underwings of adult males.*

[*Hypocolius ampelinus*, Ghantut, United Arab Emirates. Photo: Hanne & Jens Eriksen]

viduals may stay overnight to roost, others simply convene before moving off again to join the main roost.

The normal flight of the Hypocolius is strong and direct, with a characteristic whirring wing action. It may glide or bank aerobatically, and it often descends rapidly from high up in a swooping closed-winged dive, almost a plummet, not unlike that of a thrush (Turdidae). It bears more than a passing resemblance to the Southern Grey Shrike (*Lanius meridionalis*) and bulbuls of the genus *Pycnonotus*, both in flight and when perched openly, and this presumably accounts for the species' alternative, but now obsolete, name of "Shrike-bulbul".

Voice

The Hypocolius is vocal at most times. Moreover, with the exception of a loud continuous "kirrr", which is a feature of courtship display, the calls are apparently the same throughout the year. No true territorial song has been described.

The flight call is a distinctive mellow, liquid and slightly querulous or whirring "tre-tur-tur", with the notes running together and the last two lower-pitched. When perched, the Hypocolius utters a descending whistled "whee-oo", this being remarkably reminiscent of the typical call of the Eurasian Wigeon (*Anas penelope*) heard from a distance. This vocalization, although construed as being the contact call of individuals concealed in thick cover, is occasionally given also in flight. When feeding, the Hypocolius often remains silent for long periods. A collective murmuring, with mewing calls almost like those of a buzzard (*Buteo*), is heard at the roost. These calls are very like the one just described, but rather muted, and are similar to those emanating from a Common Starling (*Sturnus vulgaris*) roost, for example.

Food and Feeding

Like its probable relatives the waxwings (see Systematics), the Hypocolius is a specialist frugivore, although it does also take a variety of arthropod prey. Aerial feeding for flying insects has been observed in winter, and individuals have been seen to drop to the ground to pick up live beetles (Coleoptera). Otherwise, this species reportedly gleans invertebrates from plant foliage and branches while perched, such feeding often taking place unobtrusively in the centre of a bush.

In summer, although it very often feeds close to the nest-site, the Hypocolius has been observed to make lengthy flights across open plains to feeding grounds away from the immediate nesting area. The quantity of invertebrate prey taken in the breeding season, particularly to provision the nestlings, may be substantial, although supporting data are lacking.

This species feeds extensively on the berries of the plant *Salvadora persica* throughout the year. The Hypocolius, while perched, leans and cranes forwards to pick fruits with rather deliberate movements, these akin to those of, for example, the larger *Sylvia* warblers. The stones and skin of fruits may be rejected after chewing, although small stones and pips are reportedly swallowed and later excreted. There is a similarity in the pattern of feeding activity to other frugivorous species, such as the Bohemian Waxwing (*Bombycilla garrulus*), to which the Hypocolius is thought to be taxonomically closely related (see Systematics). A period of active feeding is often followed by a sojourn in nearby cover, where the bird preens and wipes its bill, and presumably also digests what it has already consumed and passes waste matter, before returning to resume feeding, often in the original spot, some tens of minutes later. Single individuals acting as sentinels on a nearby tree are often an indication of the presence of feeding groups.

During the non-breeding season, when foraging habitats includes date-palm groves with citrus trees, irrigated plantations, wooded farmland and gardens, the diet is again dominated by fruits. In Bahrain, where most study of this species has been undertaken, the food is stated to consist primarily of fallen unharvested dates gathered from the ground. This is not invariably the experience elsewhere in the region, where, although large areas of date groves exist, they are often wholly shunned. When available, the fruit of planted mulberry (*Morus alba*) is taken. The berries of the woody desert shrub *Lycium shawii* are consumed avidly in western Saudi Arabia, and similar observations have been made in Qatar. The Hypocolius may on occasion feed on the apple-like fruits of the "sidr" tree (*Zizyphus spina-cristi*) in Arabia and on those of *Zizyphus nummularia* in southern Makran, in Pakistan. In the latter country, it has also been observed to eat young leaf shoots of *Prosopis spicigera*. Winter visitors in the Rann of Kutch, in western India, were found to have consumed the berries of both *Salvadora persica* and *Lantana aculeata*, the latter being an invasive introduced species there. In Iraq, in the breeding quarters, this species is again reported as favouring ripe dates.

Departure from the winter feeding grounds to the roost begins up to one or two hours before dark, the birds climbing steeply away at intervals over a period of 45 minutes. Perhaps surprisingly, little or no feeding takes place at the roost-site, even when an apparently suitable food supply is present.

Breeding

Nesting takes place from April to July, and two broods are reared annually. Pairing takes place on the breeding grounds, and the first pairs form up to twelve days after the arrival of the first females. Nest duties are shared by both sexes.

The Hypocolius breeds in small, loose colonies of about five to 40 pairs, each of which defends its own small nest-site territory. In favourable habitats fairly high densities can be reached; in south-western Iran, for example, 20–30 nesting pairs were recorded within an area of 200–300 ha, and about 40 pairs were present in 200 ha in the Murgab Valley, in south Turkmenistan. The distance between nests varies from a few metres to 50 m or 100 m.

At the start of the season, males attract females by indulging in short bursts of activity during which the black-and-white wing pattern is prominently displayed. Courtship feeding takes place during the nest-building and egg-laying stages, when pair-members will also perform circling display-flights. In the latter, the partners rise to some 20 m or more above the ground and, keeping a metre or two apart, fly in circles about 20 m wide while giving repeated loud "kirrr" calls. Other features of courtship, observed mostly during the nest-building phase, include bill-rubbing and, in particular, a complex dance in which the male, carrying food, circles the female in a series of hops while shivering his slightly drooping wings. This courtship dance can last for up to five minutes, at the end of which the female begs and is offered the food by the male.

Nest-building begins in April. Both sexes take part in the work, which is completed in four days. The grass-lined cup-shaped nest is constructed in a tree fork, usually in dense cover, between 1 m and 4 m above the ground. The preferred nesting sites are in tamarisk and acacia or in another thorny tree.

Eggs are laid between May and July. In a two-year study in Iraq, the first eggs were recorded on 11th May and the latest laying date was 12th July. It is probable that egg-laying sometimes starts earlier, at least in some parts of the range, as a nearly completed nest has been found in southern Iran on 22nd April. The eggs are oval, smooth and glossy, with a white to very pale grey ground colour, usually patterned with dark grey or grey-brown blotches around the broad end. The clutch is of three to five eggs. The most frequent clutch size appears to be four eggs, and clutch size generally diminishes through the course of the season. Eggs are laid during the early morning, at one-day intervals, but occasionally two days elapse between the laying of consecutive eggs.

Incubation, which begins with the first egg and lasts for 14 days, is undertaken by both sexes, although the female's share of the task is the greater. The eggs hatch asynchronously, over a 73-hour period in one study. Both sexes also care for the chicks, the female again taking on a greater proportion of this duty. For the first five to seven days, the nestlings are brooded more or less continuously. During the daytime when they are not being brooded, one parent will nearly always remain perched on the rim of the nest in order to shade the chicks from the sun. The young leave the nest at 13–14 days, and the family-members stay together for at least a short period thereafter, the duration of this union being unknown.

Movements

The Hypocolius occupies its breeding areas from April or May until August or September. The species then undertakes relatively short-distance movements, primarily in a southerly or south-easterly direction. Although it is clearly not nomadic, it is erratic in terms of the numbers appearing annually in traditional winter and passage stopover resorts. Except in the Karun district, in western Iran, where the Hypocolius is still found in winter, the entire population leaves the breeding grounds in autumn. Migration is nocturnal, and most movement is probably over distances of no more than 1000 km, and perhaps substantially less. There are no ringing recoveries.

The core of the wintering range lies in southern Iran and Pakistan, in the regions of Makran, Baluchistan and Sindh, and in western and central Saudi Arabia and coastal districts of the western Gulf States, primarily Bahrain. A number can also sometimes be found at this season in the United Arab Emirates. This species occurs as a vagrant in Oman, Yemen, Palestine and Israel, and in north-east Africa, where it has been recorded in Egypt, Sudan and Eritrea. Its status in western India is generally regarded as that of a vagrant, although it may be a regular non-breeding visitor in the state of Gujarat.

Autumn passage through southern Iraq lasts from late September until mid-November. In the western Gulf, the Hypocolius makes its first autumn appearance typically by mid-October, after which a rapid build-up takes place, with peak numbers generally present from November to January. The number of individuals overwintering in this region, however, varies annually, and may be exceeded by the total of passage migrants passing through, at least in the southern Gulf. The species is a localized winter visitor to Bahrain, appearing in variable numbers from year to year. It arrives there from early October, with the highest counts being made in November or December. Smaller numbers remain into the early part of the year, and the species is usually scarce by mid-January, although in some years small flocks have remained into March or early April. After the Hypocoliuses have left Bah-

One link between Hypocoliidae and Bombycillidae is the fact that both families are highly mobile and gregarious in the non-breeding season. At this time of year, the ***Hypocolius*** *forages in groups, sometimes moving considerable distances between food patches. These groups coalesce to form communal roosts at night. Flocks arrive from different directions, sometimes circling the roost site for several minutes before swooping down to sheltered perches.*

[*Hypocolius ampelinus*, Ghantut, United Arab Emirates. Photo: Hanne & Jens Eriksen]

The flight of the ***Hypocolius*** *is strong and direct, as befits its itinerant lifestyle. Although it has a rather limited breeding range, centred on Iran and Iraq, virtually the entire population vacates this region in winter. Most birds migrate to the south and east, usually travelling no more than a thousand miles, but some individuals regularly turn up in north-west India or the United Arab Emirates, or further afield.*

[*Hypocolius ampelinus*, Manama, Bahrain. Photo: Hanne & Jens Eriksen]

rain in mid-winter, no return spring passage has been detected. This lends support to the hypothesis that a circular migration is performed (see below).

In Saudi Arabia, the Hypocolius is locally numerous in western areas, from the Hejaz mountains northwards, arriving here in force from the second half of December onwards and remaining to beyond mid-March. Many are present in the winter months also in central parts of this country and around the oases and farmland of the Eastern Province. Spring migration takes place along the northern Gulf coast of Saudi Arabia and Kuwait, as well as through mainly coastal districts of the United Arab Emirates, although in the latter areas very few pass through in some years. In the UAE, it is recorded inland only in March or early April, corresponding with the period when a strong passage is recorded in coastal resorts, which usually reaches a peak in the second half of March. Spring stopovers can continue for several weeks, with numbers of individuals progressively decreasing into the early or middle part of April. The species occurs as an occasional late-autumn migrant on southern Gulf islands, being far rarer on the return passage in spring, although occasional overwintering has been noted on larger UAE islands where cultivations, including those of mature *Salvadora persica* (see Food and Feeding), are present.

The timing of respective departures and appearances in northern and southern Gulf States supports the hypothesis that this species performs a circular or "loop" migration through the Arabian Peninsula. In fact, it is a double-loop, with return passage northwards following both western and eastern routes. There is also some suggestion that its migration patterns are changing in response to the recent availability of man-made habitats, particularly plantations and shelterbelts. Certainly, the appearance of flocks in winter or on passage is a recent and increasing phenomenon in many areas.

Although it is uncertain whether any movements are made in response to cold weather, this remains a possibility. Nevertheless, the irregularity with which flocks appear in some sites is perhaps more likely to be due to the effects of the strong north-west wind, the *shamal*, which prevails in the Arabian Gulf, and which could easily displace individuals during periods of active migration. A further factor is the availability of food supplies, which must also be of importance and contribute to the almost irruptive appearance of flocks in certain years. In this context, the irregularity and typically wide variability in annual rainfall throughout most of the species' winter range may be of some significance.

The breeding areas are reoccupied in spring from April onwards. Arrival is slightly later in the north of the range, such areas then being occupied until August or early September, at least. There is an apparent tendency for males to arrive back on the nesting grounds a few days before the females. This was noted in a study in Iraq, for instance, and it seems likely to apply throughout the species' breeding range.

Relationship with Man

The Hypocolius appears to have no practical significance to man, and no noticeable impact on human interests. There is perhaps a single exception to this generalization, and this relates to ecotourism. This is one of the species most sought-after by birdwatchers in the Middle East. Many birders will travel to the Gulf countries especially to see it in its relatively accessible winter roosts and feeding areas. It is not known to be hunted or in any way persecuted, and, although a fruit-eater, it is not regarded as a pest.

In both its breeding areas and its winter quarters, the Hypocolius frequently associates with humans. It feeds in gardens, palm groves and fruit plantations, often close to occupied buildings, and it regularly makes use of plantations, shelterbelts and date-palm groves for the purposes of roosting. As it requires a readily available supply of water, it will visit water tanks and even lawn sprinklers to drink in the arid lands bordering the Arabian/Persian Gulf. In fact, it is possible that the species has benefited from human activities, especially where otherwise inhospitable wintering areas have been planted with fruit-bearing trees and are irrigated.

Status and Conservation

Although the Hypocolius is regarded by BirdLife International as not being globally threatened, this may be somewhat conjectural. The world population of this species, which has a small range restricted to the Middle East and south-west Asia, is not known, nor are there any data on its population trends or any precise mapping of its breeding distribution. As the greater part of the population breeds in Iraq and Iran, where it may be difficult to conduct field surveys, any attempts at population estimates are probably best done in its winter haunts. Several large roosts have been discovered in these (see General Habits), but the present information is insufficient to enable even an approximate guess of its total numbers to be made.

There is some evidence of destruction of the species' riverine-forest breeding habitat in Iran, and the extensive drainage schemes undertaken in Iraq in the past two decades are unlikely to have been beneficial. In the non-breeding season, flocks tend to exhibit fidelity to their roosting sites, at least in the southern Arabian Gulf, and it is important that these sites are not destroyed and that they are kept free of disturbance. In one instance, a large part of one winter roost in Bahrain was bulldozed in April 2000, although the birds remained tenacious in continuing to utilize the small area left. In north-west India, there is concern that scrub-jungle habitat used by wintering individuals is being destroyed as a result of overgrazing.

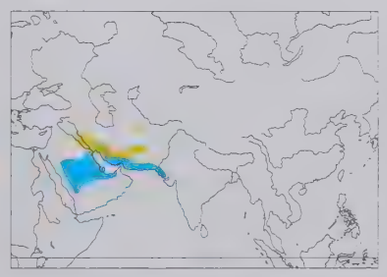
On the other hand, as pointed out above (see Relationship with Man), this species has probably also been helped in recent years by the creation of favourable new habitats.

Genus *HYPOCOLIUS* Bonaparte, 1850

1. **Hypocolius**

Hypocolius ampelinus

French: Hypocolius gris **German**: Seidenwürger **Spanish**: Hipocolio
Other common names: Grey Hypocolius



Taxonomy. *Hypocolius ampelinus* Bonaparte, 1850, "California"; error = coast of Abyssinia. Relationships uncertain. Often considered to constitute a subfamily, Hypocoliinae, within the family Bombycillidae; suggested by some authors to be closer to Pycnonotidae. Further research required. Monotypic.

Distribution. Breeds E Iraq, SW & S Iran, S Turkmenistan and W Afghanistan; non-breeding mainly S Iran, S Pakistan, W & C Saudi Arabia and coastal districts of W Gulf States.

Descriptive notes. 23 cm; 48–57 g. Distinctive passerine with shape like that of a sleek, long-tailed *Pycnonotus* bulbul. Male has greyish-buff crown, black face mask extending to nape; otherwise pale blue-grey above, primaries black with extensive white tips, tail broadly black-tipped; paler, pale buff or whitish, below; iris dark brown; bill blackish, paler at base; legs yellowish-flesh to straw-coloured. Female lacks black mask, is duller, pale grey-brown above, with narrow whitish tips to primaries and ill-defined dark terminal tailband, pale creamy throat contrasting with dark ear-coverts and lighter grey-brown underparts. Juvenile is pale sandy brown, with washed-out blackish tips to tail feathers, flesh-coloured base to lower mandible. Voice. Mellow "tre-tur-tur", last 2 notes lower in pitch; descending "whee-oo" when perched, occasionally also in flight; loud continuous "kirrr" during courtship display.

Habitat. Mostly confined to wooded areas of lowland drainage basins and riverine valleys of subtropical zones when breeding; particularly important are date-palm groves and *Populus euphraticus* woodland, with tamarisk (*Tamarix*), acacia (*Acacia*) or other thorn trees for nesting. Non-breeding habitat similar but more wide-ranging, including desert scrub, irrigated plantations and fruit groves. Presence of fruiting trees (especially *Salvadora persica* and date palms) essential; supply of drinking water also important.

Food and Feeding. Specialist frugivore; some invertebrates also taken. *Salvadora persica* berries form major part of diet throughout year; dates also locally important, these generally gathered as fallen unharvested fruits on ground. Other fruits regularly taken (records mostly from non-breeding range) include those of mulberry (*Morus alba*), the desert shrub *Lycium shawii* and *Zizyphus spina-cristi*; in Pakistan observed to eat fruits of *Zizyphus nummularia* and young leaf shoots of *Prosopis spicigera*, and in W India berries of the introduced invasive plant *Lantana aculeata*. Feeds socially in small groups, usually unobtrusively within dense foliage. Forages usually from perch, by leaning and reaching forwards; also on ground. Stones and skin of fruits may be rejected after chewing, but small stones and pips reportedly swallowed and later excreted. Invertebrates are gleaned from foliage and branches; seen also to to drop to ground to pick up beetles (Coleoptera); aerial feeding for flying insects observed in winter.

Breeding. Egg-laying from mid-May at latest, continues to mid-Jul; two broods appear to be typical. Semi-colonial, up to c. 40 pairs in loose association; each pair defends only immediate area around nest-site. Cup-shaped nest built by both sexes, of grass and vegetable down on base of small twigs, lined with finer grass, down, sometimes also hair and wool, placed 1–4 m off ground typically in tamarisk, acacia or other thorny tree. Clutch 3–5 eggs; both sexes incubate and both feed and brood chicks; incubation period 14 days, nestling period 13–14 days.

Movements. Short-distance migrant. Small numbers remain in W Iran throughout year; majority migrate S & E, main wintering areas in S Iran, Pakistan, W India, W & C Saudi Arabia, and Arabian Gulf States (notably Bahrain). Departure from breeding areas mainly Aug–Sept; arrives back mostly Apr, later in N of range. Vagrants recorded in several countries S to Egypt, Sudan, Yemen and C India.

Status and Conservation. Not globally threatened. Reasonably common; population size, precise range and trends poorly known, thus difficult to assess true status. Restricted to SW Asia/Middle East. Evidence of destruction of riverine forests in which it breeds, and also of winter roost-sites; conversely, the planting of fruiting trees and irrigation will have been of benefit to this species. Not persecuted; not considered a pest, despite fruit-eating habits.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family DULIDAE (PALMCHAT)

- Medium-sized, olive-brown passerine with streaked underparts, deep and strongly curved bill, longish, rounded wings, and sturdy legs and feet.
- 18-20 cm.

- Hispaniola.
- Open and semi-open habitats, especially savanna with royal palm, also open forest.
- 1 genus, 1 species, 1 taxon.
- No species threatened; none extinct since 1600.

Systematics

The Palmchat (*Dulus dominicus*) is the sole representative of its family, Dulidae. It is restricted to the West Indian island of Hispaniola, an island shared between the countries of Haiti and the Dominican Republic. Most modern authors consider the Palmchat to be allied to the waxwings (Bombycillidae) and the silky-flycatchers (Ptilogonatidae), although there is ongoing debate as to whether it is sufficiently distinct taxonomically to merit independent family status.

References to this species date back at least to the sixteenth century, and it was formally classified in 1766, by Linnaeus, who included the Palmchat with the euphonias (*Euphonia*) in his genus *Tanagra*. Subsequently, the Palmchat was placed with the waxwings and silky-flycatchers in a family Ampelidae, and this treatment remained the consensus with most authors until 1904, when R. Ridgway split this group into three separate families, the Bombycillidae, the Ptilogonatidae and the Dulidae. Many twentieth-century taxonomists continued to follow this classification, although some treated the three taxa as subfamilies within Bombycillidae, and a few authors even included the Hypocolius (*Hypocolius ampelinus*) of south-west Asia in a fourth bombycillid subfamily.

In the last decades of the twentieth century, many previously held beliefs were challenged by the findings of molecular-genetic studies. C. G. Sibley and J. E. Ahlquist, in their comprehensive reappraisal of avian phylogeny and systematics based on DNA–DNA hybridization, suggested that the oscine passerines formed two major lineages, which they treated as "parvorders", each of which they further subdivided into three superfamiles. The perceived fundamental relationships of the Palmchat, however, remained unaffected. These authors included the Palmchat, the waxwings and the silky-flycatchers in the family Bombycillidae, within their parvorder Passerida.

Evidence regarding the taxonomic affinities of *Dulus* is sometimes conflicting. In a 1951 study of plumage coloration, nesting and feeding habits, skeletal characters, certain muscles and the digestive tract, M. D. Arvey concluded that the waxwings, the silky-flycatchers and the Palmchat were closely related and that they should, indeed, be included in the same family. Further support for this arrangement comes from the fact that the humeral fossa is single in these three groups, as it is also, incidentally, in the woodswallows (Artamidae), which Sibley and Ahlquist placed in their parvorder Corvida; this situation provides a rare exception to the general rule that members of the Passerida possess two such fossae and those of the Corvida one. Jaw-muscle characters have been interpreted as indicating that the waxwings, the silky-flycatchers, *Dulus* and *Hypocolius* are all related to one another, and also to the cuckoo-shrikes (Campephagidae) and the bulbuls (Pycnonotidae). Analysis of egg-white proteins by electrophoresis, however, seems to have shown no close relationship between *Dulus* and either *Bombycilla* (Bombycillidae) or *Phainopepla* (Ptilogonatidae).

The plumage of the Palmchat is somewhat hard and harsh, unlike the silky, blended plumage of the waxwings and silky-flycatchers, and, whereas the latter groups build typical open cup-nests, the Palmchat builds a massive, domed communal nest. In addition, the absence of natal plumage in *Dulus*, again an unusual condition among passerine birds, is a feature shared with *Bombycilla*.

Sibley and Ahlquist's analyses, based on DNA–DNA hybridization, support the long-held view that the waxwings and the silky-flycatchers are the closest living relatives of the Palmchat, and indicate that the three taxa share a common ancestor, the Palmchat having diverged from the ancestral lineage before the split between the waxwings and the silky-flycatchers occurred. DNA from *Hypocolius* was not available for analysis. These authors suggested that the Palmchat should not be accorded a family of its own but, rather, that it should be considered as a tribe, the Dulini, within the family Bombycillidae. This revision has yet to gain wide acceptance. They also suggested that, despite the single humeral fossa, *Dulus*, *Bombycilla* and *Phainopepla* are, indeed, members of the parvorder Passerida, and that they seem to be closest to the dippers (Cinclidae), the thrushes (Turdidae), the Old World flycatchers (Muscicapidae) the starlings and mynas (Sturnidae) and the mockingbirds and thrashers (Mimidae). Evidence to support a relationship with the latter groups is, however, somewhat equivocal.

At the species level, the Palmchat is generally considered monotypic. The population on the island of Gonâve, off the west coast of Haiti, was once believed to represent a geographical subspecies, described by A. Wetmore, in 1929, as *oviedo*. The validity of this race has, however, been questioned, and the taxon has never been generally accepted. It has not been included in any recent check-lists.

Fossil specimens of *Dulus* dating from the Pleistocene have been found in cave deposits on Hispaniola, indicating that the species has been on the island for at least 25,000–50,000 years.

Morphological Aspects

A moderately odd bird in the field, looking most like a coarse-plumaged tanager (Thraupidae) or Old World oriole (Oriolidae), the Palmchat's large bill, small head and long, mobile neck give it a somewhat ungainly appearance. It is easily recognizable because of its noisy and gregarious nature, and because there are no other Hispaniolan species with which it is apt to be confused.

The Palmchat has a deep and strongly curved bill, which is decidedly shorter than the head, and a relatively long, rounded wing. The tail is of medium length, and the legs and feet are large and sturdy, with strongly curved claws. The long wings are an adaptation to this species' largely arboreal habits, and its sturdy feet and strong bill enable it to break off and manipulate the large sticks that it uses in the construction of its massive communal nest (see Breeding). The Palmchat's ability to grasp heavy sticks securely in its beak is made possible by the presence of a shallow trough in the lower mandible.

The plumage of both the male and the female is olive-brown above, including the head, with the back, scapulars and upperwing-coverts decidedly more brownish. The lower rump and uppertail-coverts are greenish-olive, and the tail is brown. The primaries and secondaries, but not the tertials, are edged with yellowish-green, which can be almost invisible in dull conditions, but quite conspicuous in bright sunlight. The underparts are pale buffy, generally broadly and sharply streaked with sooty brown, although the degree of streaking is quite variable. The throat colour also varies somewhat, from buffy white to dusky. The legs and feet are dark grey, the bill is bone-coloured and the eye is red. In the field, there are no evident differences between the two sexes that would enable them to be distinguished. Juvenile plumage is similar to that of the adult, although somewhat darker, with the throat and foreneck almost entirely dark brown, and the rump is buffish, rather than greenish.

Less obvious structural features include rounded nostrils and obvious but minute rictal bristles. The wing contains ten primary feathers, of which the longest are the sixth, seventh and eighth. The tail is shorter than the distance from the bend of the wing to the tip of the secondaries, and the tail feathers are rather narrow, with a broadly rounded tip and stiff shafts.

The Palmchat is of medium size for a passerine, measuring 18–20 cm in length. Measurements taken from museum skins indicate little sexual size dimorphism, although the wing length of males may be slightly longer, on average, than that of females. Few data are available regarding the weight of adult Palmchats. W. J. Arendt and co-workers reported a mean weight of 51 g for two adult males and 47·5 g for five unsexed individuals, and H. J. Temple found that the mean weight at fledging of 15 nestlings was 41 g.

Habitat

Palmchats are found in a wide range of open and semi-open habitats, as well as in broadleaf and pine (*Pinus*) forests, but they are most numerous in low-elevation savannas with abundant royal palms (*Roystonea hispaniolana*). This plant is the Palmchat's preferred nesting site, and its fruits make an important contribution to the bird's diet. Palmchats have been reported as occurring regularly from sea-level to altitudes of up to 1800 m, in areas with both high and low levels of rainfall, although they are absent from the highest mountains and from very dense closed-canopy woodland. The highest elevation at which the species has been reported is 1825 m, below Morne la Selle, in Haiti, and it is described as common at up to 1800 m in La Visite National Park, also in Haiti. In the Dominican Republic, on the other hand, the Palmchat is rarely seen above 1500 m.

Since much of Hispaniola would have been forested in pre-Columbian times, this species may well have benefited from anthropogenic habitat change. Farmland, parks and gardens all provide suitable habitat. Indeed, Palmchats seem quite undeterred by human disturbance and thrive even in the centre of Santo Domingo, the capital of the Dominican Republic and harbouring a human population of more than two million.

General Habits

Although the Palmchat is a conspicuous bird, moving around in flocks in the treetops, and it is readily encountered in open country throughout the island of Hispaniola, it is not a well-known species. It is not particularly wary, but it tends to remain in the higher strata of vegetation, with the result that it is more difficult to observe than other common Hispaniolan species.

The sole representative of the family Dulidae, the ***Palmchat*** *is a heavy-billed, ungainly bird, not so much odd-looking as out-of-place, resembling an Old World oriole or Australasian figbird (Oriolidae), and yet endemic to the Caribbean island of Hispaniola. It is traditionally grouped with waxwings (Bombycillidae) and silky-flycatchers (Ptilogonatidae), and these are still considered to be its closest relatives. There have been moves to join all three in a single family, but the Palmchat is so odd in the pattern and coarseness of its plumage, as well as major features of its behaviour and voice, that its separation in a monotypic family seems unavoidable.*

[*Dulus dominicus*, Santo Domingo, Dominican Republic. Photo: Don Roberson]

Palmchats are highly social at all times of the year. They can frequently be seen perched along a branch, each in physical contact with its neighbour, or flying after one another while carrying the bulky twigs with which they construct their massive communal nests. These nests are used by the group-members not only for breeding, but also for roosting outside the breeding season. They are added to continually over the years, and can exceptionally reach dimensions of several metres in diameter. Other birds, including the Greater Antillean Grackle (*Quiscalus niger*) and even species as large as the Yellow-crowned Night-heron (*Nycticorax violacea*), have been reported as building their own nests atop occupied Palmchat nests.

The Palmchat has a swift and often notably direct flight, the bird taking a beeline from the nest to other trees containing berries or nest twigs. The flight action combines rapid wingbeats with occasional glides, rather like that of its close relative the Bohemian Waxwing (*Bombycilla garrulus*). It is agile in tree and bush foliage, where it sometimes makes use of its long legs and hooked claws to cling to the underside of branches. Its feeding actions and gait are reminiscent of those of a large tit (*Parus*) or crossbill (*Loxia*). It is almost never seen on the ground.

Unfortunately, the Palmchat has been the subject of only a few scientific studies. As a consequence, relatively little is known about its social organization, or, indeed, its natural history in general.

Voice

The Palmchat is quite a noisy and vocal bird, particularly when close to its nest. It has a repertoire of strange calls, some harsh and others more tuneful. Cheeps, gurgles, caws and whistles may all be heard. These are sometimes emitted singly, while at other times they are uttered as a sustained "chattering" that sounds rather like that given by a Common Starling (*Sturnus vulgaris*), although less complex than the latter's. The species has no true song.

Little is known about the context of particular calls, with the exception of the alarm call. Palmchats have a well-developed sentinel system. When a raptor appears, a loud "cheer, cheer, cheer", a musical whistle that drops in pitch, is instantly given, sometimes by the whole group in chorus. Thereafter, the flock immediately becomes quiet and still, and any individuals in flight or otherwise exposed dive for cover. This alarm call is apparently specific to raptors, and is not given when human intruders approach or climb towards the nest.

Food and Feeding

Palmchats have fairly broad dietary habits, and reports demonstrate that they feed on a wide range of fruits, insects, and even flowers and leaves. A dissection of the stomachs of 58 adult Palmchats revealed that, in 57 cases, the contents consisted entirely of vegetable matter. Similarly, faecal samples taken from 99 nestlings consisted largely of fruit seeds, with a small percentage of arthropod material. This species appears, therefore, to be primarily frugivorous, supplementing its diet with a little animal matter. G. Mauersberger speculated that apparent folivory, or leaf-eating, by the Palmchat might be a result of its consuming leaves containing the mining larvae of insects.

An interesting feature of this species' ecology is that its nest-sites serve also as food resources. Palmchats nest almost exclusively in royal palms, which typically bear a heavy crop of berries. They can frequently be seen feeding on these berries, and seeds of royal palm were often found in the faecal samples taken from nestlings. Other plant species exploited for food by this species include guano palm (*Coccothrinax argentes*), caya colorado (*Bumelia salcifolia*), penda (*Citharexylum fruticosum*) and almacigo (*Bursera simaruba*), as well as *Bunchosia glandulosa*, *Mammea americana*, *Inga fagifolia*, *Piper aduncum*, *Cecropia peltata*, *Rauwolfia nitida*, *Wallenia aurifolia*, *Sabal umbraculifera* and species of *Annona* and *Cordia*.

Palmchats often or, indeed, almost always forage in groups. They show a strong preference for the upper levels of trees and palms, rarely being seen in bushes, and they never forage on the ground. The insect items in the diet are gleaned from trees and plants or caught on the wing.

Breeding

The most striking aspect of this species' behaviour is its unusual nesting habits. Groups of Palmchats build bulky stick nests, often over 1 m in diameter and height, and occasional nests with dimensions of up to 2 m have been recorded. Within this communal structure, each pair has its own separate nest-chamber, which is crudely lined with dried grass and strips of palm leaves. Generally, each compartment has its own separate entrance tunnel, measuring 5–40 cm or more in length, although some nests have a central chamber with the individual egg-chambers leading off this. Each pair apparently lives independently of the others. Oc-

*The **Palmchat** conducts most of its foraging activity at considerable heights above the ground, rarely descending to lower bushes, and much less the ground. It is essentially a vegetarian generalist: both adults and young consume a wide range of plant materials, especially fruit, supplementing this with very minor quantities of invertebrate prey. The range of fruit types noted in the diet is broad, deriving from several types of palm, and both native and exotic trees.*

[*Dulus dominicus*, Dominican Republic. Photo: Doug Wechsler/ VIREO]

By contrast with its important role as a major seed-dispersal agent on Hispaniola, the ***Palmchat*** *has a rather detrimental impact on an earlier stage of the plant reproductive cycle. Not only does it eat leaves, but it seems to be partial to devouring flowers, as these photographs attest. Indeed, initial observations of foraging groups suggest that folivory and florivory are rather common traits of this conspicuous species.*

[*Dulus dominicus*, Santo Domingo, Dominican Republic. Photos: Don Roberson]

casionally, two or more females may lay eggs in the same chamber, but whether this is due to parasitism or is an example of co-operation is unknown. Exceptionally large nests can be occupied by more than 50 pairs, although a more typical group size is of 4–10 pairs, and some nests are occupied by just a single pair.

The nest is used communally for roosting outside the breeding season, and it may remain occupied for several years. Nest-building and nest maintenance take place throughout the year.

Only a handful of bird species worldwide regularly construct multi-chambered communal nests; they include the Sociable Weaver (*Philetairus socius*), the Monk Parakeet (*Myiopsitta monachus*) and the Red-billed Buffalo Weaver (*Bubalornis niger*). It is worth remembering that the waxwings and the silky-flycatchers, supposedly the Palmchat's closest relatives (see Systematics), build open cup-like nests.

In the lowlands, the usual nest-site is in the frond bases of a royal palm, at a height of 6–25 m. The preference for royal palms is very strong; of 722 nests surveyed in 1985, as many as 699, or 97%, were situated in this species of palm. Conifers are utilized at higher altitudes, but nests built in these trees tend to be smaller, often housing only one pair. Palmchats have also been recorded as nesting on telegraph poles, although this apparently occurs less frequently than it did in the past. A more recent and fully documented record concerns a Palmchat nest built in an entirely unexpected site. In 2001, a nest of this species was discovered on a rock, surrounded by the waters of the Caribbean Sea, close to the shoreline at Cabo Rojo, in the south-west of the Dominican Republic. Only one pair of Palmchats appeared to be using the nest. This is the first terrestrial nest recorded for this species, and is clearly quite exceptional.

Breeding takes place from February through to August, or even later. The precise timing varies from year to year, and may also vary with geographical location. In the Dominican Republic, for example, the onset of breeding in the dry south-west was found to be in February, while in the north-east, an area with much greater rainfall, breeding in 2001 did not start until late April. In the Caribbean region in general, the onset of breeding for most passerine species is quite variable, and tends to coincide with the start of the rainy season.

During the courtship stage, the female Palmchat opens her bill and shakes her wings, whereupon the male provisions her with food, before mounting her. Observations made by S. Guerrero indicate that, rather surprisingly, pairs of Palmchats occasionally copulate in mid-air.

The Palmchat lays 2–7 eggs. The average size of 45 clutches was 3·7 eggs. Palmchat eggs are extremely variable in terms of both background colour and patterning. Background colours range from pale green through off-white and cream to mid-beige, and markings include blotches, speckles or scrawls in brown, purple-brown or grey. The markings may be light or heavy, and they may be concentrated at one end, usually the broad but sometimes the narrow, or evenly distributed over the whole surface. The eggs within a single clutch, however, are typically of a standard appearance. The fact that inter-clutch variability is so much greater than variability within a clutch suggests that intraspecific brood parasitism may occur, and that egg colour and pattern may be used as a "signature" to enable a female to recognize her own eggs. Of 44 clutches examined in 2001, eleven contained one, two or, exceptionally, three eggs that did not match the rest of the set. Furthermore, there were at least two instances of eggs appearing out of sequence, after the clutch had been completed, and this is likely to be an underestimate of the true rate, as nests were checked only every four days in this study. Because so little is known about the Palmchat's breeding behaviour, however, it is impossible to say whether this apparent brood parasitism may, in fact, be due to some form of co-operative breeding. The only thing that seems certain is that Palmchats have an unusual and fascinating social life, of which we know far too little.

Incubation lasts for about 15 days, and the nestlings fledge at approximately 32 days. Both the male and the female feed the chicks. Palmchats reach reproductive maturity at one year of age, and juveniles start to help with nest-building and with maintenance of the nest at the age of three months.

Botfly (Gasterophilidae) parasitism is a common problem for the Palmchat, and is significantly correlated with reduced nest success. This may be a cost of the Palmchat's highly social lifestyle. Predation may also be of some significance. Known nest predators of this species include snakes, Palm (*Corvus palmarum*) and White-necked Crows (*Corvus leucognaphalus*), the Sharp-shinned Hawk (*Accipiter striatus*) and the American Kestrel (*Falco sparverius*).

The Palmchat is one of six reported host species on Hispaniola for the Shiny Cowbird (*Molothrus bonariensis*), an invasive South American brood parasite which arrived on the island in 1972. A generalist, the Shiny Cowbird sometimes parasitizes its hosts at extremely high levels, over 90% in some instances, and it has been implicated in the decline of several Caribbean endemics. In the case of the Palmchat, parasitism rates in areas of the south-western Dominican Republic where cowbirds were known to occur were reported as 5·3% of 243 nests in 1974–77 and 25·8% of 62 nests in 1982; in the north-east, however, none of the 58 clutches located in 2001 was parasitized.

One of the most interesting aspects of ***Palmchat*** *biology is its habit of building massive domed nests almost exclusively in the high crowns of the royal palm* (Roystonea hispaniolana), *an association which gives rise to the bird's English name. These nests often exceed a metre in diameter and are usually attended by 4–10 pairs, although in exceptional cases nests have been found to house more than 50 pairs. It appears that each pair has its own independent nesting and roosting chamber, and it is not clear whether, or to what extent, breeding in the Palmchat is a co-operative endeavour.*

[*Dulus dominicus*, Santo Domingo, Dominican Republic. Photo: Doug Wechsler/ VIREO]

This species may not be an ideal host, as the nestling cowbirds require a diet high in animal protein, whereas Palmchats feed their chicks mainly on fruit (see Food and Feeding). It certainly seems that the Palmchat does not recognize the Shiny Cowbird as a threat. Female cowbirds are not harassed by this species, and have even been observed perched next to Palmchats within a few metres of the nest.

Movements

The Palmchat is resident throughout the year on Hispaniola, and does not undertake long-distance migration. Little is known about the local movements of this species. Mauersberger speculated that it may make some kind of seasonal migration between different altitudes or different habitat types. He based this theory on the fact that he observed fewer Palmchats during the post-breeding period than he had done before the breeding season started; this is contrary to the expectation that bird populations should be at their highest at the end of the breeding season.

Although this species is resident on the offshore islands of Gonâve and Saona, it appears to be a poor disperser. It is absent from small islands, such as Île-à-Vache, lying less than 10 km from the coastline of Hispaniola. There is, however, an anomalous report of a possible Palmchat observed in 1975 in Jamaica, although this remains uncorroborated.

Relationship with Man

Because of its conspicuous nests and its striking social habits, the Palmchat is well known to the general public. Indeed, it bears the title of the "National Bird" of the Dominican Republic. Despite this familiarity, however, the species does not appear to feature in Hispaniolan folklore. In the past, it was killed and eaten by man, as were virtually all bird species on Hispaniola. Today, in the Dominican Republic, at least, this practice is on the decline.

It is not really known if the Palmchat, being primarily a frugivore (see Food and Feeding), causes any real damage to commercial farming interests. If it is responsible for any losses, it makes up for these in its role as a seed-disperser.

Status and Conservation

Dulidae is one of only two families, the other being the todies (Todidae), having a world range confined to the West Indies. The Palmchat has a relatively small global range. It is restricted to the Caribbean island of Hispaniola, which covers a surface area of approximately 76,000 km². Within this range, however, it is an extremely abundant and widespread species, occurring also on the offshore islands of Gonâve and Saona. Mauersberger commented that the Palmchat was so common in the habitats around his residence that, of every ten songbirds seen outside shrubbery, at least eight or nine were likely to be of this species, often to the disappointment and frustration of birdwatchers visiting the island from abroad.

In a point-count survey carried out in the north-east of the Dominican Republic in 2001, the Palmchat was found to be by far the commonest species locally, with a population density roughly ten times greater than that of its numerically closest rival. This survey was made in royal palm savanna, prime Palmchat habitat. Nevertheless, as appropriate habitat for the species is widespread on the island, the Palmchat is certainly a strong candidate for the title of Hispaniola's commonest bird.

As the Palmchat adapts well to man-made habitats, it is less likely to be at risk from habitat loss than are many other species of fauna. There is, however, some evidence of fluctuations in Palmchat numbers over time. In suitable habitat in the Dominican Republic, for example, many fewer nests were found in 1996 than were located in the same areas in the years from 1974 to 1976.

Little is known about the current status of the Palmchat in Haiti, where human social and environmental problems are greater than they are in the neighbouring Dominican Republic. Although habitat loss in Haiti has been extensive, and hunting, especially for food, widespread, there are signs that the situation may be improving. Again, it is to be hoped that the Palmchat's adaptability will help to ensure that it continues to thrive in that country.

Fears have been expressed that nest parasitism by the Shiny Cowbird could have a negative impact on the species. This, however, seems improbable. Parasitism rates appear to be relatively low and, as discussed earlier (see Breeding), the Palmchat is unlikely to make a suitable host owing to the very low protein content of the nestling diet.

PLATE 33

Genus *DULUS* Vieillot, 1816

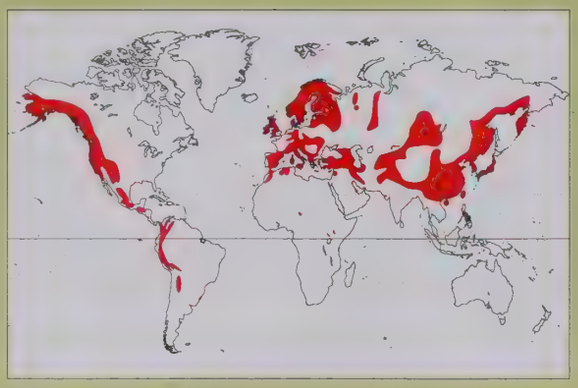
Palmchat

Dulus dominicus

French: Esclave palmiste **German**: Palmenschwätzer **Spanish**: Sigua Palmera

Taxonomy. *Tanagra dominica* Linnaeus, 1766, Santo Domingo, Hispaniola.
Taxonomic position debated. Generally considered to be allied to families Bombycillidae and Ptilogonatidae, and sometimes included as a subfamily within former. Birds from I de la Gonâve (off W Haiti) described as race *oviedo*, but appear inseparable from those elsewhere in species' range. Monotypic.
Distribution. Hispaniola, including I de la Gonâve and Saona I.

Descriptive notes. 18–20 cm; 41–52g. Medium-sized, dull-plumaged passerine with short deep bill strongly curved on culmen. Plumage is olive-brown above, rump greenish, tail brown; primaries and secondaries with brighter yellowish-green edges; pale buffy below, boldly but variably streaked with brown, entire throat sometimes dusky; iris red; bill dull horn-coloured to dull yellowish; legs dark grey to brown-grey. Sexes alike, male possibly on average longer-winged than female. Juvenile differs in having throat and foreneck almost entirely dark brown with only faintly paler edges, and rump buffish. VOICE. Variety of short, harsh notes, sometimes likened to those of Common Starling (*Sturnus vulgaris*); distinctive alarm call a musical whistle dropping in pitch, often given in chorus by group-members; no true song.



Habitat. Primarily royal palm (*Roystonea hispaniolana*) savannas, also other open areas with scattered trees, including urban parks and gardens; absent from dense forest. From near sea-level to 1825 m; usually commonest at low elevations.
Food and Feeding. Diet primarily wild fruits, also flowers and, apparently, leaves; some arthropods also taken. Fruits eaten include those of, especially, *Roystonea hispaniolana*; also guano palm (*Coccothrinax argentes*), caya colorado (*Bumelia salcifolia*), penda (*Citharexylum fruticosum*) and almacigo (*Bursera simaruba*), and *Bunchosia glandulosa*, *Cordia nitida* and *C. alliodora*, *Mammea americana*, *Annona reticulata* and *A. muricata*, *Inga fagifolia*, *Piper aduncum*, *Cecropia peltata*, *Rauwolfia nitida*, *Wallenia aurifolia*, *Sabal umbraculifera*. Typically found in small flocks or family parties; active, noisy. Arboreal forager, with distinct preference for upper levels of trees; occasionally forages in bushes. Arthropods taken by gleaning from substrate; also hawks insects in flight.
Breeding. Season Feb–Aug, with some regional variation, apparent peak in Mar–Jun. Communal breeder, single nest occupied by 1–50 pairs, typically 4–10 pairs. Nest a massive communal "apartment block", up to 1 m × 1 m, occasionally bigger (to c. 2 m), constructed of twigs, each breeding chamber usually with separate entrance tunnel 5–40 cm long, each lined with dry grass and palm-leaf strips; placed at height of 6–25 m, almost always in royal palm, sometimes in other palm (e.g. *Cecropia schreberiana*, *Sabal umbraculifera*) or tree (e.g. conifer in higher areas), rarely on telegraph pole; exceptional record of nest on rock just off coast; nest used also for roosting outside breeding season, often occupied for several years. Clutch 2–7 eggs, mean c. 4; incubation period c. 15 days; chicks fed by both sexes, nestling period c. 32 days. Nests parasitized by Shiny Cowbird (*Molothrus bonariensis*). Nest predadors include snakes, Palm Crow (*Corvus palmarum*), White-necked Crow (*Corvus leucognaphalus*), Sharp-shinned Hawk (*Accipiter striatus*) and American Kestrel (*Falco sparverius*); reduced success significantly correlated with botfly (Gasterophilidae) parasitism.
Movements. Resident. Unconfirmed record of vagrant in Jamaica.
Status and Conservation. Not globally threatened. Very common to abundant, and widespread. One of the commonest bird species on Hispaniola; numerous everywhere apart from highest mountains. Has adapted extremely well to man-made habitats, such as farmland, parks, town squares and city gardens. Some evidence of fluctuation in numbers; many fewer nests found in appropriate habitat in Dominican Republic in 1996 than found in same areas in 1974–76.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family CINCLIDAE (DIPPERS)

- Medium-sized, plump passerines with short cocked tail, relatively short, broad rounded wings, slender bill with slight hook, long strong legs, and soft, dense plumage.
- 14–23 cm.

- Nearctic, Neotropical, Palearctic and Oriental Regions.
- Fast-flowing streams and rivers, mostly in uplands, occasionally slower or still waters.
- 1 genus, 5 species, 24 taxa.
- 1 species threatened; none extinct since 1600.

Systematics

The family Cinclidae comprises five species in a single genus, *Cinclus*, with a combined geographical range covering North, Middle and South America, north-west Africa, Europe and Asia. The dippers are extraordinary in being the only passerines adapted to exploit aquatic habitats fully, by swimming and diving. They are similar in shape to large wrens (Troglodytidae), a fact which led taxonomists in the past to place Cinclidae close to Troglodytidae. Nevertheless, the dippers strongly resemble the thrushes (Turdidae) in general morphology and in the spotted juveniles of some species. Electrophoresis of egg-white proteins appears to confirm this affinity, and more recent DNA-sequencing studies suggest that the dippers should be placed close to both the Turdidae and the starlings (Sturnidae) in the proposed superfamily Turdoidea.

Among the dipper species, global distribution combined with genetic evidence derived from mitochondrial cytochrome *b* and ND2 genes suggest, with only minor uncertainty, that the genus *Cinclus* arose in Eurasia around four million years ago, but soon spread into the New World. Phylogenetic interpretation indicates close affinities between the two Old World species, the Brown Dipper (*Cinclus pallasii*) and the White-throated Dipper (*Cinclus cinclus*), and between the two South American ones, the White-capped Dipper (*Cinclus leucocephalus*) and the Rufous-throated Dipper (*Cinclus schulzi*), these two pairs being separated by the American Dipper (*Cinclus mexicanus*). The New World species and the Old World species are considered, in turn, to represent two sister-clades.

Geographical progression from the Old World into the New World was accompanied by the development of morphological variations. These are most obvious in the plumage differences among the species (see Morphological Aspects).

Of the five members of the family, one, the Rufous-throated Dipper, is considered monotypic. The other four have been divided into subspecies, but these are often based on slight plumage differences, on the characters of type specimens and on geographical distribution. Moreover, for the White-throated Dipper, initial genetic evidence from investigation of the mitochondrial cytochrome *b* gene suggests that the current intraspecific taxonomy could well be misleading and in need of reappraisal. Up to 20 races of this species have been described, these differing mainly in the colour of the head, nape, breast and belly, in the presence and width or otherwise of a chestnut band between the dark belly and the white breast, in the width of dark feather fringes on the underparts, and in size. Several of the named subspecies are distinct, notably the eastern *leucogaster*, the belly of which is white. In Central Asia, however, polymorphism occurs, and all-dark individuals can be found living alongside white-chested ones. Otherwise, Palearctic races have a rufous-brown or blackish-brown breast and belly. Some geographical populations are uniform, but others are highly variable. In Europe, the nominate race in the north and west has a blackish-brown belly and no chestnut band, whereas the British population has a strong chestnut area below the white breast, the chestnut extending onto the flanks and mid-belly. The British dippers have, therefore, been separated as the subspecies *gularis*, juveniles of which are also darker than juveniles of the nominate race. Other described subspecies are less distinct and may grade into each other, even a relatively small area. In general, dark-breasted forms of the White-throated Dipper, such as the nominate race, inhabit cooler, wetter climates, while rufous-brown forms are found in warmer, drier areas, such as those in southern Europe and north Africa.

Ironically, the north African race of the White-throated Dipper, despite its scientific name of *minor*, is one of the largest subspecies. Measurements of live dippers caught in the Atlas Mountains, in Morocco, revealed that these had exceptionally long wings and were heavy, the mean weight of nine males being 76 g and of three females 68 g; these figures have been confirmed by more recent samples. This subspecies was originally described on the basis of a small specimen.

The Brown Dipper, found in the eastern and southern parts of Asia, is divided into three geographical races, which vary in the degree of richness of the brown plumage. A few additional subspecies have been described, but these appear to be indistinguishable from pre-existing races.

In the New World, the American Dipper is distributed from western North America southwards through to Panama. One of its subspecies has an extensive range extending down the whole length of the Rocky Mountains; four others are usually recognized, all of them in Middle America, which differ only slightly in the shade of the plumage, and they may perhaps represent only clinal variation. In the Andes, the three currently recognized subspecies of the White-capped Dipper differ principally in depth of coloration and in the amount of white in the plumage, *leuconotus* from west Venezuela south to Ecuador being the most distinct of the three.

Morphological Aspects

All dippers are dumpy thrush-like birds with a short cocked tail, males being larger than females. They are medium-sized passerines, most individuals falling in the approximate size range of 16–20 cm, and they weigh about 50–80 g. They are highly adapted for an aquatic lifestyle, and their size, strength and general hydro-dynamic shape are ideally suited for swimming and diving in fast-flowing water (see Habitat, and Food and Feeding). They also have soft, long plumage and a thick layer of down, and they possess more body contour feathers than do passerines of comparable size. Dippers have a large oil-gland at the base of the tail, the oil being used during preening in order to maintain waterproofing. The dense and well-oiled plumage enables dippers to survive in near-freezing water and in the low temperatures found at high latitudes and high altitudes. In higher temperatures, dippers achieve thermoregulation by standing in shallow water so as to increase heat loss through the legs and feet, or they use shade as a means of protection from direct heat.

All five members of the family have short, broad wings with a powerful musculature, allowing the use of the wings for propulsion in water, often in torrential conditions. In order to ensure that they lose this power for only the briefest period during the annual moult, White-throated Dippers are unusual among passerines in shedding all of the inner primary feathers almost simultaneously, in keeping with the moult strategy of other aquatic birds. The energy expenditure does not increase at this time, but behavioural changes mean that the actions of flying and diving become infrequent. The moult sequences of other dipper species are not well known. Juvenile White-throated Dippers undergo their first moult 4–6 weeks after fledging. During this moult, they replace the body feathers and the lesser, median and inner greater wing-coverts, and then bear a closer resemblance to the adults.

The legs of dippers are long, strong, and equipped with sharp curved claws that grip rocks and mosses on the riverbed or riverbank. The nostrils are narrow, and have a broad membrane or nasal flap to enable closure during submergence. The bill is slender and slightly hooked. The eyelids are covered with white feathers, so that a flash of white is evident when the bird blinks. Bobbing, or dipping (see General Habits), is always accompanied by blinking, and the latter action is probably a signal in courtship (see Breeding), in threat displays and in alert-signalling to warn of potential predators (see General Habits). White-throated and American Dippers can blink 40–50 times per minute. The nictitating membrane has been described variously as milk-white or bluish-white and as cloudy or semi-transparent. This membrane can be moved across the eye independently or as a dipper blinks. It is thought to have a protective function when the bird is underwater, and it may serve to remove water droplets or dirt from the eye. The eye itself has enhanced powers of accommodation for vision in both air and water as a result of the well-developed sphincter muscles of the iris, which can change the curvature of the lens. The eye colour of adult White-throated Dippers is a rich chestnut, but young birds have eyes that are more olive-brown.

So far as plumage is concerned, two members of the family are uniform in coloration, the American Dipper being pebble-grey and the Brown Dipper chocolate-brown. The Rufous-throated Dipper is uniformly grey-brown, apart from the chestnut-coloured throat. The remaining two species have varying amounts of white in the plumage. In the case of the White-throated Dipper, this is confined to the throat and breast in most populations, but one of the Asian subspecies, *leucogaster*, has the entire underparts white. The White-capped Dipper of the northern and central Andes has, as its name suggests, a white crown, and two of its three subspecies, the nominate race and *rivularis*, have a white throat and upper breast. The third subspecies, *leuconotus*, possesses a white patch on the back, and the underparts are wholly white except for the lower flanks and vent. The two Neotropical cinclids, the Rufous-throated and White-capped Dippers, both have a white wingbar, this becoming evident particularly when the wings are flicked. At present there is no firm explanation for these intraspecific differences in colour pattern, although natural selection for cryptic coloration, coupled with features used by three of the species in interspecific or intraspecific signalling, seems most likely. Given the employment of some plumage features, such as the breast feathers, in courtship (see Breeding), elements of sexual selection are possible.

Little sexual dimorphism is apparent. Males have been reported as being darker than females, but dippers become darker with age, in addition to which individuals vary greatly through the year because of feather wear. Size varies within populations, but males are always larger than females.

The dipper family is a well-defined grouping of five, sexually monochromatic riverine species, all notably homogenous in shape, behaviour and ecology, differing only in size and pattern. The ***Brown Dipper*** *is typically robust and streamlined, as befits its semi-aquatic lifestyle. With a fairly stout bill, short wings and stumpy tail, it gives a somewhat rotund impression, often exaggerated by the fact that its tail is habitually cocked. This is one of the two Eurasian species, the other three all belonging to the New World.*

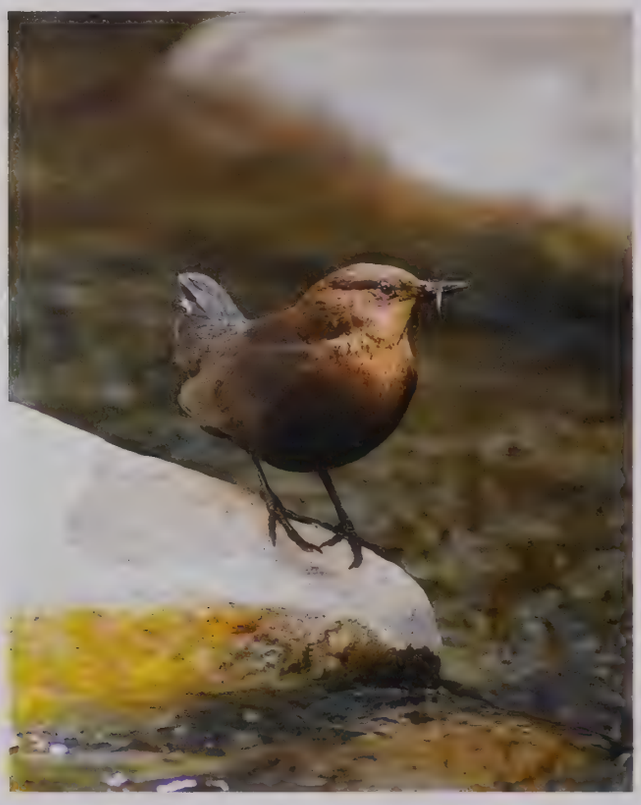
[*Cinclus pallasii pallasii*, Guangdong, China. Photo: John Holmes]

Juveniles of the American and Rufous-throated Dippers differ from the adults only in being paler, especially below, with the underparts mottled, and in having a paler bill. In contrast, juvenile White-throated Dippers are grey-brown above, much paler than the adults, and have buffy underparts with darker speckling. They acquire the adult plumage after about six weeks, sometimes later, but are still distinguishable until the second spring by having pale edges on the greater upperwing-coverts. The juvenile Brown Dipper is grey-brown with white spots above, and the wing feathers and wing-coverts are tipped white; the feathers of the underparts are whitish with brown tips, giving the bird a mottled appearance.

Habitat

The Cinclidae frequent upland fast-flowing streams and rivers, even to the most torrential reaches in mountain ranges, from the Rocky Mountains and the Andes in the New World to the Himalayas of Asia. Most mountain ranges in Eurasia are occupied either by the White-throated Dipper or by the Brown Dipper, or occasionally, as in the Tien Shan Mountains and the Himalayas, by both species. Although the White-throated Dipper occurs in north-west Africa, where it breeds in the Atlas Range in Morocco and in other mountains eastwards to Tunisia, no member of the family is present on apparently suitable mountain rivers elsewhere in that continent. Similarly, rivers in the mountains of eastern North America are unoccupied by cinclids. Dispersal across extensive unsuitable habitat, such as the Great Plains of North America or the Sahara Desert of Africa, has clearly never been achieved.

Although most dippers live in hill and mountain ranges up to elevations of at least 5000 m, altitude itself is non-limiting, and fast-flowing rivers, even those near sea-level, are commonly occupied. The basic requirements are well-oxygenated, clear and largely unpolluted water where stony beds have abundant invertebrate prey, especially, during the breeding season, caddis-fly larvae (Trichoptera), stonefly nymphs (Plecoptera), mayfly nymphs (Ephemeroptera) and calcium-rich molluscs, crustaceans or small fishes (see Food and Feeding). An abundance of salmonid eggs, as found, for example, in rivers around the Pacific rim, can also promote large dipper densities. The birds require rocks from which to feed or dive, and riffles, stony shoals and a stony or rocky substrate on which to find prey. Sites suitable for nesting and roosting are important, but they are often abundant in this habitat type. Cliffs, moss-covered rocks and waterfalls, and walls or bridges with ledges or crevices all provide ideal nest-sites and roost-sites.



Artificial structures such as weirs, mill streams, walls and bridges can sometimes provide fast-flowing water and nest-sites at what would otherwise be the edge of the dippers' range. In addition, White-throated Dippers in Britain sometimes forage around the rocky edges of clear, nutrient-poor (oligotrophic) lakes and on seashores, particularly outside the breeding season.

Watercourses in forests are favoured locations. This is partly because trees provide a supplement of terrestrial insects, notably caterpillars, to the river margins, but also because falling leaf litter is ultimately important for the production of stream insects. Dippers will nest on rivers in villages, towns and other urban sites, and tolerate more open watercourses, provided that the basic requirements are met.

The five species of dipper are, for the most part, geographically isolated from one another, with the exception of a zone of overlap between the Brown Dipper and the White-throated Dipper in Central Asia. In the Himalayas and mountains to the north of there, Brown Dippers are common from about 900 m to at least 3500 m, occasionally ascending above 5000 m where streams remain unfrozen, while White-throated Dippers occur from about 3500 m to 4800 m, occasionally coming lower outside the breeding season. The two species therefore overlap at higher elevations in the Tien Shan Mountains and on the northern Himalayan slopes. There is some suggestion, but little quantitative evidence, that in these cases White-throated Dippers occupy smaller streams than those utilized by Brown Dippers. The extraordinarily rich variety of river-dwelling birds in the Himalayas means that ecological segregation from other abundant river passerines, such as forktails (*Enicurus*), the Plumbeous Water-redstart (*Rhyacornis fuliginosa*) and the White-capped Water-redstart (*Chaimarrornis leucocephalus*), is far more of an issue, and this is achieved by subtle partitioning in habitat use, prey size and diet.

General Habits

In addition to diving, the most conspicuous habit of three of the five species of dipper is the exaggerated bobbing of the body

*The most widespread member of the family, the **White-throated Dipper**, ranges across the Palearctic from western Europe to China. This distribution is broad but patchy, prompting diversification into some twelve races. The most uniform birds are found in the Himalayas, where some are almost entirely brown, a dark morph originally described as a separate race,* sordidus. *By contrast, across the Tibetan Plateau, not far to the north in central Asia, the resident white-bellied race is dramatically bicoloured.*

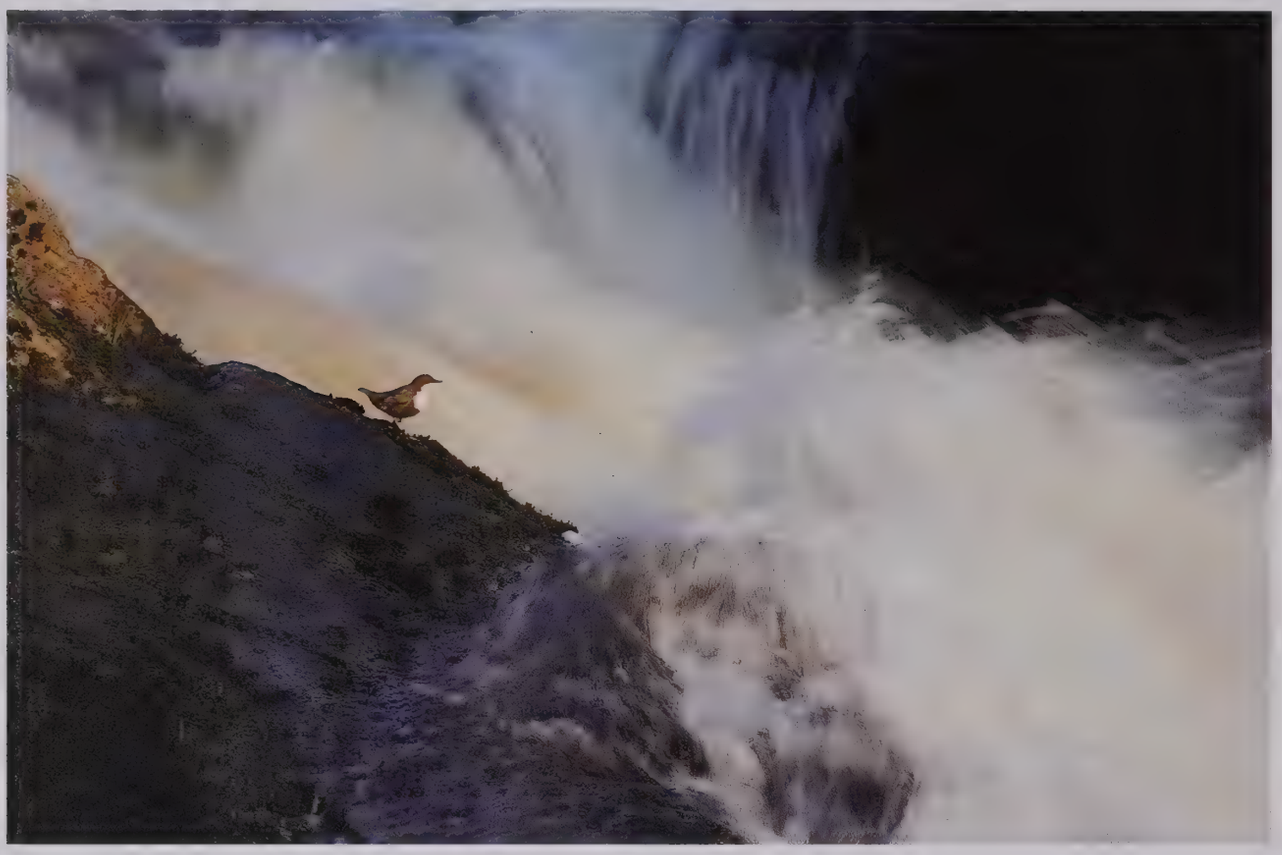
Dippers are strongly tied to fresh water, rarely being found more than a few metres from its edge. Their favoured aquatic habitats are lotic, rather than lentic, meaning they prefer fast-running streams rather than lakes, in part because stagnant waters do not support the types of larval insect on which they prey. This ***White-throated Dipper*** *is foraging in a classic locale, a clear, well-oxygenated, unpolluted stream with rocks and shallow riffles. Given that these features apply most commonly to stretches of waterway that drop 5-20 m with every kilometre, there is usually a strong correlation between dipper density and stream gradient.*

[*Cinclus cinclus aquaticus*, Mangfall, Germany. Photo: Günter Ziesler]

and, at the same time, the flicking-down of the tail and the blinking of the white upper eyelid. It is from the conspicuous bobbing, or dipping, behaviour that the vernacular name of "dipper" is derived. The two Andean species appear to bob infrequently but, instead, they rapidly flick their wings, thereby revealing a white flash as they expose the white inner webs across parts of the primary feathers.

Other river-inhabiting bird species bob, wag the tail or flick the wings, but this behaviour has often been interpreted as providing a form of disguise, helping to make the bird less conspicuous against the movement of fast-flowing water. In the case of the dippers, however, there is now clear evidence that bobbing or tail-wagging is an interspecific signal to predators that the bird is fit and alerted to the latter's presence. In addition, cinclids commonly exhibit dipping and wing-flicking in courtship displays, territorial disputes and aggressive behaviour towards conspecifics, probably as a signal of fitness.

Three of the dipper species commonly dive in shallow water, often less than 1 m in depth, and they can remain on the riverbed for up to 20 seconds. The majority of such dives, however, are only three to four seconds in duration, and they are often made in series of about five per minute over a period of five minutes or more. How dippers are able to remain fully submerged while maintaining position in torrential water was a subject of much controversy, until filming of individuals in tanks showed conclusively the behaviour involved. Rapid wingbeats essentially keep the dipper in position underwater, and also allow forward movement; although of secondary importance, the legs are used as in a running action to help to propel the bird, or are used for clinging briefly to rocks on the bed. When diving, dippers present a silvery appearance, the result of air bubbles entrained in the plumage.



Dippers have many of the physiological adaptations for diving that are possessed by other aquatic birds. For example, there is an immediate drop in the heart rate as a bird plunges underwater, and a further decline during the period of submersion. As the dipper surfaces, the heart rate increases. Dipper blood has a higher concentration of haemoglobin than that found in comparable passerines, allowing for greater oxygen storage.

The members of this family have a fast and direct flight, usually low over the water, and invariably following a watercourse. They fly higher only when pushed to the edge of their territory, at which point they then double back, often flying over the observer. During displays, too, they may fly high into the air. Of course, dippers also gain more height than usual when dispersing over mountain ridges, or on migration (see Movements).

All five of the Cinclidae maintain linear territories along rivers. These range from about 300 m to 2-3 km in length, variation depending on the area of feeding habitat and the abundance of prey animals. Productive rivers have breeding territories that are contiguous, but on marginal rivers there may be unoccupied gaps of unsuitable habitat. Densities vary, therefore. For the White-throated Dipper, the most widely studied member of the family, recorded values per 10 km of river are 0·7-10 pairs in Wales; 1·4-7·7 pairs in Scotland; 1·4-2·2 pairs in south-west Norway; 2·4-2·7 pairs in Germany but four pairs in the Harz Mountains; and 2·3 pairs in Austria. In mountains of the Khamar-Dhaban, in the extreme south of central Russia, dippers are scarce, with a recorded density of only 0·4 birds per 10 km. There may be 1-2 km between pairs, but on frozen sections none occurs. At the other extreme, dippers can reach such high densities, as, for example, outside the breeding season along rivers in the Pacific Northwest of North America, that territories break down and individuals occur within a few tens of metres of each other.

Dippers are territorial when breeding, and often throughout the year. In conditions of extreme cold, however, they may associate together at places where rivers remain unfrozen, and small gatherings may occur in circumstances of unusually high food production. Similarly, they sometimes collect at roosts. Although the majority of White-throated Dippers roost singly or in pairs, some gather at communal roost-sites in the autumn and winter. In the United Kingdom, such sites are often bridges having ledges, girders, crevices in stonework or drainage holes in which the dippers can perch. These roosts can contain nine or ten individuals, although they seldom perch in close contact. During the winter months, when the dippers are no longer roosting close to nest-sites, and when bridges have the thermal advantages of insulation from wind and cold, numbers attending collective roosts increase. No comparable aggregations are known to occur at natural sites, and the birds are often more dispersed in, for example, canyons, under boulders and, probably rarely, in trees.

White-throated Dippers remain faithful to roosting sites, both within and between seasons, throughout their entire life. In stud-

*Like its congeners, the **White-throated Dipper** can survive on waterways with steep gradients, even though this results in an abundance of seemingly inhospitable cascades and white-water torrents. Around these they forage by picking insects or debris from rocks, or by immersing themselves in surprisingly turbulent water. At the other end of the extreme, non-breeding or migrant birds turn up regularly on lowland lakes, mill-ponds and even along the shores of brackish coastal lagoons and rocky beaches. Here they can subsist for some time, but never seem to breed.*

[*Cinclus cinclus cinclus*, south-east Norway. Photo: R. Sorensen & J. Olsen/NHPA]

ies in Wales, for example, fewer than 6% of White-throated Dippers changed roosts from one year to another. Although about 95% of individuals fly less than 3 km, and often less than 1 km, to reach a roost, some arrive from as much as 8 km away, implying knowledge of roost locations well beyond their territories. For some individuals, these movements will be the largest that they make at any time in their life.

Few data exist on the roosting behaviour of other members of the Cinclidae. The American Dipper is known to utilize a range of sites alongside or over rivers similar to those used by White-throated Dippers, and it has been recorded once as roosting in trees.

Ectoparasites are apparently uncommon on cinclids. Few louse-flies (Hippoboscidae) were found on a large sample of Welsh White-throated Dippers, but two widespread species, known from other birds, were collected. These were *Ornithomya avicularia* and *O. chloropus*, the latter representing the first record on a dipper host. *O. avicularia* had already been found on dippers in Germany, where eight of 232 individuals examined were infested, each with just one fly. The feather lice *Philopterus cincli* and *Myrsidea franciscoli* have been collected from White-throated Dippers in Wales and in Germany, and from American Dippers in Colorado.

The relatively low incidence of ectoparasites on dippers may reflect a lack of systematic assessment, but the solitary and aquatic nature of these birds, and their frequent preening and waterproofing of the plumage, may also help to prevent the occurrence of parasites. In this connection, it is of relevance that "anting" behaviour has been recorded for both White-throated and American Dippers.

It may be of interest to add that dippers probably carry a wide variety of internal parasites, ranging from acanthocephalans and cestodal tapeworms to cutaneous trematodes and trypanosomes. Trematodes of the species *Laterotrema cincli* have also been reported in Brown Dippers in Japan. In the United States, the stomachs of ten American Dippers from Oregon contained 441 trematodes identified as a new species, *L. cascadensis*. In Bolivia, two new cestodes of the family Dilepididae, *Cinclotaenia minuta* and *C. boliviensis*, were also recorded from White-capped Dippers. Further new species in this genus, *C. georgievi* and *C. paradehiscens*, have been recorded in White-throated Dippers from the Carpathian Mountains, in south-east Europe.

Voice

All five dipper species have a loud, musical, bubbling and wren-like song, given by both sexes throughout much of the year. Only when feeding young and during the moulting period do they cease singing. White-throated Dippers sing particularly vigorously in September and October, when they are establishing winter territories, and again from January–March onwards, as they establish breeding territories. Dominant individuals probably sing more than do others. The typical song is high-pitched, with a variety of notes, repeated short phrases and a rather simple repertoire, and it can often be heard above the noise of adjacent rushing water in the species' environment (see Habitat). The song of the female can usually be distinguished from that of the male by the fact that it contains a series of whistles and is more scratchy and less melodious or sweet. Most observers agree that the male is more vocal, although some have claimed that both sexes sing equally.

The song is delivered from a rock low in the water, from the edge of ice, from a fence post or low stump, or from the bank. It is also given on the wing. As members of a pair approach each other, they sing in a manner similar to that demonstrated during high display-flights or pursuit-flights (see Breeding). There is a sustained sweet subsong.

Contact-alarm calls of all five species are similar. They also are loud, high-pitched, and sufficiently penetrating to be detected by conspecifics against the noise of a fast-flowing river. Calls are variously rendered as "zzit" or "clink" or similar. The notes are repeated quickly, two to four times in succession, whenever an individual is alarmed, apparently excited or signalling to predators, and also when approaching its nest or when in flight. Flight calls may vary slightly, being a shrill metallic "zlint" or a high musical "zlink". Other calls described for the White-throated Dipper are "zrik" or "zerrrb", uttered in stressful situations, and a rattling "r-r-r-r" or low rolling "zur-r-r-r" greeting at the nest between pair-members and by the female when soliciting, often near the nest. Other calls include "gri gri", given by a dipper emerging from a roost and flying downriver, and a low-pitched "go", "zo" or "kep". Wing-whirring has been reported, as has a rapid slapping sound heard during nest-building.

Nestling White-throated Dippers begin to call from the age of about 6-7 days. As the adults approach the nest and during

Even though waterfalls do not provide ideal foraging habitat, dippers are regularly seen walking about on rocks behind these rushing screens of water, presumably gleaning edible items washed up on the abundant moss. More often, waterfalls are utilized as safe areas for nesting. Although this type of site is by no means typical, dippers will sometimes lodge their nests under the overhanging lip of a waterfall, joining a rather short list of species known to do so. In choosing this location, a ***White-throated Dipper*** *presumably benefits from the fact that its nest is virtually inaccessible to predators.*

[*Cinclus cinclus cinclus*, Ceguilla, Segovia, Spain. Photo: Javier Echevarri]

begging, they emit shrill and squeaky calls, "zip zip zip" or "zi zi zu zu zu", which have been likened to the contact call of a Common Sandpiper (*Actitis hypoleucos*). Fledglings continue to utter begging calls for some days, until they start to forage independently. Juveniles begin to sing in their first autumn, just before completing the moult.

In studies of the American Dipper, it was noted that the adults, immediately after feeding fledglings, frequently sang from a perch within 1 m of the young. This was thought to be an adaptation to the noisy habitat in which they live, which would otherwise possibly have prevented the young from hearing, and thereby learning, the species' song.

Food and Feeding

Upland streams support a rich diversity of aquatic invertebrates, and it is on these that the five cinclids largely depend. Small fishes or salmonid eggs can also be locally important at some times of the year. Dippers spend 45–55% of the daylight hours in foraging, although this proportion increases on less productive streams, during the shorter days of winter, and during the brood-provisioning period.

Foraging behaviour includes wading in riffles or shallow water, probing among pebbles, leaf-turning, gleaning from the wetted surface of rocks, picking prey from vegetation and, very occasionally, aerial flycatching. In particular, the White-throated, American and Brown Dippers are renowned for their habit of diving and swimming for prey in deeper water, frequently submerging completely, although the two Andean species have not been observed to dive in this manner. Dippers deal with large items, such as fish, cased caddis-fly larvae or large dragonflies (Odonata), by beating them on rocks before swallowing them. Diving and wade-picking are the main foraging techniques of White-throated Dippers. Diving is more common during the winter months, when river flows are higher. At times of major floods, however, water turbidity and turbulence appear to prevent effective or selective foraging, and the dippers then feed in smaller side streams or in more terrestrial habitats.

Among dietary studies of passerines, those undertaken on the dippers have been among the most illuminating in terms of avian ecology. This is because dippers take prey from a relatively narrow and easily identified spectrum, food availability is easily assessed, and many potential contrasts in behaviour are observable in the dippers' easily measured habitat. Prey remains found in pellets or faeces, such as insect mouthparts and fish bones, can be counted accurately, and can also be used as a means of establishing the original size or weight of the prey selected. Indigestible items found in faeces are similar in nature to those found in pellets, and there is no evidence that remnants of larger prey are ejected in the regurgitated pellets.

By far the best-known and the most-studied member of the family is the White-throated Dipper, in part as a result of extensive work carried out on this species by S. J. Ormerod and S. J. Tyler in Wales, but also following studies by other workers in Germany, Ireland, Spain, Scandinavia, north Africa and elsewhere. Dietary trends have been quantified over the year, on streams of different quality, and also for both adults and chicks during the nesting period.

There appears to be little variation in the diet of the White-throated Dipper throughout its wide range. This species' prey items are almost entirely of aquatic origin, with the aquatic stages of insects most numerous, but supplemented numerically by molluscs, crustaceans and fish. Fish in particular, and often small sculpins (Cottidae), because of their larger size, can make a disproportionately large contribution to the diet in terms of biomass.

The annual energy requirements for a territorial pair of White-throated Dippers range from 148,000 kJ to 158,000 kJ, depending on whether one or two broods are reared. On the basis of body mass, approximately the same figures apply to the other members of the family. Allowing for assimilation efficiency, these requirements represent around 10·5–11 kg dry mass of food per annum. During the breeding season, the diet is dominated by two insect orders, the Ephemeroptera and the Trichoptera, respectively mayfly nymphs and caddis larvae. On base-poor streams however, where these insects are scarce, stonefly nymphs, in the order Plecoptera, are the most numerous prey. The diet of nestlings changes remarkably with age, providing evidence of very marked prey selection. Small nestlings are fed mainly with mayflies of the genus *Baetis*, but, as the chicks grow, they are fed increasingly with larger limnephilid and hydropsychid caddis larvae. Calculations indicate clearly that any other strategy would be

Flowing water freezes much less readily than stagnant pools, a fact that helps dippers to survive the depths of winter at fairly high latitudes. Unfortunately, even turbulent waterways are liable to freeze when conditions are very severe, whereupon dippers are robbed of their food supply and forced to move downstream. Some even migrate. This Finnish ***White-throated Dipper****, for example, will probably travel up to 1000 km southward each year, perhaps reaching central Europe, or the Atlantic seaboard, where the winters are milder and the streams less often locked with ice.*

[*Cinclus cinclus cinclus*, Finland.
Photo: Markus Varesvuo]

unable to provide sufficient energy for the brood, and the parents compensate by taking increasingly smaller prey for themselves as their chicks grow. Unusual prey are sometimes taken, one example being moth larvae, such caterpillars of the green oak tortrix (*Tortrix viridana*), that fall into the riparian zone where oak trees (*Quercus*) overhang the river.

During the moult period, immediately after breeding, and during the winter months, White-throated Dippers are more opportunistic. While they still feed on mayflies and caddis flies, they now take large numbers of smaller prey, including smaller mayflies such as those in the family Baetidae, but also blackflies (Simuliidae). Fish are important energetically at this time, and in Wales they provide 5–6% of prey items and up to 65% of prey biomass. The bottom-dwelling bullhead (*Cottus gobio*) comprises 80% of fish prey. In some parts of Europe, freshwater shrimps (*Gammarus*) are eaten in large numbers at these times of the year. Moreover, dippers in coastal areas periodically occupy the high-tide line among sea wracks. In a Norwegian fjord, individuals apparently took the marine molluscs *Littorina saxatilis* and two species of *Gammarus*. In west Scotland, dipper pellets found on the coast of the Isle of Rhum contained mostly *Gammarus* and *Orchestia* amphipods. Fish and other calcium-rich prey, such as crustaceans and molluscs, may be particularly important in the late winter and early spring, when reserves of calcium for the forming of eggs become crucial.

In addition to seasonal changes, short-term changes in the environment can also affect the diet. This was demonstrated, for example, during floods on rivers in south-west Ireland, where the diet of White-throated Dippers during base flow was dominated, as is normal, by caddis larvae, especially those of the family Limnephilidae. When the rivers reached storm-flow levels, however, smaller baetid mayflies and blackfly larvae became dominant. The species' diet during the spate period also contained more terrestrial invertebrates, either because the birds took to terrestrial foraging or because terrestrial prey, dislodged by rainfall, contribute increasingly to casual drift in rivers. Similar patterns have been found in Britain, and may be general throughout the dipper's range.

Studies in Wales have addressed not only the diet of the White-throated Dipper, but also its possible impacts on prey abundances. Annual exploitation could reach around 1–2·5 g dry mass per square metre, which, for some highly selected prey, could account for a considerable proportion of annual production. For example, dippers probably take annually up to 0·25–0·3 g per square metre each of stonefly and mayfly nymphs, and the estimated figures for fish and caddis larvae are, respectively, up to 0·8 g and 1·2 g. On the basis of available data on production for cottid fishes, or hydropsychid and limnephilid caddis flies, the influences of this level of out-take on prey density could be substantial. So far, these energetically based estimates have not been tested for White-throated Dippers, but enclosure experiments on American Dippers, carried out by B. C. Harvey and C. Marti indicate that they may well be real.

While many ornithologists concentrate on bird behaviour when undertaking foraging studies, the behaviour of the prey is also crucial. R. K. B. Jenkins and Ormerod investigated the ways in which the behaviour of prey animals altered their exposure to real or simulated foraging dippers. They found that blackfly larvae and hydropsychid caddis larvae lacked effective escape mechanisms, and this could help to explain the heavy predation that they incur. Other families often delayed drift or movement until the dipper's bill made contact, which could well be too late for them to avoid being eaten.

Data on the foraging ecology of the Brown Dipper are available from studies made in Japan, by K. Eguchi, and in the Himalayas of Nepal and India, by S. T. Buckton. In both locations, Brown Dippers foraged for large prey by diving deeply among submerged rocks, and sought small prey by wading and pecking in shallow water. Foraging by diving was seldom observed in the months from May to October, but increased from December to April, the latter months coinciding with the breeding period in Japan. Mirroring the pattern of food-provisioning exhibited by White-throated Dippers, adult Brown Dippers fed themselves mainly by wading, thus taking small prey, but fed their nestlings on items obtained by diving, thus large prey. Specific food items were identified only in the Himalayan study, where the major prey were, in decreasing order of importance, ephemeropterans, mostly baetids, and trichopterans, mostly hydropsychids, followed by dipteran flies, plecopterans and beetles (Coleoptera).

Also an increasingly well-known species, the American Dipper forages on many of the same groups as those taken by the two Old World species. Mayfly nymphs, such as those of the family Heptageniidae, and caddis larvae of several families in

which the larvae are enclosed in a hard case dominate the diet in the breeding season, and these groups, together with fly larvae, mostly chironomids, are eaten in the winter. The distribution of these prey groups appear also to affect the distribution of the dipper. In Pacific coastal rivers, however, seasonal food abundance in the form of Pacific salmon (*Oncorhynchus*) eggs can contribute very substantially to the species' diet. Some of these eggs come from the corpses of spent fish, which have spawned and died in very large numbers after breeding.

Comparatively little is known about the diets of the two remaining cinclids, both of which are confined to the Andes of South America. The White-capped and Rufous-throated Dippers, as their congeners, appear also to feed largely on caddis, mayflies and blackfly larvae, even though they do not plunge for food but, instead, pick items while standing or wading. In addition, they sometimes forage among vegetation on riverbanks, and in Ecuador White-capped Dippers have been observed to take terrestrial prey, such as earthworms.

Breeding

As with all other aspects of this family, the breeding biology of the White-throated, American and Brown Dippers is far more completely known than is that of the two Andean species.

Most dippers are monogamous, the members of each pair defending a linear breeding territory and helping with the rearing of the young. In some cases, the territory is occupied and defended throughout the year. While there may be some potential for reassortment before breeding begins, mate-fidelity between successive years and successive breeding attempts is strong. There is, however, one record of a female American Dipper in Montana which, within a single season, reared a brood with one male and then moved 5 km, to a different watershed, and there raised a second brood with a different male.

Some males are bigamous or polygynous, helping to rear the broods of two, three or, rarely, four females. Usually the associated females are in contiguous territories, but one instance of poly-territoriality is known. The incidence of polygyny varies greatly, both within and among populations, generally occurring in situations where females outnumber males on a river. So far, polygyny has been reported for White-throated Dippers in Germany, Wales and Scotland, and for American Dippers in Colorado, although it may be more widedspread, given the fact that dippers share some of the key attributes of polygynous species, such as sexual size dimorphism. In a study in Colorado, polygyny was practised by four of 31 males, but the intervals between laying dates of females were 14–40 days, so that males were able sometimes to provision more than one nest.

In Wales, DNA "fingerprinting" confirmed that one male was the father of the broods of two different females. It was also found that, in general, polygynous males have greater breeding success than do monogamous males. In polygynous relationships, the breeding success of primary females is not significantly different from that of monogamous females, but secondary and tertiary females suffer a 25% reduction in brood size, probably because of reduced parental assistance from the male. Even though females in polygynous pairings increase their provisioning rate, the total of brood-feeding visits falls when females feed alone. This happens, for example, when the time required for chick-rearing prevents a male from helping at more than one nest simultaneously.

Displays observed for the White-throated Dipper include an advertising display in which the male perches upright, throws back his head, holding the bill more or less vertical, ruffles the white breast feathers, and moves his head slowly from side to side; at the same time, he partly opens his wings and droops them, and fans and lowers his tail. During courtship, the male first approaches the female, but she frequently flies away. Later, as the female becomes more used to the male's attentions, he runs closely around her, dipping and blinking, often rapidly quivering his wings and giving a rattling call. These displays, which are given also by the female, are indistinguishable from those directed at rivals. Partners also perform high display-flights or pursuit-flights, frequently accompanied by song, throughout much of the nesting period. Display behaviour in the other species is less well described, but there are close parallels at least in the Brown Dipper.

All five dipper species build their nests by or over running water. Typical sites include crevices in cliffs or on cliff faces, cliff ledges, similar places behind waterfalls, hollows among roots in the bank and on or under rocks in mid-river. When sites behind waterfalls are selected, the adults fly spectacularly through the curtain of falling water in order to reach the nest. Artificial sites, such as holes or crevices in stone or brickwork of walls and bridges, or girders or other ledges under bridges, are readily used. Bridges and walls provide relatively safe nest-sites, as such structures rarely collapse and rarely become flooded. Indeed, where dippers have a choice of a natural nest-site or an artificial one,

Dippers have unusually dense plumage, an adaptation to an aquatic lifestyle that provides effective waterproofing and insulation against the cold, allowing them to tolerate prolonged exposure to low temperatures. They have been recorded wintering at sites where ambient temperatures regularly drop below -40°C, as long as open water is available. Thus, this ***American Dipper*** *is probably not suffering unduly, despite the encroachment of ice into its territory. Only if its lifeline freezes over will it need to move downslope.*

[*Cinclus mexicanus unicolor*, McDonald Creek, Glacier National Park, Montana, USA. Photo: John Winnie Jr/ DRK]

they often choose the latter. In Switzerland, bridge sites allowed White-throated Dippers to build earlier and to lay eggs earlier than was the case at natural sites. Certainly, on marginal lowland streams where natural sites are limited, bridges enable dippers to breed successfully and to extend downwards from their upland strongholds. Nests are occasionally built in a fork of a tree, in a hole in a riverside tree, on fallen branches over the river or in overhanging branches, and about 6% of nests in Wales were in such sites. Nestboxes erected under bridges or on walls have been utilized by both White-throated and American Dippers, and would probably be used by other cinclids if they were made available to them. Very occasionally, dippers nest in or on buildings away from water, even up to 100 m from it, but such instances are exceptional.

In some territories, a pair may use two or three different nest-sites in the same season or in different seasons, even after having bred successfully at one. Normally, however, dippers exhibit strong fidelity to a particular site within the territory from year to year. Often the same nest, repaired and relined, is used for successive broods, or the pair may build another nest alongside or adjacent to the remains of the first. Where similar and equally suitable nesting sites exist side by side, as with ledges and girders below bridges, a pair may start to build two or three different nests on adjacent ledges before deciding on the final choice. In extreme cases, they may finish two nests and lay in both. Nest-sites can be used traditionally for many years, over 30 years not being unusual, and in one extraordinary instance a particular site has been used by White-throated Dippers for as long as 123 years. Clearly, individuals and pairs do not live that long, so that either some intrinsic attribute of the location or "cultural" knowledge transferred between successive members of breeding pairs must be involved.

Nest construction is much the same for all five cinclid species, and reflects the intrinsic, evolved aspects of building methods and the availability of similar materials in all upland river environments, but also, more importantly, the adaptive value of a warm, waterproof, concealable design. The nest is a large globular structure of moss, with or without the addition of grass, and has an outer diameter of up to 30–45 cm, although it is often smaller. When the site is a cliff face or wall, the birds first build a circular base for the back of the nest, sometimes adding mud to the moss in order to secure the structure better. On ledges, a large platform of moss may be formed on which the rest of the nest is constructed in an upward and outward direction, resulting in a miniature "haystack". Where the nest is in a confined space, as in a crevice or in a nestbox, it may lack the dome and sides, being no more than a mossy base and inner cup. The cup is made from roots and grass and is lined usually with leaves, but occasionally with hair. In Russia, feathers have been recorded as the lining. In Europe, the White-throated Dipper's preferred material for nest lining is dry beech (*Fagus sylvatica*) or oak leaves, although leaves of ivy (*Hedera helix*), bramble (*Rubus*), birch (*Betula*) and willow (*Salix*) are also used, as occasionally are dry bracken (*Pteridium aquilinum*) fronds. American Dippers have been reported as using cottonwood (*Populus tremula*) leaves and ponderosa pine (*Pinus ponderosa*) needles in the lining of their nests, and Rufous-throated Dippers as using Andean alder (*Alnus acuminata*) leaves, as well as morphologically similar pieces of paper and plastic. Strips of plastic have also been found in a nest of the other Neotropical species, the White-capped Dipper. Brown Dippers in Nepal lined the nest with leaves of Himalayan alders (*A. nepalensis*).

The circular or elliptical entrance hole is low down at the front of the dome, and faces downwards, almost invariably over running water. Nests of White-throated Dippers in Europe are usually located less than 3 m above the stream or river, and 60% of nests in Wales were only 1–2 m above water. They may be only a few centimetres above water when the stream is no more than a stable trickle, but rivers in flood in the spring rise and fall dramatically, and nests need to be above high-flood level. Some nests under railway bridges and on buildings are up to 10 m above the river. Nests of American Dippers in the Rocky Mountains are generally higher up, on average, than are those of White-throated Dippers in Europe. F. E. Price and C. E. Bock, who studied a population of American Dippers in Colorado, considered that high, inaccessible and wide ledges were the best-quality nest-sites because they were safer from predators and flooding, the latter being a major cause of nest failure.

Both sexes can be involved in the building of the nest, but it is the female that usually completes the cup and adds the lining. Sometimes she alone does the building, or the male may bring moss and other material to the nest vicinity, where the female

*The **White-capped Dipper** is one of two South American forms, both of which glean almost all their food by picking prey from rocks, or from just beneath the waterline. In so doing they regularly immerse their heads, sometimes becoming temporarily submerged under fast-flowing water, but they never seem to dive beneath the surface, unlike their congeners. Given that they spend so much of their lives close to the waterline, it comes as no surprise that their toes are long and strong, and their claws curved and sharp, attributes that help all dippers to gain purchase on steep or slippery rocks.*

[*Cinclus leucocephalus leuconotus*,

collects it and incorporates it into the structure. In the case of the White-throated Dipper, either the female or both members of the pair build, and the same applies generally to the American Dipper, although some authors report that the male of the latter species undertakes only a minor share of the work or none at all. G. Shaw found that nest-building in Britain required an average of 28 days, with a range of 25–32 days, whereas K. W. Perry recorded periods of 10–21 days in Ireland. Construction periods of 9–28 days, with an average of 18 days, and of 5–45 days have been reported in different studies in Germany, and durations of 6–39 days in Switzerland. Cold or wet weather can extend the length of time taken for building, and nests built early in the year are formed over a longer period of time than are later ones. When the breeding season is short, as at high altitudes, or when the first nest has failed, construction work may be more rapid.

For all species, the basic tendency is to breed very early in the spring. In the Northern Hemisphere, breeding starts from February or March, and the Brown Dipper sometimes begins earlier, in January or even December. The situation in the Andes is less well known, but the Rufous-throated Dipper appears to commence breeding at the end of the austral winter, from September onwards. Nests of White-capped Dippers have been found in February and March in Venezuela, in the north of the species' range, but farther south breeding seems to take place over a wider period of the year, with eggs, nestlings and fledglings reported variously from September through to July from south Colombia southwards to Peru and Bolivia.

Exact timings of breeding, however, vary from one location to another, owing to a number of ultimate influences and proximate cues. For example, in far northern populations, short winter day length and the consequent need for migration results in breeding being delayed in some regions, such as in north Scandinavia, by comparison with those farther south. River hydrological regimes, surprisingly predictable in seasonal locations, also exert an effect. In temperate, maritime areas such as Britain, breeding begins as the winter risk of high rainfall and flooding declines, from February or March onwards. In contrast, dippers in alpine environments need to avoid floods generated by snow-melt, while Brown Dippers in the Himalayas must avoid both snow-melt and subsequent monsoonal rainfall and probably breed before both. Annual cycles of food abundance probably also have effects, and the emergence of large benthic invertebrates as adults from spring onwards depletes rivers of key prey, thus favouring early breeding. Finally, dippers need to fit other requirements, such as moult, into the annual cycle while conditions are still favourable for easy feeding, and this fact alone can truncate the breeding season. Proximate influences include temperature and actual food abundance, with low temperatures and reduced food abundance tending to delay breeding sometimes until unfavourable periods. In Wales and Scotland, for example, White-throated Dippers at acidic sites where invertebrates and calcium-rich prey were scarce laid significantly later than did pairs at good-quality sites, and this had major consequences for post-fledging survival.

The results of case studies reflect this array of features affecting the timing of breeding. In Britain and Ireland, nest records from the British Trust for Ornithology reveal that White-throated Dippers lay from late February to mid-June, with a peak in laying in late March and early April. There is one record of a clutch of eggs being incubated in the second week of February. In south Wales, laying reaches a peak in the first week of April, with 52% of 364 clutches started before 7th April. In a wider study area in middle and south-east Wales, where 1263 clutches were found 1978–1993, there was a peak in laying in late March and a smaller but clear second one in early May. The breeding season on the River Esk system, in southern Scotland, begins significantly later than it does among populations farther south and west in the British Isles. In Austria and Germany, the earliest clutches of White-throated Dippers are laid in the first half of March, whereas farther north, in Norway and Finland, clutches are not laid until April or early May and, in the northernmost areas, not until mid-May. Similarly, in parts of Russia, chicks from the first and only brood do not leave the nest until mid-July, indicating laying dates in early June. The American Dipper lays earlier at lower altitudes in North America, as do White-throated Dippers in Europe. In Austria, Germany and the former Czechoslovakia, White-throated Dippers lay 5–6 days later for every 100 m increase in altitude, while the corresponding figure in the Swiss Alps was as much as 18–19 days later per 100 m.

Climates are non-static, as is now realized, owing to local influences such as urbanization, to larger periodic variations such as the North Atlantic Oscillation and the Pacific Oscillation, and to progressive climate change. Any of these could have an effect

*Anyone watching an **American Dipper**, and unacquainted with the details of its lifestyle, is soon likely to be taken aback when its head disappears underwater. In fact, underwater foraging is the most famous aspect of dipper ecology, and the trait which separates them from all other passerines. The need for underwater vision and waterproofing has resulted in a few unique adaptations, including specialized lens musculature, nasal flaps and hydrophobic plumage. Moreover, the feathers are frequently preened with oily secretions from the uropygial gland, which in dippers is unusually large.*

[*Cinclus mexicanus*, Kern County, California, USA. Photo: Brian E. Small]

Anyone surprised when a dipper's head vanishes underwater is likely to be astonished when, with a quick dip of the body and thrust of the legs, the bird disappears altogether. Not only does it dive, but once underwater it swims comfortably, propelling itself downward with flipper-like wings. When this ***White-throated Dipper*** *reaches the bottom it will forage there for up to 20 seconds, or more, before returning to the surface with cork-like buoyancy. It was once thought that it held itself down by clasping rocks and pebbles with its feet, but it has now been proven beyond doubt that the wings do most of the work.*

[*Cinclus cinclus.* Photo: Konrad Wothe]

on dippers. J. P. W. Scharlemann estimated the laying dates of White-throated Dippers from collecting dates of museum egg collections; although the findings were subject to some uncertainty, the dippers have started laying progressively earlier over the past 150 years, with the onset of breeding correlated significantly with mean March temperatures. In an intriguing phenological study in Switzerland, J. Hegelbach investigated the timing of laying by this species along rivers and streams flowing into lower Lake Zurich. He found that the dippers initiated breeding in February or March of each year, but actual first dates varied annually, from 9th February, in 1995 and 1997, to 9th March, in 1992. The median date for the first 25% of all broods advanced significantly with increasing February water temperatures and with February air temperatures, and was significantly correlated with the flowering of two early plants, the coltsfoot (*Tussilago farfara*) and the wood anemone (*Anemone nemorosa*). Comparison with historical data shows that White-throated Dippers at Lake Zurich now begin breeding earlier in the year than they used to in Britain, Germany and elsewhere in Switzerland. In this case, the strongest explanatory factor was increased water temperatures caused by urbanization. The effects of these higher water temperatures, through accelerating the life-cycles of aquatic invertebrates, must have been greater than the direct climatic effects on the dippers' condition.

The eggs of all dipper species are white, in keeping with those of many other avian species that use domed nests or nest in cavities. They are subelliptical, smooth and glossy. The eggs of the large Brown Dipper are the heaviest and largest, and those of the small Rufous-throated Dipper are the lightest in weight. Egg shape varies somewhat within species. Further, the eggs of White-throated Dippers in Wales, Scotland and Norway are thinner-shelled and of lower weight at acidic sites than they are elsewhere, probably because of a relative scarcity of calcium-rich prey.

White-throated Dippers lay 3–6 eggs, and much less often one, two or seven eggs, usually, but not always, at one-day intervals. Clutches of four and five eggs predominate. Similar figures apply to the Brown and American Dippers. The few data available for the two Andean dippers suggest a smaller clutch, two eggs being normal for Rufous-throated Dippers in Argentina and Bolivia. Mean clutch sizes of White-throated Dippers, derived from large study samples, are 4·2–5 eggs. Slightly larger clutches are laid in Poland, the Swiss Alps, some areas of Germany and south-west Norway, where the average was 4·9–5·1 eggs, than in Britain in general, in Wales or in south-west Ireland, the respective means for the last three being 4·4, 4·7–4·8 and 4·16 eggs. In Wales, 67% of clutches were of five eggs and 24·3% of four eggs. First clutches started in March or April were significantly larger than were later ones, mainly re-layings or second clutches. In Europe, seasonal reduction in clutch size is common, as in Germany, Switzerland and Britain, but not universal, as it was not recorded in studies on the Esk system, in Scotland. There is no clear altitudinal effect on clutch size, but in Wales individuals at better-quality sites lay larger clutches than do those at poorer acidic sites, probably reflecting differences in food availability and quality. In Germany, White-throated Dippers on south-facing slopes produced larger clutches than did those on north-facing slopes, a fact which W. Zang related to differences in food supply. In Scotland, clutch size did not differ with parental age.

In the case of the three better-known species, the White-throated, American and Brown Dippers, the female alone incubates. Very occasionally, males have been reported as incubating or as covering the eggs in the partner's absence. Females sometimes sit on eggs before the clutch is completed, possibly incubating from the penultimate or earlier eggs, as asynchronous hatching has been noted on a few occasions for both the White-throated and the American Dippers. Incubation usually lasts for 16 or 17 days, sometimes a day or two fewer, but the period can be longer at higher altitudes and for earlier clutches. Furthermore, females have been known to sit for up to 42 days on infertile eggs, before abandoning the clutch. During the incubation stage, the male may feed his mate on the nest and he spends much of his time, 40% or more, in guarding the nest or, rather, the incubating female against intruding males. Neighbouring males have been reported as removing eggs or young, a strategy that would increase their chances of copulating with the female.

Newly hatched dippers, being passerine birds, are naked, are incapable of regulating their body temperature and are totally

By adopting an underwater lifestyle dippers are able to forage on prey items unavailable to other passerines. They commonly feed on large numbers of aquatic larvae, which form their staple diet through the summer months. Using the bill, they dig among underwater pebbles and poke about in rocks, extracting invertebrates from their hiding places. In winter, they are forced to take a wider variety of prey, including a few fish, as illustrated by this ***American Dipper****. They have been noted taking the fry or eggs of commercially important salmonids, but not in significant numbers.*

[*Cinclus mexicanus*, Kern County, California, USA. Photo: Brian E. Small]

dependent on both parents for food. The female broods them almost continuously during the first days, leaving the nest only for a few minutes after 1–2 hours of brooding. The male thus brings most of the food in these early stages, either feeding the chicks directly or passing food to the female. Brooding periods decrease as the nestlings grow, generally ceasing when the young reach 12–13 days of age. With monogamous pairs, both parents then play an equal role in provisioning the chicks. When the chicks are young, the adults enter the nest in order to feed them. There is then a "carousel" system of feeding, whereby the chick that has just been fed retreats, or is pushed, to the back of the nest, its place being taken by the one immediately behind it. As the chicks grow, they beg and call at the nest entrance, where they reveal the orange-yellow gape edged with white flanges. It seems that older chicks, presumably because they are noisy, are more vulnerable to predation that are younger ones. The adults remove faecal sacs from the nest and drop them into the river, but when the chicks are big enough, at 9–10 days or more, they defecate outwards from the nest. Faecal sacs sometimes accumulate on rocks or in water below the nest, and the adults sometimes dispose of fallen sacs, at least early in the nestling period. One pair of Rufous-throated Dippers feeding well-feathered young, at least 18 days old, was still carrying away faecal sacs.

The nestling period, from hatching to fledging, lasts for about three weeks or more. Young White-throated Dippers remain in the nest in Britain for 20–24 days, the average being 22 days; the corresponding figures for Germany are 23–27 days, and a mean of 21·5 days is recorded in Switzerland. The nestling period of American Dippers is similar, at 23–28 days, while that of Brown Dippers is 21–24 days. Chicks will leave the nest prematurely if disturbed by a real or potential predator. In such circumstances they "explode" from the nest, dropping or plunging into the river, where they swim and dive expertly. They soon scramble out on to the bank and hide among rocks, vegetation or tree roots, where the adults will continue to feed them. For this strategy to have evolved, it is obvious that some youngsters must survive. The alternative, that of being eaten by a predator, clearly has no survival value.

Brood sizes of White-throated Dippers generally follow the same temporal and geographical trends as those detailed for clutch sizes, although broods are generally slightly smaller than clutches owing due to a small number of egg failures or early mortalities. Broods are larger at higher latitudes and, in Wales, broods were larger earlier in the season than later. This pattern has sometimes been repeated in other European studies. Brood size is also affected by territory quality, notably prey abundance; broods are smaller on acidic streams, where prey are scarce, than on circumneutral streams. In south-west Ireland, the mean brood size at fledging was 3·48 young per successful pair.

Dippers have relatively high hatching and fledging success, presumably because their nests, located over fast-running water, are often inaccessible to many predators. The domed structure of the nest also makes it more difficult for predators to see eggs or chicks than is the case with open cup-nests, and the large mossy structures are often camouflaged. Hatching success of the White-throated Dipper in British and European studies varies from 61% to 76%, and fledging success from 81% to 94%. Overall breeding success, in terms of the percentage of nests that produce at least one fledged young, ranges from 56% to 68·4%, and the mean number of young produced per nesting attempt varies from two to four. All of these measures of success are, of course variable both annually and seasonally. In Wales and elsewhere, first broods are generally more successful than are second broods. In the Swiss Alps, on the other hand, nests were more successful as the season progressed, this being due to the effects on earlier nests of flooding following snow-melt or of predation. Among White-throated Dippers studied in Scotland, parental age was found to influence breeding success: pairs in which both partners were full adults enjoyed greater success than did pairs in which at least one member was a first-year individual. The three better-known species usually start breeding at one year of age, although some males may not breed until they are two to three years old.

The incidence of second broods is very variable. In general, double-brooding requires that first attempts are completed early in order to allow sufficient time for a further attempt to be made. This possibility is clearly limited for later-breeding pairs at high latitudes, at high altitudes or on poor-quality streams, and all case studies bear out these trends. On high-quality streams in the

catchment of the lower River Wye, in Wales, about 24% of White-throated Dipper pairs had second broods and in some years, on particularly good-quality streams, 80–90% might attempt a second brood. In contrast, pairs at sites on acidic rivers rarely made a second attempt. Similarly, in eastern Scotland, the incidence of second broods was much higher on the lower reaches of the River South Esk, which had abundant prey, than on upriver stretches. In Norway and Sweden, where early breeding is probably limited by day length, as few as 5–6·5% of pairs had second broods. In Switzerland, the likelihood of second broods was less at high altitudes, above 1300 m, while at lower altitudes the incidence of double-brooding varied from 3% to 38%. Likewise, Austrian dippers breeding at elevations above 500 m rarely had a second brood. In other central European studies, 10–49% of pairs had second broods.

The duration of the breeding season and the lengthy incubation and fledging periods make a third brood almost impossible. In some instances in which three broods have been claimed, it is probable that one or more broods failed at an early stage, encouraging the adults to make a further attempt. Nevertheless, there are several records of White-throated Dipper pairs in Germany successfully rearing three broods.

American Dippers are frequently double-brooded. Indeed, in a celebrated study area in Colorado, Price and Bock recorded that about 40% of pairs had two broods, although the number attempting a second brood varied annually, from 5·5% to as high as 70%. These figures, however, are inflated, because the researchers included not only genuinely double-brooded pairs, but also pairs which re-laid following failure of first nests. Brown Dippers had only one brood in Japan, but in other parts of their range they are not uncommonly double-brooded. It seems very likely that the two Andean species may also rear two broods in a season, but there is insufficient information to enable this to be confirmed.

Once fledged, young dippers are fed by both parents for 1–2 weeks, the parents sometimes diving the brood so that each tends one or two juveniles. Some authors have found that females fed the juveniles more than did the males. In cases when the female lays a second clutch during this post-fledging period, however, the male may play a larger role. Newly fledged White-throated Dippers sit quietly on rocks or pebble shoals near the nest, waiting for a parent to bring food. As a parent approaches, the young move towards it and flutter or quiver their wings, calling loudly and begging. Those juveniles which gain more food from begging generally gain more energy than do those which attempt to feed themselves. Sometimes they peck rather inexpertly at prey, especially small blackfly larvae on rocks. If danger threatens, the youngsters dive or flutter away to hide among rocks or tree roots.

With increasing age, young dippers devote longer periods to foraging independently, and their movement, flying and foraging skills improve markedly. Two to three weeks after leaving the nest, they are able to use a variety of foraging techniques and can survive on their own. The time required to gain independence is variable, however, even within broods. The young often remain within the parents' territory until they have completed the post-juvenile moult, at four to six weeks after fledging (see Morphological Aspects).

Post-fledging survival is particularly difficult to assess in any population study. This is partly because of the difficulty of retrapping sufficient survivors, but also because of the difficulty in separating post-fledging survival from overall nest survival. In Wales, Ormerod and colleagues monitored the fate of White-throated Dipper chicks from 743 broods in relation to brood size, time of hatching and territory quality. For all brood sizes, post-fledging survival varies through the breeding season, and most survivors are from nests in the peak breeding period, implying that dippers time their breeding correctly. This effect was so strong in this study that it almost exactly cancelled out the benefits in fitness of double-brooding. This implies that there is a fine balance between the benefits to adults of breeding once in the optimum period, in late March and early April, and those of breeding twice at suboptimum periods, very early and again later in the season. There is also evidence that the most common brood size among Welsh dippers, of four, is also the most productive, although, again, this changes subtly through the season. Territory quality, particularly with regard to the negative effects of acidity, probably has major impacts on survival by delaying breeding, and hence fledging, such that this takes place in periods when post-fledging survival falls dramatically. The reduced weights of fledglings at acidic sites will also reduce their survival chances.

*Pair-formation behaviour in the **White-throated Dipper** is relatively modest. Both males and females vocalize strongly, often giving rattle calls and occasionally an unexpectedly musical and complex song. They also chase each other a good deal, and signal at close range with two unusual displays. One of these involves the frequent and conspicuous blinking of white eyelids, and another is the abbreviated curtsy which gives rise to their English name. They dip their bodies quickly and repeatedly, fluttering their wings when especially excited.*

[*Cinclus cinclus cinclus*, Bagà, Spain.
Photo: Jordi Bas]

*In the **White-throated Dipper** copulation is usually preceded by solicitation. To communicate her willingness, the female bows and crouches low in submissive posture, with wings aquiver. The male may ignore this signal for some time, or the female may rebuff his advances, but eventually he mounts in ungainly fashion, maintaining his balance by beating his wings. The whole process lasts a few seconds at most, after which both pair members dally in the vicinity with much excited ruffling of feathers, dipping and blinking; or else they fly away calling loudly, or even singing.*

[*Cinclus cinclus cinclus*, Bagà, Spain. Photo: Jordi Bas]

Unless events of predation are witnessed directly, something that rarely happens, it is notoriously difficult to assess which species of predator are implicated. Observers more often reconstruct events from putative clues, and many records are also biased towards causes that are more likely to be detected. Small mammals, notably brown rats (*Rattus rattus*), appear to be one of the main predators of eggs and chicks of White-throated Dippers. In an analysis of British nest records, Shaw attributed 60% of nest failures to rats, while Perry found that rats caused up to 75% of "natural" nest failures in Ireland. Feral American minks (*Mustela vison*) are probably also important predators in several parts of Europe, but the scale of any effect that they may have is unknown. In Ireland, they were thought to be one of the major causes of mortality of young dippers either just before or just after fledging. The native European mink (*M. lutreola*) also causes some nest losses, as do stoats (*M. erminea*), weasels (*M. nivalis*) and otters (*Lutra lutra*), and a dormouse (*Eliomys quercinus*) was reported as taking a brood of chicks in Poland. Some newly fledged dippers fall victim to domestic, feral or wild cats (*Felis*). Of 77 British-ringed White-throated Dippers found dead and for which the cause of death was known, about 43% had been killed by cats, although this figure included adults as well as juveniles. Corvids, especially Carrion Crows (*Corvus corone*), Eurasian Jackdaws (*Corvus monedula*), Eurasian Jays (*Garrulus glandarius*) and Common Magpies (*Pica pica*), are all known predators of White-throated Dipper eggs or chicks. Juveniles and adults are vulnerable to predation by Eurasian Sparrowhawks (*Accipiter nisus*), Merlins (*Falco columbarius*), Common Kestrels (*Falco tinnunculus*) and Peregrine Falcons (*Falco peregrinus*), and Tawny Owls (*Strix aluco*) occasionally take full-grown dippers.

In North America, predators of eggs or chicks of American Dippers include martens (*Martes*), striped skunks (*Mephitis mephitis*) and long-tailed weasels (*Mustela frenata*), and bushy-tailed woodrats (*Neotoma cinerea*). Water snakes and even brook trout (*Salvelinus fontinalis*) are known to have taken fledglings.

Information on predators of other cinclid species is extremely limited. An Andean Pygmy-owl (*Glaucidium jardinii*) was suspected of having eaten a female White-capped Dipper on its nest. Interestingly, A. F. Kovshar believed that Brown Dipper nests were almost inaccessible to terrestrial and aerial predators.

Brood parasitism appears not to be a particularly widespread source of problems for the Cinclidae. Cuckoos (*Cuculus*) only very rarely parasitize nests of White-throated Dippers, although Brown Dippers seem to be more commonly exploited as cuckoo hosts.

Northern fowl mites (*Ornithonyssus sylviarium*) occasionally infested broods of White-throated Dippers in Wales, but the nestlings fledged successfully. In Germany, the same parasite species has been found on feathers and in the nostrils of dippers, as well as in their nests, and in some instances infestation of broods can be high. One nest of an American Dipper contained about 400 northern fowl mites. Many other mites can occur in cinclid nests. The best examples are from seven nests of the White-throated Dipper in Wales, in which 54 mite species, from 46 genera, 27 families and four orders, were found. The array of species included several pests of stored food, species able to invade houses, species known to produce respiratory allergies, and species usually found in moss or leaf litter. Examples included *Tyrophagus putrescentiae*, *T. longior*, *T. palmarum*, *Acarus farris*, *Dermatophagoides farinae* and *Kleemannia plumigera*.

Several fleas, especially the moorhen flea (*Dasypsyllus g. gallinulae*) and the hen flea (*Ceratophyllus gallinae*), were commonly found in White-throated Dipper nests in Wales, and attacks on dipper nestlings by moorhen fleas were reported as a main cause of failure of first broods in the Swiss Alps. In the Neotropics, likewise, nests of White-capped Dippers can be infested with fleas, as shown by a total of 592 fleas found in the nest of a second brood. Other ectoparasites include blowfly larvae (*Protocalliphora*), which suck the blood of nestlings. Such larvae have been found on nestlings of American Dippers in California, Utah and Colorado, very occasionally causing mortality.

Individuals captured and recaptured during ringing programmes have allowed very detailed assessments of survival and population dynamics, some of these studies being classics in ornithology. Because they have linear territories, and are easy to capture or observe, and because the recording of environmental variation in dipper habitats is not difficult, the cinclids have been "model" species for the development of novel techniques and methods. First-year mortality of young White-throated Dippers is 60–65% and annual adult mortality is 40–50%, so that some

*In the **White-throated Dipper**, as with other members of the family, the basic breeding system is monogamy. Even so, many cases of bigamy (and rarely trigamy) have been reported, especially on productive waterways where separate nests are regularly less than 100 m apart. In most cases both sexes build the nest, although the contribution of polygamous males is often much reduced. The finished product is a large, almost circular, domed structure, around 20 cm high, built largely of moss, with an inner layer of grass, stems and rootlets, and a lining of leaves. It is almost invariably built by or over running water, usually on rocks or ledges.*

[*Cinclus cinclus cashmeriensis*, Rumbak Valley, Ladakh, India. Photo: Otto Pfister]

individuals can live to about eight years. Remarkably similar values were obtained by Price and Bock for American Dippers, with annual adult mortality of 38–52% and first-year mortality of 68–78%.

Among adult White-throated Dippers, the time when most deaths occur is the period following breeding, when the body mass is lowest and the stress of rearing young probably apparent. Survival is variable in both space and time, however, and in northern populations, for example, reduced winter temperature diminishes the over-winter survival of both adults and young. B. E. Sæther and colleagues have used this remarkably robust observation, derived from 4000 marked individuals, to suggest that future climatic warming might lead to a population increase. This effect cannot be generalized, however, and in more temperate areas of Europe, such as France and Britain, mortality increases in years with marked floods or droughts.

Movements

Being so well adapted to a wide temperature range, many dippers throughout the world are relatively sedentary over the annual cycle. This includes the winter period, provided that there is sufficient daylight in which to feed, and provided that sufficient areas of river remain unfrozen to allow access to food.

True long-distance migration is, however, exhibited by White-throated Dippers breeding in the Urals and in Fennoscandia, where intolerably short winter days force movement. In this latter case,

*Incubation in dippers is almost invariably undertaken by the female alone, although males will occasionally attend to the eggs in her absence. Males are also reported to provision the incubating female with food, although she usually leaves the nest to forage independently. More often, males stand guard in the vicinity of the nest during the breeding cycle, possibly keeping an eye out for intruding males or predators. On occasion, males will even make direct flights at humans standing too close to the nest. The eggs of this **Brown Dipper** will probably hatch after a period of 19–20 days.*

[*Cinclus pallasii pallasii*, south Ussuriland, Russian Far East. Photo: Yuri Shibnev]

dippers fly south-eastwards each winter into southern Finland, Latvia, Estonia, Denmark, the Netherlands and Belgium, and some even reach Britain. Their annual cycle of weight gain is adapted to accommodate this migration, for example in allowing sufficient gain in reserves to enable the birds to make the return flight across the Baltic in spring.

Other regular migratory movements are made more locally, even within watersheds, where some members of the population, but not all, vacate higher-lying breeding territories during the winter months. The reasons for the variation in this strategy, and its dynamics and consequences, are still poorly understood, but the best-documented examples involve the American Dipper. In the Chilliwack watershed of British Columbia, in south-west Canada, about 65% of American Dippers are sedentary and 35% are migrants. Residents, in this case those at lower elevations, gained the advantage of earlier nest initiation, a greater chance of second broods, greater nest success and larger annual productivity. The migrants, those breeding at higher elevations, demonstrate a very marked fidelity to wintering locations. Similarly, in the Front Range of Colorado, in the United States, the proportion of individuals vacating higher-lying watersheds appeared to be large, perhaps over 70%.

In the Old World, some White-throated Dippers in the south Russian mountains of Khamar-Dhaban make post-breeding movements to more southerly regions, while others remain on open river channels and brooks that do not freeze. At the beginning of May, the migrants move back into the mountains, first concentrating at river mouths. Males then sing from perches on the edge of ice or on rocks. Likewise, some Brown and White-throated Dippers in the Himalayas are altitudinal migrants, whereas others can still be found at over 4500 m even in December, and the species is probably far less migratory than are other river-dwelling passerines in this region. Brown Dippers are believed to be partially migratory in north-east China, but they are essentially sedentary in Japan. Some Japanese individuals make vertical movements in response to low temperatures, and the species has been recorded in the winter months at sea-level on the Shiretoko Peninsula, in north-east Hokkaido. A similar phenomenon is evident in western Europe, where White-throated Dippers in the UK may move down to the coast in harsh weather conditions.

Given that dippers generally demonstrate high fidelity to breeding sites, the only other major movements that they make during their lifetime occur during the period of juvenile dispersal. In the case of the White-throated Dipper in Ireland and Britain, where populations are largely sedentary, juveniles begin to leave the natal territory within weeks of fledging, and movements are largely complete by the autumn, in September–October. Following the well-established pattern of other passerines, natal dispersal is sex-biased, females moving farther than males; young females move a median distance of 5–8 km and, occasionally, up to about 45 km, whereas males disperse over an average distance of 3–5 km. Only around 8–10% of males leave the natal watershed in making such movements, while 20-25% of females cross one or more watersheds. Generally similar figures on natal dispersal are apparent from studies of the American Dipper, albeit from smaller samples. The mean distance travelled by juveniles of this species is about 18 km, and approximately 10% of all ringed individuals were subsequently observed in different watersheds from the ones in which they hatched.

Relationship with Man

The charismatic underwater abilities of the Cinclidae, their special adaptations and "flagship" studies of their ecology have combined to give dippers a public image that is overwhelmingly positive. Moreover, their widespread use of man-made structures as nest-sites, sometimes even within urban areas, means that contacts between people and dippers are not uncommon.

In most European countries, the White-throated Dipper is now fully protected, but until the start of the twentieth century the species carried a bounty in such countries as Germany and Scotland. It was perceived, erroneously, that the dippers might have an adverse effect on fish populations, and on one Scottish estate alone 548 White-throated Dippers were killed between March 1831 and March 1834. Even today, some landowners will still not tolerate dippers on their waters. In North America, predation by American Dippers on fish eggs has also led to persecution of the species. In this case, impacts on wild salmonid populations are unlikely, however, because the fish fry and eggs taken by the dippers are, in any case, subject to major natural mortality. At fish farms, any predation by dippers and other bird species can easily be prevented by protecting the rearing ponds with netting. Finally, many of the fish eaten by cinclids, at least by White-throated Dippers, are of species other than salmonids.

Some hunting of White-throated Dippers by man, either for sport or for food, still takes place in the Mediterranean region and in north Africa. The Berbers in Morocco apparently

When the time comes for provisioning, both male and female ***White-throated Dipper*** *contribute almost equally, with a heavy input by males over the first few days when females continue to brood the newly hatched nestlings. On British rivers, young dippers are initially fed a diet largely comprising* Baetis *mayfly larvae, except on acidic waterways, where stonefly larvae are the main prey. As days pass, and chick weight increases, the adults bring more limnephilid and hydropsychid caddis larvae, as well as adult insects.*

[*Cinclus cinclus*, Scotland. Photo: Michael Callan/ FLPA]

*According to behavioural research, broods of **White-throated Dippers** initially adopt a carousel system of egalitarian provisioning. This involves each nestling moving to the back of the nest as soon as it is fed, allowing a hungrier sibling to receive food at the next visit. This seems suspiciously altruistic, and is duly replaced with a more normal system of cut-throat competition after about seven days. Thenceforth, whenever they see or hear an adult, all the young jostle at the entrance, clamouring loudly and signalling their hunger with brightly coloured gapes.*

[*Cinclus cinclus cinclus*, Redes Natural Park and Biosphere Reserve, Asturias, Spain. Photo: Isolino Pérez]

regard these birds as having aphrodisiacal properties. Elsewhere, there is little evidence that man has any major impact on the Andean or Brown Dippers through direct persecution, although indirect impacts through habitat modification and pollution are more likely.

The role of dippers as biological indicators has been increasingly highlighted since work carried out by Ormerod and colleagues during the 1980s–1990s, in Wales, provided the first evidence that birds could be affected by acid ran. Extensive studies of White-throated Dippers revealed that density, territory size, laying dates, clutch size, shell thickness, egg mass, brood size, the incidence of second broods, total productivity, nestling growth and adult condition were all markedly inferior on acidified streams than on better-quality, or circumneutral, streams. The differences were striking. At acidic sites, for example, pairs began laying 13–22 days later than they did elsewhere, clutch and brood sizes were smaller by more than 0·5 eggs or chicks, and densities were often 10–50% of those on good-quality streams. Many of these results were subsequently replicated in other parts of Europe, and new evidence showed that the palisade layer of eggshells from acidified areas was almost 11% thinner than that of shells from non-acidified areas. Additional British evidence demonstrated that populations declined when streams became more acidic, and also that population distribution matched the expectation of the effects of acid deposition. The process involved also became clear. In what are now some of the best-known examples of pollution impacts on streams and rivers, acidification reduced the abundances of key prey types for dippers, including mayflies, caddis larvae and, crucially for pre-breeding females, also calcium-rich prey such as molluscs, shrimps and fishes. Blood calcium was significantly lower in both males and females at acidic sites in the pre-breeding period than it was at circumneutral sites, whereas alkaline phosphatase, a major enzyme in calcium metabolism, was elevated. Serum calcium was also lower in young nestlings at acidic sites, while bone growth appeared retarded. Pre-breeding individuals on acidic streams had to increase foraging time markedly, at the expense of resting and self-maintenance, in order to maintain energy gain. Finally, no other explanation for these effects, such as pesticides or PCBs, was apparent. By 1995, the last major survey of acidification effects on White-throated Dippers showed that populations had probably thinned out even further.

Ten years later, in the middle of a new decade, there is now unequivocal evidence that acid deposition over Europe has decreased considerably, and average river quality is improving slowly. Biological recovery, however, has been partial and patchy, and probably offset over extensive areas by the continued effects of acid episodes. Full recovery of White-throated Dipper populations to pre-acidification levels is therefore still decades away.

The realization that all the dippers had general value as indicator species, coupled with measurements of contaminants in eggs made in conjunction with studies of acidification, has led to much further research. Their value as indicators of a wide range of contaminants, for example, reflects the position of dippers as high-ranking predators in river food webs. Moreover, observers can be relatively certain that any substances contained in eggs or tissues must have been accumulated within a well-defined territory: contaminant sources have sometimes been pinpointed with accuracy. More recently, dippers are being seen as important indicators of the physical quality of river habitats.

In Wales, failed and deserted eggs have been analysed for well over 20 different pollutants, including mercury, DDT and its metabolites DDE and TDE, lindane, hexachlorbenzene, dieldrin and its metabolites (HEOD), and individual PCB (polychlorinated biphenyl) congeners. In general, contaminant burdens are now below those at which major biochemical or reproductive effects have been detected in other passerines. Even though infertile eggs sometimes contain elevated concentrations of some PCBs, the congeners found have relatively low toxicity. Moreover, even at apparently contaminated sites, breeding performance and post-fledging survival have been unaffected. Partly as a consequence, White-throated Dippers have been particularly effective in revealing variations in pollutant conditions between geographical regions, and between catchments in different land uses, and even those due to individual point-sources. For example, one tributary of the Welsh River Severn, the Afon Mule, contained not only the highest PCB concentrations ever recorded in dippers, but also a very distinct "signature" of PCB congeners. Subsequent analysis of the river water confirmed a small dismantler's yard as a source of contaminated drainage, although

this same source had never been revealed by routine chemical monitoring.

Researchers in America have now started to use American Dippers as bioindicators and have assessed blood, egg and feather contaminants. Along the Arkansas River, for example, blood from dippers breeding on metal-impacted streams was compared with reference samples and found to have both higher lead concentrations and lower concentrations of ALAD. This enzyme is involved normally in manufacturing a part of the haemoglobin protein, but it may also be strongly bound by lead. Lead concentrations in birds, in turn, reflected concentrations in prey, so that the dippers in this case indicated food-web contamination. In the Chilliwack Watershed, in British Columbia, American Dippers have been used as a means of assessing contamination by both metals and organochlorines. Concentrations of mercury, cadmium and copper in feathers, and of total organochlorines, PCBs and mercury in the eggs of birds resident along the main river were higher than those found in migrants that bred on tributaries but spent the winter on the main river. In other words, contaminant profiles reflected the breeding site far more strongly than the wintering site. Accompanying research, using stable isotopes, revealed that the birds contaminated by most of these compounds were taking a greater proportion of Pacific salmon eggs or fry. In other locations, such contaminants are transported into river systems from the Pacific coastal shelf in migrating salmon, so that American Dippers in these cases have a pivotal indicator role at the interface of terrestrial and marine systems.

Status and Conservation

Four of the five members of the family have relatively large ranges in which they are common on suitable streams. Local declines have occurred as a result of pollution or the degradation of riverine habitats, and this has been recorded even in upland locations and on small streams, often considered the cleanest and the least acidified. None of these species, however, is considered to be under any serious threat on a global level.

The fifth species, on the other hand, is globally endangered. The Rufous-throated Dipper has a relatively small range and a restricted population, confined to south Bolivia and northern Argentina. It was listed as a Red Data species of global concern in 1992, and in the recent *Threatened Birds of the World* it is categorized as Vulnerable because of its small, fragmented range and declining populations. It appears to exist as a large number of subpopulations, none of which is thought to number more than a few hundred individuals, and the combined distributions of which cover about 19,000 km². This cinclid's world population is thought to be in the range of 3000–4000 individuals. There is little evidence for any recent declines in Bolivia, where the species occurs on rivers draining east-facing slopes of two ridges of the Andean foothills in the province of Tarija. On the western of the two ridges, dippers have been found at relatively low densities, of one pair per 1–2 km, on at least four tributaries of the River Guadalquivir and the River Camacho. Possibly up to 200 pairs occur on this ridge. On the better-forested rivers on the eastern ridge, the species is more numerous. Here, dippers have been located in the Tariquía National Reserve, south of Narvaez, on the Escalera, Achirales and Lorayo rivers, and an estimated 250–500 pairs are believed to be present on rivers between Entre Ríos and the Argentine border. Rufous-throated Dippers occur also, less commonly, to the north of Entre Ríos and Narváez, as on the River Villa, where pairs can be found on the upper reaches at intervals of 350–500 m, and more sparsely in the province of Chuquisaca, to the north of Tarija, where the species was first discovered in the mid-1990s.

In north Argentina, Rufous-throated Dippers are known from only a few sites in Jujuy, Catamarca and Tucumán. In Salta, they occur on forested western slopes of Valle de Lerma in the Orán and Baritú areas and near San Lorenzo, where they have been recorded on the River Pulares, the River Blanco and the River Mazano; they have been reported also at higher elevations on a tributary of the Santa Victoria and on the River Sacha Runa. The species is present in Baritú and Calilegua National Parks and in Portrero de Yala Provincial Park, and its total population in the country is thought not to exceed 1000 pairs.

Rufous-throated Dippers are believed to be declining in Argentina, mainly as a result of changes in water management and, possibly, deforestation. Threats include river pollution from mining effluent and nutrient enrichment, siltation of riverbeds fol-

*Given that the usual clutch size of the **American Dipper** is 3–5 eggs, this adult seems to have a slightly below-average brood of three, unless one or two more chicks are lurking invisibly in the shadowy interior. Whatever the total brood size, the nestlings are likely to remain ensconced in the nest for anything between 23 and 28 days, after which they will be spread out at intervals along the riverbank begging from secluded locations. For a cup-nesting species of this size, such a nestling phase would be exceptionally long, but it is more normal for a dome- or cavity-nester.*

[*Cinclus mexicanus unicolor*, near Uray, Colorado, USA. Photo: Jeff Foott/DRK]

*As in other dippers, a recently fledged **American Dipper** is dependent on its parents for between one and two weeks, after which it forages independently. Despite the high level of skill required in diving and swimming after food, young dippers seem very quick in achieving levels of foraging success in line with those of adults. The juvenile in this species is almost uniformly greyish brown, a characteristic that suggests the dipper lineage is far removed from thrushes (Turdidae), wherein a cryptically speckled juvenile plumage is the norm.*

[*Cinclus mexicanus unicolor*, Olympic National Park, Washington, USA. Photo: Rob Curtis/ The Early Birder]

lowing deforestation, and the abstraction of water from upland rivers for the irrigation of tobacco, sugar cane and other crops. The species also faces possible competition with introduced trout (*Salmo*) for invertebrate prey. The construction of dams and hydro-electric schemes are additional threats. Nevertheless, the species does seem still to be reasonably common on some rivers in northern Argentina, where densities of one pair per 400–500 m have been recorded.

Some subspecies of the American and White-throated Dippers have small ranges and could be vulnerable to extinction. In Europe, the status of the White-throated Dipper is considered secure, but only provisionally so, because data from many areas of its range are lacking. G. M. Tucker and M. F. Heath estimated that, in more than half of European countries, information on population sizes was inadequate, and that data on population trends was insufficient in 23% of all countries. The White-throated Dipper has suffered a decline in Hungary, and possible local declines have occurred elsewhere. For example, dippers had apparently disappeared from parts of Ireland, west Wales, south-west and north-east England and parts of Scotland between the periods 1968–1972 and 1988–1991. These areas have acidic streams, many of them draining catchments planted with conifers. On islands, in particular, dippers may have suffered. The race *olympicus* of the White-throated Dipper became extinct on Cyprus soon after 1945. This species bred on the Orkney Islands and the Isle of Man before the 1950s, after which it disappeared, but a slight recovery was evident by the late 1980s. In north-west Russia, the numbers of White-throated Dippers nesting in Karelia have considerably decreased, but the decline there may have happened in the early decades of the twentieth century. There are about 300 pairs nesting in near-polar regions of Finland, where there is, again, a trend of decrease.

The effects on dipper populations of water acidification and pollution have already been discussed (see Relationship with Man). More "traditional" forms of pollution also have an adverse effect on dippers. In the Tiber river system in Italy, and in the Peak District of northern England, for example, White-throated Dippers are more likely to be absent from streams polluted by organic waste and/or suspended solids. In the Italian case, they had disappeared after the quality of water had become degraded. In Britain, many rivers are now recovering from past organic pollution, and dippers have slowly returned to former sites. At the same time, new threats are arising, examples being those presented by climatic change and by agro-chemicals such as the ones used in sheep dips.

Pollution from industrial effluents has caused declines in White-throated Dipper populations in Britain, Poland, eastern Germany and possibly elsewhere across Europe. Dams and hydro-electric schemes remove or alter stretches of river used by these birds, and the modification of rivers by dredging or straightening may have adverse effects by reducing habitat diversity. M. Sara has reported declines in White-throated Dippers in Sicily following river modification, including the concreting of channels. Irrigation and abstraction can reduce flows, while alterations resulting in extreme drought or flooding can also have negative consequences for dippers. Mining operations in the Andes cause both pollution and siltation, and are believed to have adversely affected the White-capped and Rufous-throated Dippers. There is also considerable speculation about the possible effects of climate change, which will change river flow regimes considerably. In many of these instances, the exact effects are poorly quantified and only partially understood, but could possibly be substantial.

Land use in river catchments can affect river systems, for example by influencing erosion and river hydrology. S. Manel and colleagues showed that, across a large extent of the Himalayas, stream habitat structure, chemistry, aquatic-invertebrate abundance and the occurrence of river birds were all affected by land use, after accounting for altitudinal patterns. Streams draining terraced catchments were particularly affected, with adverse consequences for Brown Dippers.

The replacement of old stone bridges with modern concrete box structures capable of supporting heavy traffic has resulted in the loss of many traditional dipper nest-sites, especially in certain areas of the United Kingdom. In these cases, it is a simple matter to install ledges, drainage holes and nestboxes, with benefit to the dippers. Boxes have been used widely in Britain, Hungary, Austria, Germany and elsewhere, in an attempt to halt the decline in dipper populations when old bridges have been destroyed. In south Germany, D. Rockenbauch found that more than a third of White-throated Dipper broods on 420 km of river over a 28-year period were in nestboxes, and A. Kaiser found 64% of nests in boxes in his study area.

*The juvenile plumage of the **Brown Dipper**, in turn, is heavily spotted on upperparts and underparts, drawing comparison with the juvenile phase of certain thrushes, such as the* Sialia *bluebirds. This similarity has been used as evidence of a turdine ancestry, although in other respects, including bodily proportions and nest architecture, dippers seem more like giant semi-aquatic wrens (Troglodytidae). Either way, evidence in favour of a relationship with thrushes or wrens is equivocal, and there is little agreement as to the origins of dippers.*

[*Cinclus pallasii tenuirostris*, Tons River, India. Photo: Otto Pfister]

Perhaps a more surprising and alarming conservation problem, in view of all these potential threats, is that rivers and river birds are often under-represented in many national monitoring schemes. Other surveys cover only a vanishingly small percentage of total river extent or are dependent on small numbers of enthusiasts. In many cases, therefore, changes in dipper populations could go undetected, and the clear value of cinclids as wider environmental indicators may well be wasted.

*The rarest and least known member of the family is the **Rufous-throated Dipper**, a species of forested mountain streams in south Bolivia and north Argentina. Although it remains locally common, it is absent from several apparently suitable river systems and its overall population size is probably small, given that it occupies a sparse and linear habitat within a highly restricted distribution. These factors give some cause for concern as to its conservation status, and it is therefore listed as Vulnerable. Pollution of relevant rivers should be monitored and controlled, as should deforestation along their length.*

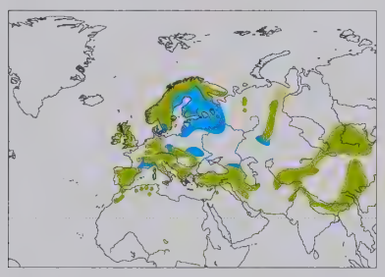
PLATE 34

inches 4

cm 10



Genus *CINCLUS* Borkhausen, 1797

1. White-throated Dipper

Cinclus cinclus

French: Cincle plongeur **German**: Wasseramsel **Spanish**: Mirlo-acuático Europeo
Other common names: Common/Eurasian Dipper, White-breasted Dipper; White-bellied Dipper (*leucogaster*)

Taxonomy. *Sturnus cinclus* Linnaeus, 1758, Europe = Sweden.
Closest to *C. pallasii*. Subspecific taxonomy in need of revision, especially since data from cytochrome *b* sequences conflict with presumed distributions of races in W Palearctic. Much variation probably clinal. Birds from EC Asia (Altai Mts E to Transbaikalia) sometimes recognized as *baicalensis*. Proposed races *meridionalis* (described from Austrian Alps) and *orientalis* (from Han Abdiposa, in Macedonia) merged with *aquaticus*, and *amphitryon* (from N Turkey) with *caucasicus*. Form described as *sordidus* is a dark morph of *leucogaster*. Cyprus race *olympicus* extinct. Twelve extant subspecies recognized.
Subspecies and Distribution.
C. c. hibernicus Hartert, 1910 – W Scotland (including Inner Hebrides) and Ireland.
C. c. gularis (Latham, 1801) – Scotland (except W), N, C & W England and Wales.
C. c. cinclus (Linnaeus, 1758) – Scandinavia E to NW Russia (E to R Pechora), also C & SW France, NW Iberia, Corsica and Sardinia.
C. c. aquaticus Bechstein, 1796 – C & S Europe (Belgium and E France S to E & S Iberia, Italy, Sicily and Greece).
C. c. uralensis Serebrovski, 1927 – Ural Mts (W Russia).
C. c. minor Tristram, 1870 – NW Africa.
C. c. caucasicus Madarász, 1903 – Turkey, Caucasus, N Iraq and N Iran.
C. c. persicus Witherby, 1906 – SW Iran (Zagros Mts).
C. c. rufiventris Tristram, 1884 – Lebanon and W Syria.
C. c. leucogaster Bonaparte, 1850 – SC Russia (Altai Mts E to Transbaikalia) S to N Afghanistan, NW Pakistan, NW China (Tien Shan, W Kunlun Shan) and Mongolia.
C. c. cashmeriensis Gould, 1860 – N side of W & C Himalayas from N Pakistan E to Sikkim.
C. c. przewalskii Bianchi, 1900 – N Bhutan and C China (S Gansu and NW Sichuan S to SE & E Xizang).

Descriptive notes. 17–20 cm; male 53–76 g and female 46–72 g (nominate), male 60–76 g and female 50–67 g (*gularis*), sexes combined c. 41–65 g (*leucogaster*). Nominate race has head down to ear-coverts and lores dark brown; upperparts darker and greyer with feathers narrowly edged blackish; flight-feathers and tail blackish-brown to grey-brown; chin and throat to breast white, belly to vent blackish-brown; iris brown; bill black; legs dark brown. Sexes similar, female slightly smaller and shorter-winged than male. Juvenile is distinctive, dark slate-grey above, feathers with black-brown margins, wings fringed pale, white chin and throat, dark-barred greyish underparts. Races differ mainly in coloration of underparts, also in tone of upperparts: *hibernicus* is darker than nominate, has narrow rufous band between breast and belly; *gularis* is paler above than previous, with broader chestnut-brown band on lower breast and central belly; *aquaticus* has paler upperparts than preceding races, head and nape grey-brown, some populations with broad bright chestnut band on lower breast and belly; *uralensis* is very similar to last, but upperparts darker; *minor* is also similar, but larger (one of largest races); *caucasicus* is paler, upperparts and belly dull grey-brown, rump and uppertail-coverts grey, some populations with tinge of rufous on lower breast and upper belly; *persicus* is similar to previous, but supposedly larger; *rufiventris* is smaller than last, has darker rufous band below; *leucogaster* is distinctive, all white below except for grey lower flanks, dark vent, also rare dark morph ("*sordidus*") entirely dark brown below, and intermediate forms; *cashmeriensis* has chocolate-brown upperparts and lower belly, paler upper belly, has pale and dark morphs; *przewalskii* resembles last, but belly wholly dark, also has pale and dark morphs. Voice. Male song high-pitched, piercing, loud melodious warbling or trilling, comprises variety of notes in any order, with short phrases repeated as single units, has been likened to that of a thrush (Turdidae) or wren (Troglodytidae); female song less melodious, consisting of scratchy whistles and disconnected units. Call a loud "zzit zzit" or "dzchit dzchit"; rattling calls in greeting and in courtship.
Habitat. Fast-flowing, clear-water rocky streams and rivers with riffles and exposed rocks, and with abundant invertebrate prey; shallow watercourses in broadleaf woodland, in semi-natural forest and on open moorland. Also glacial lakes. Requires rocky cliffs or artificial sites, e.g. bridges, for breeding. Occasionally slower-flowing lowland rivers and seashores in non-breeding season. Mostly in uplands, e.g. in NW Africa commonest on permanent streams of High Atlas at 900–2600 m; breeds 2000–3500 m in Afghanistan and 3000–5500 m in Himalayas; in non-breeding season sometimes lower, down to 2400 m in Himalayas and to c. 1000 m elsewhere in Asia, and locally down to sea-level, especially in Europe. Many present throughout year at high altitudes, so long as some water remains free of ice.
Food and Feeding. Freshwater insects and larvae; more rarely, marine invertebrates in coastal areas. Principal prey mayfly (Ephemeroptera) and stonefly (Plecoptera) nymphs, and larvae of caddis flies (Trichoptera), also dragonfly nymphs (Odonoata) and fly larvae (Diptera), especially blackfly (*Simulium*); shrimps (*Gammarus*) also taken; occasionally small fish, mostly bullheads (Cottidae), some salmon fry (*Salmo*). In study in Britain, Apr–Jun, mayfly nymphs formed 56·7% of diet by number, and caddis-fly larvae 25·3%, stoneflies 7·5%, dipteran larvae 2·8%, beetles (Coleoptera) 2·5%. In 337 stomachs from W Germany, Mar–Aug, caddis-fly larvae present in 92·6%, stoneflies in 21·4%, *Gammarus* in 17·2%, molluscs in 8%, beetles in 7·4%, plant material in 6·5%, fish in 6·2%. Seasonal analyses show predominance of mayflies, stoneflies and caddis flies during breeding season, shrimps, molluscs, beetles and fish becoming more important during winter. Requires up to 79 g of food per day. Diet of young similar to that of adult. Forages on rocks and stones on riverbed, also on wetted surface of rocks above water; sometimes on riverbank among tree roots and leaves; rarely, on coastal shorelines. Feeds mostly by plunging into swift-flowing water; wades in shallow water, but in deeper water generally submerges completely. Swims against current, using wings as main source of locomotion, "walking" on river bottom. In various studies, mean duration of dives 3·2 seconds, range 2·4–7·4 seconds, generally increasing with depth of water, but rarely longer than 10 seconds; exceptionally, up to c. 30 seconds. Maximum rate of dives 11·5 per minute. .
Breeding. Laying Feb–Jun in British Is, mid-Mar to May in NW & C Europe, early May to early Jun in Scandinavia; mid-Mar to May in NW Africa; in Asia, breeds Apr–Jul in N and mid-Feb to Aug in S; 1-2 broods, rarely 3 in S of range. Mostly monogamous, but some males polygynous; solitary nester. Nest built by both sexes, a large globular structure up to 30–45 cm across (often less, c. 20 cm) with side entrance hole, made mainly of moss, lined by female with dry leaves; in rock crevice or cliff ledge, in masonry or on ledge in wall or under bridge, sometimes behind waterfall, rarely in tree, almost invariably over running water, rarely in building away from water; will use nestbox; linear territory of 400–500 m or more, longer (up to 2·5 km) on less favourable watercourses such as acidic streams. Clutch 3–6 eggs, rarely 7, normally 4 or 5; incubation by female, starting with last or penultimate egg, period 15–18 days, rarely to 20 days; chicks brooded by female, fed by both parents, fledge at c. 20–24 days in Britain, 23–27 days in Germany, average 21·5 days in Switzerland; juveniles fed by adults for 1–2 weeks. Of 1986 eggs in 455 nests in Britain, 61·05% hatched and 84·1% of hatchlings reared to 14 days, overall success 51·4%; of 258 eggs laid in 66 clutches in W Germany, 80% fledged, mean 3·91 young per nest.
Movements. Resident, but some post-breeding descent from high altitudes to more lowland rivers, sometimes to coast; more migratory in extreme N, e.g. N Scandinavia. In Europe, some migrate S or SE from Norway and Sweden to Denmark, Finland and SE Baltic region, occasionally to E Britain; some movement S in Ural Mts; male ringed as nestling in Switzerland and female ringed as nestling in C Sweden, both in Jun 1992, both retrapped in Nov of following year in N Poland (where bred together in 1994). Altitudinal movement recorded in NW Africa and Asia, dependent largely on presence or otherwise of ice-free water; many remain at high altitudes even in extremely cold temperatures, so long as running water available; sometimes wanders for long distances. Limited juvenile dispersal, generally over very short distances. Accidental in Faeroe Is and Malta.
Status and Conservation. Not globally threatened. Common and widespread on suitable watercourses. Estimated European population 120,000-300,000 pairs. Densities highest in shallow, fast-flowing streams, thus tend to increase with gradient, altitude and presence of rapids; 1·4–2·2 pairs/10 km in SE Norway, and in C Europe mostly 0·7–10 pairs/10 km; 1·15–2·67 pairs/10 km in Wales, 2·1 pairs/10 km in NW England (Cumbria) and up to 9·7 pairs/10 km in S Scotland (Perthshire); 2·4 pairs/10 km in W Germany and 2·3 pairs/10 km in Austria. Apparently reasonably stable, but periodic fluctuations in small, isolated populations (e.g. on some islands); Cyprus race (*olympicus*) now extinct; formerly bred in lowlands of NW France, and no recent confirmed breeding in lowlands of E Germany; occasional breeding in Netherlands. In NW Africa (race *minor*), probably maximum of 1000 pairs in Morocco (Rif Mts, Atlas Mts); fewer than 100 pairs in Algeria, where known from very few localities (mainly in Hodna and Aurès Mts, in NE). No comparable data from elsewhere in range. Common to locally common in Asia, but scarce to rare on S side of Himalayas; fairly common in China. Throughout range, status and abundance strongly reflect water quality and habitat structure of rivers, and this species is widely recognized as an indicator of environmental quality; pollution that adversely affects aquatic prey also has an impact on dippers. Chemical pollution, as from acidification ("acid rain"), industry, organic effluent, sheep dips and other xenobiotic substances, are potential threats. In parts of Europe (e.g. Wales, Scotland, Scandinavia), shown to suffer severe adverse effects from acidification of rivers, from which recovery likely to be slow (taking decades, even centuries); in Germany and Poland, reported declines more directly attributed to industrial pollution. Poor water quality revealed in impaired breeding, subtle changes in survival, or territory selection; moreover, "pollution" reported cause of death in 3% of recoveries; on other hand, effects on survival of persistent pollutants such as PCBs appear now to be negligible or non-existent. In S Europe and elsewhere, hydro-electric and irrigation schemes may be causing declines by reducing flow rates in watercourses. Habitat degradation, water abstraction and water impoundment are negative factors in parts of range.

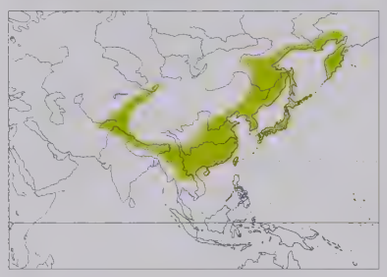
2. Brown Dipper

Cinclus pallasii

French: Cincle de Pallas **German**: Pallaswasseramsel **Spanish**: Mirlo-acuático Pardo
Other common names: Pallas's/Asian/Asiatic Dipper

Taxonomy. *Cinclus Pallasii* Temminck, 1820, "Crimea"; error = eastern Siberia.

On following pages: 3. American Dipper (*Cinclus mexicanus*); 4. White-capped Dipper (*Cinclus leucocephalus*); 5. Rufous-throated Dipper (*Cinclus schulzi*).



Closest to *C. cinclus*. Proposed races *yesoensis* (described from Hokkaido, in N Japan), *hondoensis* (Hondo, in S Japan) and *marila* (Taiwan) are considered indistinguishable from nominate; similarly, *undina* (from Khasi Hills, in NE India) is merged with *dorjei*. Three subspecies currently recognized.

Subspecies and Distribution.

C. p. pallasii Temminck, 1820 – E Russia, C & E China, Korea, Sakhalin I, S Kuril Is, Japan (S to Yakushima) and Taiwan.

C. p. tenuirostris Bonaparte, 1850 – Tien Shan Mts S to N Afghanistan, and from NW Pakistan (Safed Koh) E in Himalayas to Sikkim.

C. p. dorjei Kinnear, 1937 – E Himalayas E to mountains of W, N & E Myanmar, S China (W Yunnan), NW Thailand, N & C Laos and NW Vietnam.

Descriptive notes. 21–23 cm; two males 88 g and 88·7 g, two females 76·3 g and 86·5 g (nominate), male 68·9–82·6 g and two females 62 g and 79 g (*tenuirostris*), one male 70 g and two females 66 g and 68 g (*dorjei*). Nominate race has plumage entirely dark chocolate-brown, back and chest slightly warmer, more rufous-tinged, than head and rump; flight-feathers and tail dark chocolate-brown; underwing dark grey-brown; iris brown, narrow white eyering; bill blackish; legs blackish-brown. Sexes similar, female somewhat smaller than male. Juvenile is distinctive, dull blackish-brown with conspicuous greyish-white spots on head and throat, greyish-white scalloping on back, breast and belly, contrasting greyish-white edgings on secondaries, tertials and rectrices. Races differ in depth of coloration: *tenuirostris* is paler brown than nominate, juvenile also paler, grey-brown with pale spots above, mottled whitish and brown below; *dorjei* is darker and smaller than previous, also juvenile more rufous than in other races, blackish- brown with pale rufous spots, less prominent pale fringes on wings and tail. Voice. Song a rich warbling, reminiscent of Thrush Nightingale (*Luscinia luscinia*), includes dry buzzing notes, clipped notes, trills and rattles, given in brief verses or in longer, more rambling version; described as somewhat more pleasant than that of *C. cinclus*. Call a buzzing "zzit zzit" or "dzit dzit", less shrill than call of *C. cinclus*, given irregularly or in short series; rattling "r-r-r-r-r" or low rolling "zur-r-r-r" in courtship or as greeting.

Habitat. Fast-flowing rocky mountain streams and shallow rivers with clear water; sometimes at upland tarns. From foothills to above 5000 m locally; breeds from as low as 450 m to c. 4300 m in Himalayas, probably ascending higher after breeding; 450–1800 m in Japan, sometimes lower, even down to sea-level, in non-breeding season. In Himalayas, often on larger, slower rivers and at lower elevations than *C. cinclus*, but much overlap; at W extreme of range, in Uzbekistan, nests of the two species alternated along a length of stream.

Food and Feeding. Aquatic invertebrates, especially mayfly (Ephemeroptera) and stonefly (Plecoptera) nymphs, larvae of caddis flies (Trichoptera) and similar items. Stomachs of birds from Russia found always to contains sand grains and small pebbles. Forages on riverbed, by diving from rock into fast-flowing water. Swims on surface; on calmer pools and tarns, frequently dives from a floating position, with initial slight upward spring as that of small grebe (Podicipedidae), apparently doing so more regularly than does *C. cinclus*.

Breeding. Dec to early Aug, depending on altitude; laying mainly from Apr in Russia, Dec–Mar in China; in Japan, lays from mid-Apr in N (Hokkaido) and from Feb in S (Honshu); often two broods per season. Monogamous; solitary nester. Nest built by both sexes, taking c. 7–10 days, a large globular structure with side entrance, outer wall made largely of moss, inner layer of finer material, small rootlets and leaf ribs, nests in Tien Shan 22·5–28 cm in diameter, walls 3·5–5 cm thick, entrance hole 8–8·5 cm across; sited in rock crevice or cliff ledge, often directly above flowing water, sometimes among mid-river boulders, sometimes in cave, less often behind waterfall or in masonry under bridge; linear territory c. 400–500 m or longer. Clutch 3–6 eggs, most commonly 4 or 5; incubation period 19–20 days and fledging period 23–24 days in E Russia, but respective figures of 15–16 days and c. 21 days reported in Japan. Nests sometimes parasitized by cuckoos (of genus *Cuculus*).

Movements. Resident, with some altitudinal movement. In breeding areas in Gissar Mts (E Uzbekistan–Tajikistan), descends to 1300–1000 m in Oct/Nov, reappearing on nesting territories in Apr or early May; general post-breeding withdrawal from higher levels in Himalayas during winter months, e.g. down to 600 m in Nepal, but many remain at high elevations throughout year. Essentially sedentary in Japan, but some vertical movements in response to temperature; recorded down to sea-level in winter in NE Hokkaido (Shiretoko Peninsula). Possibly some migration in N China. Recorded as vagrant in Hong Kong.

Status and Conservation. Not globally threatened. Considered common and widespread on suitable watercourses throughout most of its extensive range; fairly common in Japan. Reported former occurrence in Bangladesh remains uncertain; no definite records. Recorded in NW Thailand but status uncertain, possibly non-breeding visitor. In Himalayan foothills, water abstraction for irrigation, deforestation, associated agro-chemicals and siltation have local negative impacts; population declines reported in Nepal. Hunted for food in some parts of range, especially China and SE Asia.

Bibliography. Abdusalyamov (1973), Ali, R. 3. American Dipper

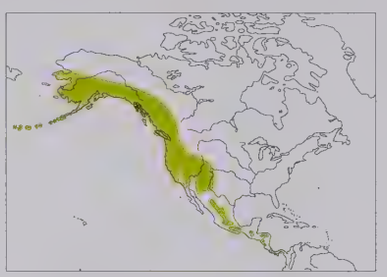
Cinclus mexicanus

French: Cincle d'Amérique **Spanish**: Mirlo-acuático Norteamericano
German: Grauwasseramsel
Other common names: Mexican/North American Dipper

Taxonomy. *Cinclus mexicanus* Swainson, 1827, Temascáltepec, Mexico.
Geographical variation rather slight, possibly clinal. Five subspecies recognized.

Subspecies and Distribution.



C. m. unicolor Bonaparte, 1827 – Alaska (including Aleutian Is) and W Canada S in W USA to California and New Mexico.

C. m. mexicanus Swainson, 1827 – N & C Mexico (Pacific slope from N Chihuahua S to Michoacán, México and W Puebla).

C. m. dickermani A. R. Phillipps, 1966 – S Mexico on Pacific slope (S Guerrero, S Oaxaca) and Atlantic slope (NE Puebla, C Veracruz).

C. m. anthonyi Griscom, 1930 – SE Mexico (E Chiapas), SW Guatemala, NE & SE Honduras and NW Nicaragua.

C. m. ardesiacus Salvin, 1867 – Costa Rica (entire Caribbean slope, and Pacific slope of Cordillera de Talamanca and Cordillera Central) and W Panama (Pacific slope in Chiriqui and Veraguas).

Descriptive notes. 14–20 cm; male average 60–61 g, female average 53–54·5 g. Nominate race has head and neck dark brown, rest of plumage dark slate-grey, slightly darker on wings and tail; iris brownish, white eyelids; bill dark grey; legs greyish flesh-coloured. Sexes similar, female smaller than male. Juvenile is mostly grey, wing feathers with pale edgings, underparts mottled light rufous, throat usually dark (sometimes whitish). Races vary in colour tone of plumage: *unicolor* has head and neck washed grey-brown, paler than nominate, juvenile with throat mostly white, underparts scalloped or mottled with greyish-white; *dickermani* has crown, lores, chin and upper throat darker than nominate, head side more sooty; *anthonyi* is paler above than previous and nominate; *ardesiacus* is distinctly paler and greyer than other races, head and neck almost concolorous with back, underparts pale ash-grey, juvenile also paler, with white throat and much white on underparts. Voice. Song piercing, often loud, audible at up to 1·5 km in still conditions, a varied and elaborate medley of single and repeated notes and trills, sweet and bell-like but with raspy "jik" call interspersed at intervals, successive note types contrasting with each other, can continue for up to 10 minutes; both sexes sing, songs of each equally varied and complex, essentially identical (no structural differences). Call a loud, harsh, burry "jik", short (mean 46 milliseconds); also lower-frequency "grawk" or "brzzzt", twice as long as "jik" call.

Habitat. Fast-flowing rocky mountain streams and rivers with abundant invertebrate prey. Streams used for breeding rarely larger than 15 m wide and 2 m deep, and have cliffs, large rocks and boulders, especially with overhanging ledges and crevices, for nesting; rocks, fallen trees and debris provide sites for refuge. Outside breeding season, sometimes forages at still waters, such as mountain lakes, tarns and beaver (*Castor canadensis*) ponds. Mostly in uplands, to at least 3500 m in Rocky Mts, but down to near sea-level in N; 1000–3000 m from Mexico S to Nicaragua; 800–2500 m in Costa Rica (and not below 1700 m in on Pacific slope of Cordillera Central), but sometimes down to 600 m after breeding; mainly 1200–2100 m in Panama, but occasionally lower (down to 750 m) in Veraguas.

Food and Feeding. Aquatic insects and larvae, especially mayfly (Ephemeroptera) and stonefly (Plecoptera) nymphs, caddis-fly larvae (Trichoptera), dipteran larvae (particularly those of simuliids); occasionally small fish, tadpoles; salmonid eggs locally important in winter. Prey selected according to relative abundance and size; prefers large prey, of abundant species. Feeds predominantly in water, by walking, swimming and diving. Typically, plunges from a rock or from edge of ice, returning to surface after 5–10 seconds. Feeding bouts of variable duration, up to 60 minutes, usually shorter. Sometimes forages on riverbanks, occasionally picks food from ice or snow; sometimes takes aerial insects by flycatching.

Breeding. Laying from early Mar to Jul, mainly Apr-Jun, in North America, and Feb–May in Costa Rica; sometimes double-brooded. Monogamous, occasionally polygynous; solitary nester. Nest generally built by both sexes, occasionally by female alone, a large globular structure with side entrance, external diameter 20–25 cm, internal 14 cm, entrance hole 7·5 × 5 cm, outer shell made of moss with small amounts of interwoven grass roots and stems and leaves (entirely of leaves and grass if no moss available), inner wall of grass and leaves, sometimes with bark added, lined with leaves; placed in rock crevice or on cliff ledge, in masonry or on ledge in wall or under bridge, sometimes behind waterfall, or in nestbox, almost invariably over running water at height of up to 9 m (mostly 1–3 m), sometimes among mid-stream boulders, occasionally on building near watercourse; often near or on top of old nest, or old nest repaired and reused; linear territory of at least 400 m, average varying from 759 m to 2070 m in different studies. Clutch 2–6 eggs, usually 3–5, average 4·1; incubation by female, period 14–17 days; chicks fed by both parents, mostly by female, fledging period 23–28 days, mostly 24–26 days.

Movements. Resident, with local movements; some altitudinal movement between breeding and non-breeding areas. Winter presence determined by availability of open water; resident at streams that do not freeze in winter. Although freeze-up is ultimate factor determining movement downstream or across drainages, some movement not coincident with freezing occurs. In study in R Chilliwack watershed (SW British Columbia), in Canada, majority of population moved to breeding grounds on higher-lying tributaries in spring; densities on main river 9·8 birds/km in early Nov, compared with 2·1/km in early Jul. In Nov and late Mar 1993/1994, observed in high-level direct flights in late afternoon in Alberta (Canada), suggesting not local movement over longer distances. Some altitudinal movements linked to seasonal food sources provided by winter-run Pacific salmon eggs. Some move considerable distances from breeding areas; record of one individual 1400 km from nearest breeding habitat.

Status and Conservation. Not globally threatened. Common and widespread throughout much of range; uncommon to locally common from Mexico S to Nicaragua; locally common in Costa Rica. Recently discovered breeding on Atlantic slope of Honduras. In United States, densities in Colorado varied from highs of 1·9–4·7 birds/km in Oct to 1–3·9 birds/km of ice-free stream in Feb; in study in Montana, population increased from pre-breeding density of 1 bird/0·77 km of stream to post-breeding density (augmented by juveniles) of 1 bird/0·50 km. In Alaska (Anaktuvak Pass), 6–8 pairs subsist in 7·770 km² of arctic mountains, snowbound for 8 months of year; in winter, restricted to tiny sections of open water a few metres long. Few major threats. This species' habitat, at least in North America, is adequately protected in high mountains, but in coastal mountains forestry-management practices can have adverse consequences. Main potential threats are water pollution and deforestation; clear-cutting, by opening up habitat, may increase temperatures in streams and alter the entire food web. Sometimes killed by fishery-managers and others because of alleged predation on young fish. Nests sometimes destroyed through acts of human vandalism, such events having occurred since 19th century, but this not thought to have any major impact on dipper populations.

4. White-capped Dipper

Cinclus leucocephalus

French: Cincle à tête blanche **Spanish**: Mirlo-acuático Coroniblanco
German: Weißkopf-Wasseramsel
Other common names: White-backed Dipper (*leuconotus*)

Taxonomy. *Cinclus leucocephalus* Tschudi, 1844, Department of Junín, Peru.
Forms a superspecies with *C. schulzi*; sometimes considered conspecific, but differs significantly in plumage coloration and pattern. Three subspecies recognized.
Subspecies and Distribution.
C. l. rivularis Bangs, 1899 – Santa Marta Mts, in N Colombia.
C. l. leuconotus P. L. Sclater, 1858 – Sierra de Perijá, and Andes from W Venezuela (S from Lara) S to Ecuador.
C. l. leucocephalus Tschudi, 1844 – Andes of Peru and NW Bolivia (S to W Santa Cruz).

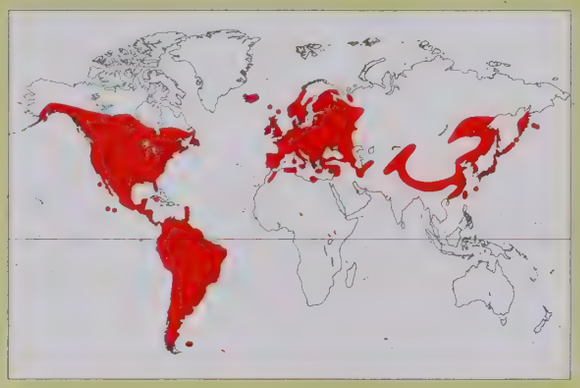
Descriptive notes. 15–16·5 cm; c. 44 g. Nominate race has whitish crown and nape with fine dark spots and streaks, blackish-brown band from lores back to nape side; upperparts, including wings and tail, blackish-brown; chin and throat to breast white, breast side, belly and flanks blackish-brown; underwing greyish-black, inner webs of secondaries white (visible when wings flicked); iris brown; bill black; legs lead-grey. Sexes similar, female smaller than male. Juvenile has crown more prominently streaked, upperwing-coverts and tertials narrowly edged whitish, throat and breast dark-streaked (throat sometimes mostly grey), belly mottled whitish. Race *rivularis* is paler than nominate, throat spotted grey; *leuconotus* is smaller, distinctive, has white patch on upper back, more extensive white below, only flanks and lower belly to vent dark. Voice. Song a prolonged loud musical trill; flight call a loud sharp "dzeet" or buzzing "zre'e'd", similar to that of congeners.
Habitat. Fast-flowing rocky mountain streams and rivers with boulders, rapids, waterfalls and similar, usually bordered by rocky cliffs or vertical rocky banks; in forested areas and also, at higher elevations, in more open areas. Clear waters preferred. Foothills to lower *páramo* zone, to c. 3900 m, occasionally to 4200 m, mostly above 1000 m; recorded at 1600–3000 m (mainly 2000–2600 m) in Venezuela; from at least 700 m to 3800 m, sometimes down to 400 m, in Ecuador; rarely, down to 100 m in Colombia.
Food and Feeding. Food includes various aquatic invertebrates, notably blackfly larvae (Simuliidae), mayfly nymphs (Ephemeroptera), caddis-fly larvae (Trichoptera); also terrestrial invertebrates, such as earthworms. Forages mainly while standing at edge of water or on mid-stream rock, by pecking for prey; dips bill, and sometimes head, beneath surface. Sometimes wades in water, and occasionally floats or swims on surface; not known to plunge. Also forages in bankside vegetation.
Breeding. Comparatively little information. Nests with eggs found in Feb and Mar in Venezuela; in Colombia, birds in breeding condition in Feb–Sept in N, and fledglings in Oct and juveniles in Dec–Apr in S; nests with eggs/young in Sept in Ecuador; fledglings in Jul in S Peru; eggs in Nov and fledglings in May in Bolivia. Large spherical nest with circular entrance hole, two nests described, one was 25 cm across, diameter of entrance hole 8 cm, outer wall made from moss, inner cup mainly of dry leaves, strips of bark and strips of plastic, built into cleft 1·3 m above water on moss-covered cliff behind waterfall, the other was in narrow niche in cliff face beside waterfall. Clutch 2 eggs; no information on incubation and fledging periods.
Movements. Resident; possibly some altitudinal movement in non-breeding season.
Status and Conservation. Not globally threatened. Fairly common throughout range; widespread, sometimes occurring on even very small rivulets. Normally at densities of less than 1 pair/km to c. 2 pairs/km of stream. Susceptible to pollution; in Ecuador, degradation of water quality has resulted in its disappearance from some streams in Quito area, where only a few birds remain in central valley towards N (e.g. along R Guaillabamba).
Bibliography. Allen (1998), Babin (2002), Baez *et al.* (1997), Bloch *et al.* (1991), Bond (1956a), Carriker (1959), Chapman (1917, 1921), Fjeldså & Krabbe (1990), Georgiev & Gardner (2004), Hellmayr (1934), Hilty (2003), Hilty & Brown (1986), Koepcke (1970), Lasso (1988), Ortiz & Carrión (1991), Remsen & Traylor (1983), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Schulenberg *et al.* (2001), Skutch (1972), Stotz *et al.* (1996), Tyler & Ormerod (1994), Varty *et al.* (1986), Walker (2001).

5. Rufous-throated Dipper

Cinclus schulzi

French: Cincle à gorge rousse **Spanish**: Mirlo-acuático Gorgirrufo
German: Rostkehl-Wasseramsel
Other common names: Argentine Dipper

Taxonomy. *Cinclus Schulzi* Cabanis, 1882, Cerro Bayo, Tucumán, Argentina.
Specific name sometimes misspelt as *schulzii*. Forms a superspecies with *C. leucocephalus*; sometimes considered conspecific, but differs significantly in plumage coloration and pattern. Monotypic.
Distribution. E Andes in S Bolivia (S Chuquisaca, W Tarija) and NW Argentina (Jujuy, Salta, Catamarca, Tucumán).



Descriptive notes. 14–15·5 cm; 39·5 g. Plumage is dull dark brownish-grey above, wings and tail slightly darker; white on bases of inner webs of primaries (visible when wing open); chin greyish, throat to uppermost breast contrastingly orange-rufous, rest of underparts grey-brown, greyer on breast, darker on belly; underwing grey, broad white band at bases of primaries; iris dark brown to blackish; bill black to dark grey; legs lead-grey. Sexes similar, female slightly smaller than male. Juvenile resembles adult, but paler, bill more pinkish. Voice. Song a loud melodious warbling or trilling, resembles that of *C. cinclus*; call a loud "zzit" or "dzchit" or "schenk", usually in series, faster when in flight.
Habitat. Fast-flowing rocky mountain streams and rivers, 5–15 m wide, with cascades, waterfalls, and rocky cliffs or banks. Breeds mainly in the Andean alder (*Alnus acuminata*) zone, at 1500–2500 m; reported also at higher levels, and in Bolivia possibly breeds on streams in pastureland at lower elevations (1200 m). In frosty conditions often descends to lower levels, down to c. 800 m, and then sometimes found on larger rivers. Rarely occurs on narrow forest streams (1–2 m wide) favoured by Sharp-tailed Streamcreeper (*Lochmias nematura*).
Food and Feeding. Food aquatic insects and larvae; one stomach contained mostly beetle imagos (Coleoptera). Forages by wading in shallow water or standing on wet rocks and on lips of waterfalls, and picking invertebrates; also probes in wet moss on rocks and in other vegetation on river margin. Occasionally jumps up or makes short flights to take aerial insects. Often feeds with head and most of body immersed, with wings flapping to maintain balance, but, despite some published statements, no definite records of plunging beneath surface. Noted as being more active on overcast days or during light rain; on clear sunny days, remains motionless for long periods in shade beneath rock overhangs. Usually makes only short flights between foraging sites.
Breeding. Nests and eggs Sept–Jan. Monogamous, so far as is known; solitary nester. Large globular nest 24 cm high, 22 cm wide and 14 cm deep, side entrance hole 7 × 5 cm, outer shell made of moss and grass, inner bowl of grass stems, algae, *Alnus* leaves, sometimes few feathers, once paper and plastic, nest cup 8 cm in diameter and 4 cm deep; placed in rock crevice, on cliff ledge, in niche of rocky wall, under overhang in earth bank, on tree roots or in brickwork of bridge, 0·5-1·25 m above rushing water; linear territory of 500–1000 m on suitable stretches of river, sometimes 2 km in less favourable places. Clutch 2 eggs; no information on incubation and fledging periods; nestlings fed by both parents.
Movements. Resident; some altitudinal movement in cold weather.
Status and Conservation. VULNERABLE. Restricted-range species: present in Argentine and South Bolivian Yungas EBA. Uncommon to locally common. Range covers approximately 600 km × 100 km, but many distributional gaps within this; area occupied probably c. 19,000 km². Has small, highly fragmented population estimated at 3000–4000 individuals, and thought to be declining. Bolivian population currently estimated as numbering variously up to 500 pairs to probably over 1000 pairs; Argentine population put at maximum of 1000 pairs. Widespread and not uncommon on rivers on E-facing slopes of two ridges of Andean foothills in S Bolivia; on one of these possibly up to 200 pairs, at low density of 1 pair/1–2 km, on several tributaries of R Guadalquivir and R Camacho; more numerous on better-forested rivers on the other ridge (farther E), where estimated 250–500 pairs on rivers between Entre Ríos and Argentina border; occurs also, less commonly, N of Narváez, as on R Villa into Chuquisaca. In Argentina, recorded in Salta in the Orán and Baritú areas as well as near San Lorenzo, on R Pulares, R Blanco and R Mazano, all on forested W slopes of Valle de Lerma, also reported at higher elevations on a tributary of R Santa Victoria and on R Sacha Runa; known from only a few sites in Jujuy, Catamarca and Tucumán. Main threats arise from changes in river management, water pollution, perhaps also deforestation; quality of rivers adversely affected by mining effluent, nutrient enrichment, siltation, water abstraction for irrigation of crops (tobacco, sugar cane and others), also dam construction and hydroelectric schemes. Logging, grazing and erosion have adverse effects in breeding areas where streams flow through forest. Food competition with introduced trout (*Salmo*) also a potential problem. Impact of these threats most marked in Argentina, and pollution, reduced flows and river-channel modifications most prevalent at lower altitudes. Nevertheless, much of this species' habitat is currently fairly inaccessible, and thus effectively protected. Occurs in Tariquía National Reserve, in Bolivia, and in Baritú, Calilegua and Campo de los Alisos National Parks and Portrero de Yala Provincial Park, in Argentina.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family TROGLODYTIDAE (WRENS)

- Small, mostly insectivorous birds with finely pointed and often decurved bill, tail variously long and graduated to extremely short; plumage mostly grey and brown, often with rufous tones.
- 9–22 cm.

- New World, one species also in Eurasia and north Africa.
- Forest, forest edge, scrubland, suburban gardens, marshes, desert brushland, rock faces.
- 17 genera, 85 species, 407 taxa.
- 6 species threatened; none extinct since 1600.

Systematics

Troglodytidae is essentially a New World family, most diverse in Central America and north-western South America, with only one species, the Northern Wren (*Troglodytes troglodytes*), having escaped to the Old World. Everywhere, the members of this family are small, highly active, and highly vocal insectivores, perhaps seldom seen but always, it seems, dominating the soundscape.

The relationships of wrens to other avian groups have been debated over the years. In 1881, R. B. Sharpe, in the *Catalogue of the Birds in the British Museum*, classified the wrens as a subfamily within Timaliidae, which also included the dippers (Cinclidae). A few years later, the American Ornithologists' Union, in its 1889 *Check-list of North American Birds*, included the wrens as one subfamily and the mockingbirds and thrashers (Mimidae) as another within the family Troglodytidae, which it placed just after the wagtails and pipits (Motacillidae) and the dippers, and before the treecreepers (Certhiidae) and the tits and chickadees (Paridae). In 1904, R. Ridgway discussed the long-suspected probability that other songbirds most closely related to the wrens were the treecreepers and the mimids, "not far removed" from the dippers. Ridgway used the relatively high degree of cohesion between the anterior toes to show that the wrens were more like the treecreepers and parids than like the mimids, the latter, which are often referred to as "mimic-thrushes", being in turn more like the true thrushes (Turdidae). E. Mayr and D. Amadon, in 1951, placed the wrens in the family Muscicapidae, which they subdivided into the seven subfamilies Muscicapinae, Timaliinae, Sylviinae, Malurinae, Turdinae, Miminae, and Troglodytinae. They thereby suggested a relationship with, among others, the Old World flycatchers (Muscicapidae), the Old World warblers (Sylviidae) and the Australasian fairywrens (Maluridae). Another group that has often been associated with the wrens is the nuthatches (Sittidae). In a typical linear classification, Troglodytidae has been placed between the dippers and the mockingbirds and thrashers, as by Mayr and Greenway in 1960, or between the treecreepers and the dippers, as by Ridgway in 1904.

In more recent decades, the data obtained by C. G. Sibley and J. E. Ahlquist from studies involving DNA–DNA hybridization suggested a novel hypothesis for the relationships of wrens. Their results indicated that the wrens, including the highly unusual Donacobius (*Donacobius atricapilla*), were the sister-group to the gnatcatchers (*Polioptila*), the gnatwrens (*Microbates*) and the Verdin (*Auriparus flaviceps*). The first two of these groups had traditionally been located within the subfamily Polioptilini of Muscicapidae, while the Verdin had been included with the penduline tits in the family Remizidae. Furthermore, Sibley and Ahlquist suggested that the wrens, the gnatcatchers and the Verdin together formed a sister-group to the treecreepers of the genera *Certhia* and *Salpornis*, and proposed that they all be combined into a single family, Certhiidae. This family, thus expanded, was a sister-group to Sittidae, which comprises the nuthatches (*Sitta*) and the Wallcreeper (*Tichodroma muraria*). In addition, these genetic data emphasized the groups to which the wrens appeared not to be closely related: the babblers, which were moved to the family Sylviidae; the mockingbirds and thrashers, which were found to be a sister-group to the traditional starling family, Sturnidae, placed in another superfamily; and the dippers, forming yet another superfamily.

These recent ideas concerning the relationships of wrens received considerable support from a subsequent genetic analysis undertaken by F. H. Sheldon and F. B. Gill, whose results were published in 1996. It was agreed that the wrens' closest relatives are the gnatcatchers and gnatwrens, the treecreepers and the nuthatches. These authors' data also supported Sibley and Ahlquist's hypothesis that the mockingbirds and thrashers and the starlings, are sister-groups, well separated from the wrens. The Verdin, however, remained with the penduline tits.

Many of these proposed relationships were, in turn, corroborated in 2002 by F. K. Barker and colleagues, and they seem now to be generally accepted. Thus, the sister-group to the wrens is *Polioptila*, and the two together are sister to the treecreepers. Somewhat less certain is that all of these birds are the sister-group to the nuthatches. Further, all of these groups appear together to represent a sister-group to a clade that includes the dippers, the starlings, the mockingbirds and thrashers, the thrushes of the genus *Turdus*, and the Old World *Muscicapa* flycatchers.

Over the last century or so, the family itself has largely been accepted as comprising a cohesive, monophyletic group of species, once several members of the Timaliidae and the Sylviidae were removed. The one remaining problem, however, concerns the Donacobius, a puzzling marsh-nesting bird found throughout most of lowland tropical South America. Details of its anatomy, social structure and behaviour (see General Habits) have suggested that it is either a wren or a mimid, and classifications over the years have alternately placed this species in either Troglodytidae or Mimidae. One of the last public statements, in

1982, declared that the Donacobius is a wren, and not a mimid, a view based on a still unpublished study of pterylosis by M. H. Clench and colleagues. That declaration was accepted by the American Ornithologists' Union in 1983. A year later, the genetic data of Sibley and Ahlquist indicated that the Donacobius was, in fact, as genetically distant from the wrens as it was from the mockingbirds and thrashers, although, somewhat surprisingly, Sibley and Ahlquist used this equivocal information to place the Donacobius among the wrens. More recent genetic analyses by Barker, however, suggest that this species is neither a wren nor a mimid but, rather, a unique "sylvioid", a group that includes the babblers and the Old World warblers, as it clusters close to *Prinia* and *Zosterops*.

For the time being, it is deemed best to retain the Donacobius among the Troglodytidae, pending its "official" transfer to a more appropriate taxonomic position.

Less effort has been expended in trying to determine the relationships among the genera within the wren family. Some debate has centred on the genera *Hylorchilus*, *Catherpes* and *Salpinctes*. In 1904, for example, Ridgway accepted all three genera, but in 1960 Mayr and J. C. Greenway placed the Canyon Wren (*Catherpes mexicanus*) with the American Rock Wren (*Salpinctes obsoletus*) in the genus *Salpinctes*. Sumichrast's Wren (*Hylorchilus sumichrasti*) was originally described in the genus *Catherpes* back in 1871, and then moved to *Hylorchilus* in 1897, although, 90 years thereafter, J. W. Hardy and D. J. Delany argued that, on the basis on vocal similarities, it should be returned to *Catherpes*. A vocally distinct former subspecies of Sumichrast's Wren was elevated to full species status in 1993, becoming Nava's Wren (*Hylorchilus navai*), and thereby providing a small point in favour of keeping these two closely related wrens in their own separate genus, *Hylorchilus*.

A recent survey of the wrens in the genus *Troglodytes*, carried out by N. H. Rice and colleagues, is consistent with some suspected relationships, but it also offers some surprises. Most of all, it encourages further study not only of this genus but also of others within the family, especially the speciose *Thryothorus*. The genetic data obtained by Rice and co-workers indicate, not surprisingly, that the Northern House Wren (*Troglodytes aedon*), the Southern House Wren (*Troglodytes musculus*) and the Brown-throated Wren (*Troglodytes brunneicollis*) represent one major clade and, perhaps less expectedly, that the Rufous-browed Wren (*Troglodytes rufociliatus*) is a sister to this clade; in their analysis, the two house wrens are sister-taxa. An association of the same group of three species had been found in the analysis made just a few years earlier by R. T. Brumfield and A. P. Caparella, but these authors concluded that the Northern House Wren and the Brown-throated Wren were sister-taxa, a disagreement that will have to be settled through further analyses. Another major clade identified by Rice and colleagues included the Mountain (*Troglodytes solstitialis*), Tepui (*Troglodytes rufulus*) and Ochraceous Wrens (*Troglodytes ochraceus*). Surprisingly, the sister-group to these two clades was the Timberline Wren (*Thryorchilus browni*), and the Northern Wren fell well outside this grouping and was considered sufficiently different to be placed alone in a monotypic genus, *Nannus*. These various hypotheses of relationships are intriguing, but they are based on relatively limited genetic sampling, and the true relationships of these species to one another must remain a matter of debate until further study is undertaken.

The only other proposed relationships among wren genera are those implied in various linear classifications, such as the sequence that is used in the present treatment. In such linear sequences, the genera *Troglodytes* and *Thryorchilus*, for example, are placed together, implying that they are closely related, but few data exist to support one linear classification over another.

Further genetic analyses, such as those by Barker, are likely to clarify relationships among the genera. In his thorough study, Barker drew genetic samples from 20 species among the traditional Troglodytidae, and from all genera except the monotypic *Ferminia*, *Thryorchilus* and *Uropsila*, although, as implied in the preceding paragraphs, *Thryorchilus* is assumed to be closely allied to *Troglodytes*. This study also incorporated close relatives of the wrens, such as treecreepers, nuthatches, mimids and a gnatcatcher, as well as several more distantly related species.

Barker's results conflict with the traditional linear series of genera, which had hitherto been the "best guess" of a sequence listed from "primitive" genera to "derived" ones. For example, although traditional linear classifications place *Campylorhynchus* first, and even within its own subfamily, these wrens are clearly not the sister-group to all other wrens, and phylogenetic trees show them nested well within, rather than basal to, the other troglodytids. In addition, such linear series place at the end those genera that tend to be ground-oriented, including *Thryorchilus*, *Henicorhina*, *Microcerculus* and *Cyphorhinus*, but this group is polyphyletic. *Thryorchilus* belongs to a clade that also includes *Cistothorus* and *Troglodytes*, while *Microcerculus* may be part of a basal radiation within the family, and *Henicorhina* and

Throughout its chequered taxonomic career, the ***Donacobius*** *has been shifted back and forth between Mimidae and Troglodytidae. It is mimid-like in size and structure, as well as in its cup-shaped nest and its habit of flaunting itself on prominent perches. Socially and anatomically, however, it is more reminiscent of a wren, an impression bolstered by the hint of barring on its flanks, as well as its duets and mutual displays. DNA results show that the Donacobius is neither mimid nor wren, but an aberrant sylvioid related to Old World babblers and warblers.*

[*Donacobius atricapilla atricapilla*, Miranda, Mato Grosso, Brazil. Photo: Edson Endrigo]

The thirteen species of large wren in the genus Campylorhynchus *are hulking versions of their more delicate counterparts in the temperate zone. They are boisterous and conspicuous birds, frequently declaring their whereabouts with raucous vocalizations, often produced as duets or choruses. Their bills are distinctly bigger than those of most other wrens, allowing them to forage on tougher vegetable matter and well-armoured arthropods. Their legs, too, are unusually hefty and strong. These species tend to be well barred above and uniformly pale below, like this* ***Rufous-naped Wren****, but some species are either heavily spotted or barred on the underparts, or relatively uniform all over, like this race of the* ***Thrush-like Wren****. Interestingly, the two races of this species distributed further north in Amazonia are very different, with much more heavy spotting on the underparts and a weaker supercilium. Spot-breasted and plain-breasted forms approach closely in north Bolivia, without much sign of interbreeding. As these photographs suggest, several* Campylorhynchus *species are especially drawn to palms, in which they often place their nests.*

[Above: *Campylorhynchus rufinucha*, La Ensenada, Guanacaste, Costa Rica. Photo: Michael & Patricia Fogden

Below: *Campylorhynchus turdinus unicolor*, Pantanal, Mato Grosso, Brazil. Photo: Luiz Claudio Marigo]

The genus Cinnycerthia *is restricted to the luxuriant undergrowth of cloudforest and elfin forest in the high Andes. It contains four species, of which the most widespread is the* ***Rufous Wren****. In common with its congeners, its plumage is relatively uniform, and notably fluffy. Like them, it is a fairly skulking bird, which would be infrequently encountered were it not for its loud communal songs. All members of the genus are gregarious, occurring in small parties, sometimes of up to 20 individuals, and it seems likely that they breed co-operatively. Because of their secretive habits and impenetrable habitat, however, most aspects of their ecology and breeding behaviour remain to be described.*

[*Cinnycerthia unirufa unirufa*, Boyacá, Colombia. Photo: John S. Dunning/ VIREO]

Cyphorhinus are sister-taxa, which in turn are probably sister to most *Thryothorus*.

Barker also concluded that *Hylorchilus* and *Catherpes* are sister-taxa, a result consistent with arguments based on similarity of song between the Canyon Wren and Sumichrast's Wren, with the distinct songs of Nava's Wren secondarily derived. It is possible that the sister-group of these wrens is the similarly petrophilous (rock-dwelling) American Rock Wren, which would permit all four of these species to be combined in the same genus, but other data suggest that *Salpinctes*, the rock wren, may be basal to all other wrens.

One of the more controversial of Barker's hypotheses is that the Carolina Wren (*Thryothorus ludovicianus*) is a sister-taxon to Bewick's Wren (*Thryomanes bewickii*), the two being sister-taxa to the *Campylorhynchus* wrens. A discovery that *Thryothorus* is polyphyletic, with, for example, *Thryomanes* nested within it, would not be so surprising in view of the large number of species currently contained in this little-studied genus, but the removal of the Carolina Wren to so distant a location is a rather novel hypothesis.

Clearly, these genetic data provide hypotheses for relationships that are worthy of further testing. Moreover, and above all, it is important to realize that the above-mentioned ideas are largely hypothetical, representing what are currently the best guesses based on limited data. It may be hoped that further research work will significantly clarify these relationships.

Research on vocalizations (see Voice) has suggested that recognition of additional species within the Troglodytidae may be warranted. The Marsh Wren (*Cistothorus palustris*), for example, consists of highly differentiated eastern and western populations in North America, as also does the Northern Wren, the Old World population of which may represent a further one or more species. As revealed by D. E. Kroodsma and co-workers, the Sedge Wren (*Cistothorus platensis*), too, exhibits substantial variation in plumage, vocal behaviour and style of song development, and habitat selection (see Habitat) within its large range, which extends from North America down through South America, and it is almost certain that more than one species is involved.

So far as the Marsh Wren is concerned, not only do the eastern and western populations differ in many perceivable ways, many of these differences being based on genetic details, but they also occur together in the same marshes in central Saskatchewan, where interbreeding between them is limited. Eastern and western males defend territories against one another, and analysis of mitochondrial DNA in the population largely reveals two types of wren, one eastern and one western, with little interbreeding. If they interbred freely, then one would expect a genetically homogeneous population of Marsh Wrens in this transition zone, but the two types of wren signal that they themselves distinguish each other as two species.

Another currently recognized species in which songs provide clues to past evolutionary history is the Northern Wren. In North America alone there are two strikingly different singers, again separated along east-west lines. Eastern and boreal males occur from Nova Scotia south to North Carolina, and west at least to Michigan and Minnesota, while western males have been documented from British Columbia south to California; it is not known where these two types of singer meet, if they do at all. In addition, the songs of Northern Wrens in the Old World are different from those in North America.

On the basis of singing behaviour alone, the emerging hypothesis is that the western Nearctic and eastern Nearctic Northern Wrens diverged first, followed by a divergence of eastern Nearctic wrens and Palearctic wrens. This hypothesis is now supported and enhanced by the work of S. V. Drovetski and co-workers, who analyzed the genomic DNA from 97 wrens from throughout North America and Eurasia. These authors estimate that the western Nearctic wren diverged from the Holarctic ancestor roughly 1·6 million years ago, and that the Holarctic ancestor diverged into eastern Nearctic wrens and Palearctic wrens about one million years ago. Within Eurasia, four more groups are now identified, having originated as follows: eastern and western Palearctic wrens diverged about 0·83 million years ago, and then each respective population diverged one more time, between 0·67 million and 0·54 million years ago. The proliferation of these groups thus occurred during the early and middle Pleistocene glaciations. How many species occur in this Holarctic distribution depends on one's definition of a species, but the best guess is that at least three should be recognized, two in North America and one in Eurasia, and that perhaps each of the four clades in Eurasia could also be recognized as a full species.

Very recently, differences in songs among supposed Grey-breasted Wood-wrens (*Henicorhina leucophrys*) were used in

helping to identify a new species in the western Andes of Colombia. This new species, the Munchique Wood-wren (*Henicorhina negreti*), is found at high elevations on the Pacific slope, in the extremely wet, stunted cloudforest that is almost continuously shrouded in fog. In the taller forest at lower elevations on the west slope, it is replaced abruptly by the Grey-breasted Wood-wren of the subspecies *brunneiceps*, and on the drier east slope by the nominate race of the latter. Compared with the adjacent populations of Grey-breasted Wood-wrens, the Munchique Wood-wren has a more distinctly barred abdomen, a darker juvenile plumage, relatively longer tarsi and a proportionately shorter tail.

It is likely that, were it not for the fact that these wrens learn their songs and therefore have geographically differentiated song dialects (see Voice), far more species of wren would be recognized. New species are rather routinely described for various suboscines, such as the tyrant-flycatchers (Tyrannidae), the songs of which are not learnt and therefore represent a vocal signature for the genotype of the bird; in the case of *Thamnophilus punctatus*, another suboscine that presumably does not learn its songs, M. L. Isler and colleagues have suggested that what was previously considered a single species, the Slaty Antshrike, in fact consists of six or more species. Most species of songbird, however, offer no such obvious vocal clue as to how their populations are differentiated, and the conservative approach is therefore to keep the highly differentiated Northern Wrens in one species. The same reservations apply to the Marsh Wrens and the Sedge Wrens and, no doubt, to other troglodytids, too. Nevertheless, future research will surely lead to the elevation to species rank of a good number of these behaviourally and vocally distinctive taxa. Indeed, very recently published work suggests that the globally threatened Apolinar's Wren (*Cistothorus apolinari*) of Colombia may, in fact, consist of two species, differentiated not only morphologically and by habitat preference but also by song. One form, currently described as the subspecies *hernandezi*, not only has a different song from the nominate race, but additionally, and in contrast to the latter, indulges in communal group song, both antiphonal and in duet.

The genus Cistothorus, *as currently delimited, contains four species. Two of these have enormous ranges encompassing such vocal and morphological variation that they might require subdivision at the species level. All* Cistothorus *wrens are diminutive, dainty birds. Their plumage is dull, usually with strong barring or streaking on the upperparts; their tails are small and habitually cocked. They are adapted to a life in tall reeds, sedges or grasses, and, since this microhabitat tends to lack horizontal perches, they have perfected the knack of clasping adjacent vertical stems with legs akimbo, as this* **Marsh Wren** *demonstrates. In morphology and some aspects of behaviour they resemble sylvioid warblers in the genus* Cisticola, *a genus that occupies similar types of habitat in the Old World.*

[*Cistothorus palustris*, Long Island, New York, USA. Photo: Tom Vezo]

Morphological Aspects

Wrens are generally small birds. In fact, in the New World, only some of the hummingbirds (Trochilidae), kinglets (Regulidae), gnatcatchers and parulid warblers are lighter in weight than the smallest wrens. The largest member of the family, the Giant Wren (*Campylorhynchus chiapensis*) of southern Mexico, is a giant only in comparison with its relatives. With a length of 22 cm and weighing up to 57 g, it is about the size of a smallish thrush. At the opposite extreme, the Sedge Wren is about 9 cm long, and the Northern Wren weighs as little as 6 g. Birds' weights do, of course, vary greatly according to the condition of the individual.

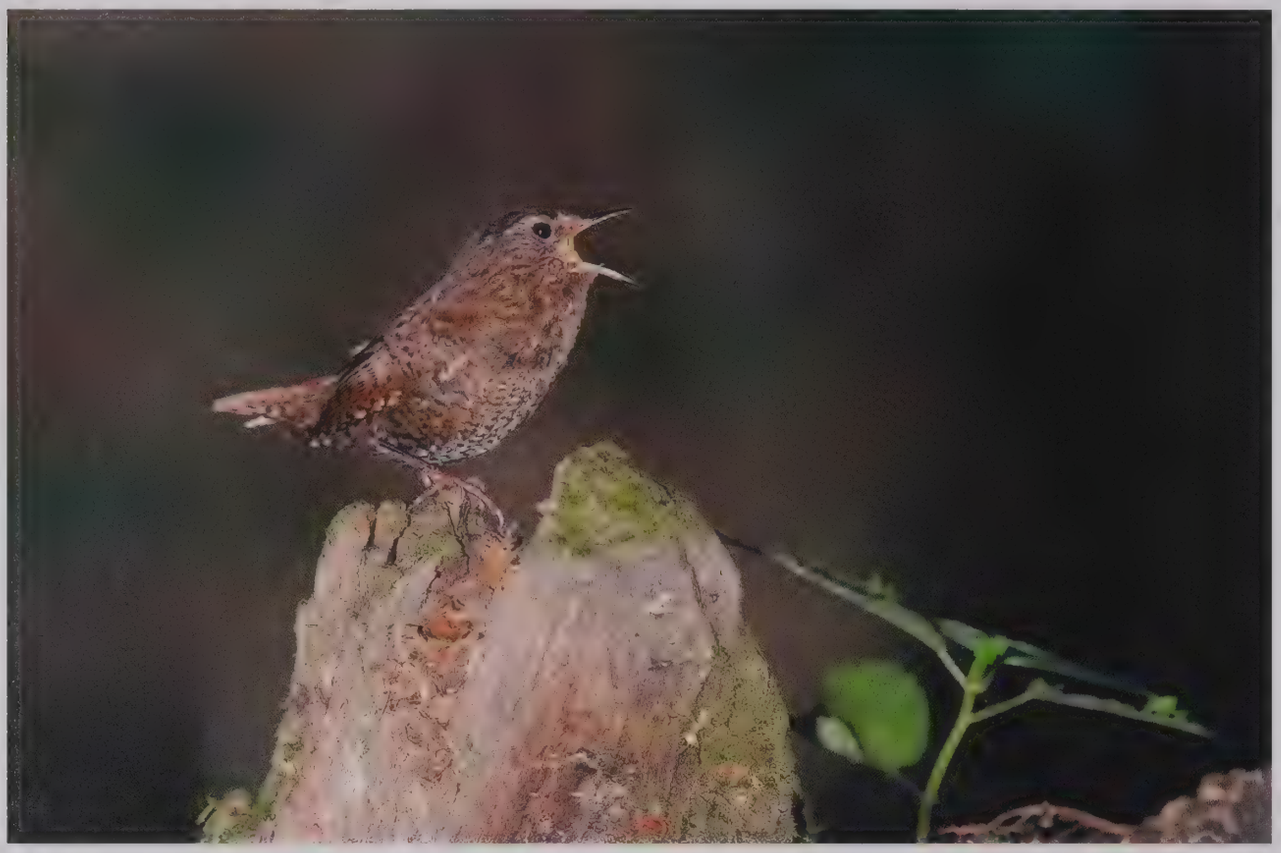
None of the troglodytids is brightly coloured in plumage, and reds, bright yellows, greens and blues are entirely absent in the family. Instead, all wrens are various shades of brown or rufous, often with areas of black and white. Despite this modesty of coloration, some species, particularly in the genus *Thryothorus*, have very attractive patterns of plumage, especially around the head and chest. One feature characteristic of virtually all wrens, and largely absent in most other passerines, is the predominance of barring on both the remiges and the rectrices. This usually takes the form of narrow alternating sections of blackish or dark brown and lighter brown on the outer webs of the primaries and secondaries; the tertials and the rectrices are typically barred on both webs. In a few species, especially the ground-dwelling wrens inhabiting thick, wet, dark tropical forest, the barring is very muted or almost absent, but, on close examination, traces are still discernible, suggesting that the ancestral wrens were barred. The plumage of wrens tends to be soft and rather fluffy.

Most members of the family have twelve rectrices, although the Timberline Wren, the two members of the genus *Hylorchilus* and the enigmatic Zapata Wren (*Ferminia cerverai*) have only ten. The rectrices tend to be rounded, with the outer ones often significantly shorter than the central ones. The tail length differs widely among genera. In the genus *Odontorchilus*, containing two South American species that appear to be converging evolutionarily with the unrelated *Polioptila* gnatcatchers, birds of similar habits and lifestyle, the tail accounts for almost half of the bird's total length. In the cactus wren group, the genus *Campylorhynchus*, it is almost as long in relative terms. More usually, however, the tail is shorter, and in some genera much shorter. The Northern Wren, for example, has a tail that makes up only 25–28% of the total body length. The most extreme instance, however, is that of the ground-dwelling *Microcerculus* wrens, which appear almost tailless in the field, the rectrices being typically no more than one-fifth of the total length of the bird. This is a further example of convergent evolution, in this case with the small *Grallaricula* antpittas in the antbird family (Formicariidae), the habitat and habits of which they share.

All wrens have ten primaries. Although the tenth primary, the outermost, may be much reduced, it is always present. They have relatively short and rounded wings, with usually the middle primaries, P5 to P7, the longest. The primaries of some species, when spread out, seem almost to describe an arc of a circle. The wing shape has clearly evolved for a lifestyle centred around short flights in dense vegetation, rather than for aerodynamic efficiency. Notwithstanding this, some species, notably the Northern Wren and the Northern House Wren, undertake long migratory journeys (see Movements).

There is no sexual dimorphism in wren plumages. Males and females are essentially identical in virtually all cases. In addition, there is frequently little distinction between adults and young. In some members of the genus *Campylorhynchus* and a few of the genus *Thryothorus*, juveniles do differ markedly in plumage from the adults of the species, but in most genera the distinctions between adult and young plumages tend to be minor and subtle.

Although the troglodytid bill tends to be long and often substantially decurved, considerable variation exists within the family, the bill morphology being dependent on lifestyle and food preferences. Some genera, such as *Salpinctes* and *Troglodytes*, have a very fine bill. Members of *Catherpes* and *Hylorchilus*, two genera specializing in foraging on rock faces, have a bill that is especially fine and decurved; they also exhibit several other specific modifications, including a flattened skull, for ob-



The most diverse genus in the family, Thryothorus, *contains 29 species, all of which are relatively uniform in size and structure. The two forms shown here, the* ***Bay Wren*** *of the northern Andes and southern Central America, and the* ***Riverside Wren*** *of Central America, are classic examples. Their plumage, while not particularly colourful, is nonetheless strikingly patterned, chiefly black, white and chestnut, with patches of strong barring. Like many congeners, these species have well marked faces with distinct moustachial streaks. As with all wrens, sexual dimorphism is very slight or absent. These two forms are sometimes treated as conspecifics, and they share many features, including strong barring on the underparts. Interestingly, the barring in the Bay Wren decreases northwards, such that the race overlapping marginally with the Riverside Wren is virtually plain below. Both species inhabit dense, low vegetation, with the latter species being particularly fond of tangled watercourses, swampy woodland and gulleys, and the former being common in humid second growth and forest edges. Throughout the genus, there is a tendency to occupy dense habitats such as regrowth, watersides, tall scrub, vine tangles or bamboo.*

The most widespread member of the family, and its sole representative in the Old World, is the ***Northern Wren****. It is a common bird of varied habitats, and some of its populations migrate southward to avoid severe weather. Its propensity to disperse across continents, and reach remote islands, has led to the description of 44 races, making it one of the world's most polytypic species. Some races are probably invalid, but others may form cryptic species. Recent DNA analysis supports this latter idea, identifying several distinct clades, and placing these at such a distance from congeners that they may warrant separation in their own genus,* Nannus.

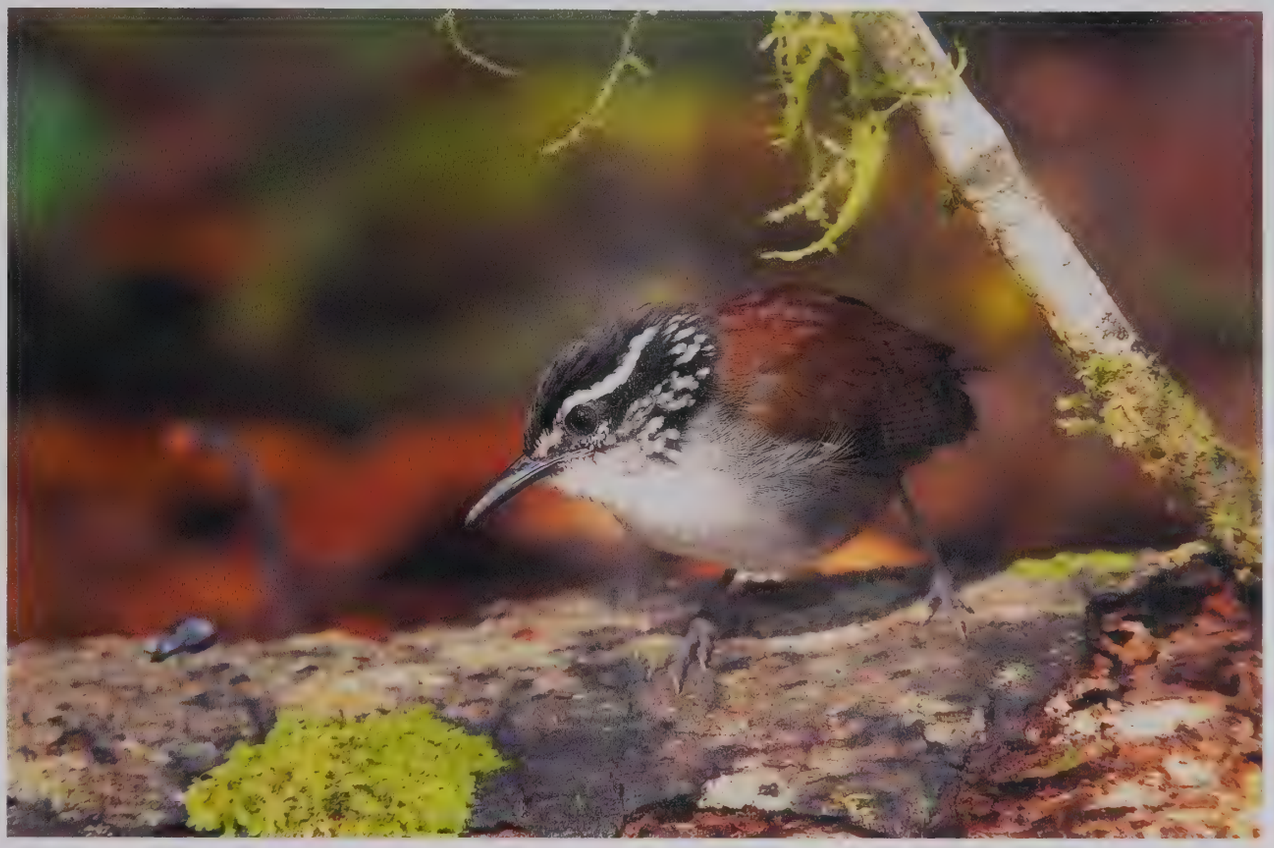
[*Troglodytes troglodytes*, Totori, Japan. Photo: Hirozo Maki]

taining prey from crevices in rocks. The two *Odontorchilus* wrens have a very fine bill with a peculiar little notch, of unknown function, two-thirds of the way down the cutting edge of the upper mandible. In the genus *Campylorhynchus*, several species of which include major quantities of hard vegetable matter as well as large, well-armoured arthropods in the diet, the bill may be quite heavy and powerful. Some members of this genus, such as the Band-backed Wren (*Campylorhynchus zonatus*), appear to specialize in probing for prey in epiphytes and, consequently, have a longer, finer bill.

The most peculiar bills in the family are found in the ground-dwelling genus *Cyphorhinus*. The bill is quite stout and powerful, with a curious upper mandible compressed into a sharp, wedge-shaped ridge along the upper surface, giving an odd "Roman-nose" appearance. The precise function of this character is not known. Another unique feature of this genus, shared with many other, totally unrelated South American suboscine passerines, is a patch of bare, coloured skin around the eye.

Rictal bristles are present in some troglodytid genera, such as *Campylorhynchus*, *Henicorhina* and *Uropsila*. In some cases, as in the three *Cyphorhinus* species and some *Thryothorus* wrens, they may be very short or unobvious, but in many genera, including *Troglodytes*, *Cistothorus*, *Salpinctes*, *Catherpes*, *Hylorchilus* and *Microcerculus*, rictal bristles are obsolete or absent.

As may be expected for a group of birds that spends most of its time in foraging near the ground, the legs and feet of wrens tend to be substantial in proportion to the small size of the birds, and in some cases they are rather heavy and powerful, with large claws. In contrast, the legs and feet of the canopy-dwelling *Odontorchilus* wrens are quite fine and dainty.



Finally, one species currently included in Troglodytidae, but almost certainly belonging elsewhere (see Systematics), differs in several respects from the "true" wrens. In general external appearance, the Donacobius resembles the mimids more than it does any wren. The wings are powerful and rather rounded, with very short primaries, and the tail is long and very graduated, almost fan-shaped in fact, with the outer rectrices much shorter than the central ones. The legs are long and very robust, and the bill is long and sturdy, with rictal bristles present but not very obvious. A unique feature of the Donacobius is the presence of a patch of bare yellow to orange skin on each side of the neck, not usually visible in the field, but distended during display.

Information on moult sequences is generally lacking for the great majority of wren species, namely those occurring in Central and South America; this would be a very fertile and productive area of study. More data are available for those species found in North America and Europe. Typically, the first moult that a bird undergoes, that in which it renews the original feathers that

The ***Timberline Wren*** *is currently placed in a monotypic genus,* Thryorchilus*, although it seems clear that this is only narrowly differentiated from either* Henicorhina *or* Troglodytes*. It resembles the former in song and nest design, but DNA analysis places it closer to the latter. In terms of plumage it appears to be somewhat intermediate. It is restricted to the highlands of Costa Rica and Panama, where it inhabits the forest-*páramo *ecotone, including stunted bamboo thickets and isolated patches of bushes in sheltered depressions at high altitude.*

[*Thryorchilus browni*, Cerro de la Muerte, Costa Rica. Photo: Marco Saborío]

The genus Henicorhina *comprises a quartet of similar species, all of which have striking head patterns. They are dinky, vibrant, but furtive birds of the humid understorey, difficult to see well, but easily detected by voice. Indeed, the scratchy alarm notes of individuals disturbed low down at roadsides and pathsides, and the loud, distinctive outpourings of duetting pairs, are so often heard in appropriate habitat that wood-wrens seem to be amongst the commonest birds present. Three of the four species inhabit the montane zone, but the* ***White-breasted Wood-wren*** *occurs in lowland evergreen forest, even at sea-level.*

[*Henicorhina leucosticta leucosticta*, Iwokrama, Guyana. Photo: Doug Wechsler/ VIREO]

it grew as a nestling, occurs within a few months of fledging and is incomplete. The body feathers are replaced, but usually only some flight-feathers are renewed. The extent of this moult is variable, not only among species but also among different individuals of a single species. In Bewick's Wren, for example, some individuals replace no tail feathers at all in the first moult and some replace all of them, but about two-thirds of individuals replace only some of the rectrices. The more southerly races of this species tend to renew more feathers than do the northern ones. Among wrens, the replacement of the remiges in this first moult is frequently incomplete and often eccentric; rather than starting at the outermost or innermost primary or secondary and proceeding inwards or outwards in sequence, it begins several feathers in, thereby producing a mixture of old and new feathers in patches. In subsequent years, the prebasic moult of all North American wrens is complete.

Most wrens do not undergo a pre-breeding moult, a spring moult that in some families, such as the parulid warblers, results in a characteristic bright breeding plumage. The exceptions to this are the *Cistothorus* wrens, which have a partial moult before breeding. In the case of the Sedge Wren, this results in the replacement of a variable number of greater wing-coverts, tertials and rectrices, but not, apparently, of the primaries or secondaries. A similar pattern is found in the Marsh Wren.

Habitat

As a family, the wrens have been highly successful in adapting to a very wide range of habitats, occupying a variety of ecological niches which, in continents other than the Americas, are taken up by several different avian families.

The largest wren genus is *Thryothorus*, which has the greatest density of species occurring in southern Central America and north-western South America. Within this one genus there is a considerable diversity of habitat requirements, as may be expected since its members are found all the way from southern Canada south to Bolivia, but, in broad terms, all require areas of trees with substantial undergrowth. Some species, such as the Banded Wren (*Thryothorus pleurostictus*) and the Happy Wren (*Thryothorus felix*), are found in dry forest and bushland. The majority, however, favour more humid habitat, while some, such as the Bay (*Thryothorus nigricapillus*), Riverside (*Thryothorus semibadius*) and Coraya Wrens (*Thryothorus coraya*), show a preference for the vicinities of actual watercourses. *Thryothorus* wrens tend to live more at forest edge than in deep unbroken forest, doubtless owing to the presence of denser undergrowth in areas exposed to sunlight. Consequently, several members of the genus, such as the Plain Wren (*Thryothorus modestus*), have thrived in somewhat disturbed habitat where climax forest has been partially cut over or allowed to regenerate. Sometimes, there is an apparent division of habitat utilization between two species. In Colombia, for example, the Bay Wren tends to occur at forest edge, being replaced in the deeper interior by the Sooty-headed Wren (*Thryothorus spadix*), while in western Mexico a frequently sympatric pair of species, the Happy and Sinaloa Wrens (*Thryothorus sinaloa*), may have slightly different requirements, the latter being able to tolerate sparser woodland. Some species are largely associated with specific vegetation; among these are the Plain-tailed (*Thryothorus euophrys*) and Inca Wrens (*Thryothorus eisenmanni*), which usually occur in areas with *Chusquea* bamboo. Typically, the Plain-tailed Wren is the first colonist of highly disturbed land, such as landslips in the precipitous Andes, a habitat which is mimicked by spoil slopes from road construction. In Bolivia, Moustached Wrens (*Thryothorus genibarbis*) are often found in *Bambusa* bamboo, whereas *Heliconia* thickets in Costa Rica are the preferred habitat of both the Bay Wren and the Black-bellied Wren (*Thryothorus fasciatoventris*). Because of their preference for secondary growth, many species in this genus have survived, or even prospered, with man-made habitat change. The Stripe-breasted Wren (*Thryothorus thoracicus*) in Costa Rica has adapted well to cacao plantations at low altitudes and to shade coffee plantations at higher elevations.

The only temperate-zone *Thryothorus*, the Carolina Wren, which, according to recent studies, may not really belong in this genus (see Systematics), lives largely in highly modified habitats, such as abandoned farmland and well-vegetated suburbs. Its natural habitats included oak (*Quercus*) hardwoods and mixed woodlands of oak and pine (*Pinus*) having a variety of other tree species, such as hickory (*Carya*) and cottonwood (*Populus*). The two insular subspecies of the Carolina Wren,

burleighi and *nesophilus*, are found in slash pine (*Pinus elliottii*) and palmetto stands.

In contrast to *Thryothorus*, the highly terrestrial members of the genus *Microcerculus* are much more restricted to undisturbed virgin lowland humid forest, and do not take at all well to habitat modification. The opening-up of the forest canopy induces lower-level growth unsuitable for these wrens. The four *Microcerculus* species are generally found at lower altitude, usually from sea-level to 1500 m, although the Flutist Wren (*Microcerculus ustulatus*) is a more montane species, being encountered at up to 2100 m on tepui summits in Venezuela.

Four troglodytids are closely associated with rocks. Ironically, the American Rock Wren exhibits the least morphological adaptation to this habitat, not differing greatly, in external form, from members of the genus *Thryothorus*. It occurs in habitats that range from fairly dry to very arid, and is usually to be seen in barren rocky places, including scree slopes, boulder falls and areas of bare, sunbaked mud. It will take advantage of mining and quarrying activities, occurring in areas of spoil and tailings, as well as colonizing areas temporarily made bare by clear-cut forestry. As a vagrant, with records over much of eastern North America, the American Rock Wren is often found in artificial situations which resemble its preferred habitat, such as concrete structures.

The three other rock-dwelling species are truly petrophilous, being associated with rock faces and showing major morphological adaptations to exploit this niche. Canyon Wrens are, indeed, associated exclusively with canyons, rock faces and, in California, sea-cliffs. Given this requirement, this species is quite catholic in its habitat choice, occurring in cool uplands at up to 3000 m, in dry oak-wood canyons or, in southern Mexico, in humid areas as low as 200 m. In contrast, the two members of the genus *Hylorchilus* are very specific in their habitat requirements and, as a consequence, have highly restricted geographical ranges. Both Sumichrast's and Nava's Wrens are found solely in forested karst limestone outcrops. The former can tolerate some slight changes to the forest cover, including the planting of shade coffee, since this does not impinge on the rock faces where it feeds, but for Nava's Wren any disturbance seems to be unacceptable.

Some wrens have radiated into marshland and swamp, exploiting niches that in the Old World are occupied mainly by various genera of the warbler families Cisticolidae and Sylviidae. The four species of *Cistothorus* have all specialized in wet, mostly monocotyledonous habitat of varying types. The Marsh Wren, as a breeding species, is usually confined to vegetation over standing waters, normally cat-tails (*Typha*), bulrushes (*Scirpus*) and reeds (*Phragmites*) in northern freshwater marshes, and cordgrass (*Spartina*) and sedges (*Juncus*) in brackish coastal marshes. Northern interior populations spend the winter in other fresh and brackish marshes, in the latter case frequently co-existing with resident, non-migrating individuals of the species. The Sedge Wren, on the other hand, in North America, usually avoids areas of standing water, preferring damp sedgy meadows, often with small bushes, although it may occur also in weedy rice paddies in the southern USA. In its extensive South American range, however, this wren's habitat varies enormously, from cold *páramo* and *puna* in the Andes to open grassy savanna in Venezuela, dry *cerrado* grassland in Brazil, wet alder (*Alnus*) forest and bamboo bogs in Colombia, the borders of tidal marshes in Argentina and tussac grass (*Parodiochloa flabellata*) in the Falklands. The great diversity of habitat occupancy, along with vocal differences, gives support to the argument for the separation of South American forms taxonomically from those in North and Central America (see Systematics).

The two subspecies of Apolinar's Wren differ markedly in their habitat requirements. The nominate race lives in similar lake-edge habitat to that occupied by the Marsh Wren, namely reedbeds dominated by cat-tails and bulrushes, albeit at altitudes of 2500 m to slightly over 3000 m. In contrast, the race *hernandezi* occurs higher up, between 3800 m and 3900 m, in boggy *páramo* with low shrubs and the hirsute leafy ground plant *Espeletia grandiflora*, known locally as "*frailejón*".

Restricted to a very small area of Cuba, and one possessing a unique habitat, the enigmatic Zapata Wren has very specific habitat requirements. These are savanna-type swamp with sawgrass (*Cladium jamaicense*) and rushes, and with some bushes which can be used as songposts. The water level in the Zapata Swamp is quite variable, but the Zapata Wren tends to live in drier areas, which allow it to forage on the ground.

Another wetland-dwelling species currently included within the family is the Donacobius. This relatively large bird, of uncertain taxonomic affiliation (see Systematics), inhabits brushy veg-

Nightingale-wrens are the most terrestrial members of the family, and they often walk with mincing gait on the forest floor, especially amongst exposed roots or along fallen logs. Their fondness for dark, humid understorey means they tend to disappear from disturbed woodland. Based on consistent differences in voice, the original "Nightingale Wren" has been split into two species. Even so, the ***Southern Nightingale-wren*** *presents a difficult taxonomic puzzle as birds on either side of the Amazon differ vocally and genetically, but not morphologically, whereas birds on either side of the northern Andes differ in plumage but not in voice.*

[*Microcerculus marginatus marginatus*,
Serra dos Carajás,
Pará, Brazil.
Photo: Luiz Claudio Marigo]

The most unusual bills in the family are found in the genus Cyphorhinus. *The culmen is compressed basally to form a narrow ridge with a slightly humped effect. This "Roman nose" is unique amongst wrens, as is the presence of bare skin around the eyes. No function has been satisfactorily proposed for either of these features but they seem likely to relate to a ground-dwelling lifestyle, and possibly a slight inclination to forage at swarms of army ants. The genus contains a trio of species, of which only the* ***Chestnut-breasted Wren*** *shuns the lowlands and lives exclusively in the Andean submontane zone. Here it keeps low in dense undergrowth, and is difficult to see.*

[*Cyphorhinus thoracicus*. Photo: John S. Dunning/ Ardea]

etation along riversides and the overgrown margins of water impoundments in the lowlands of tropical South America. Although it sometimes forages away from such areas, it invariably nests only in marshy vegetation.

In North America, the Northern Wren occurs in such boreal-type habitats as moist coniferous forest with extensive underbrush, but also in mixed hardwood-conifer stands. In addition, it is also found, in an extensive range of subspecies, on treeless or nearly treeless oceanic islands in the Aleutian chain. The same species, having invaded the Old World via the Bering bridge, has, in the absence of competition from other troglodytids, expanded into a catholic range of habitats in three continents. In western Europe, the most favourable habitat is damp woodland, either deciduous or mixed, with extensive undergrowth, but the species is also common in suburban gardens, in moorland scrub and on oceanic islands with scanty vegetation. In other parts of its Old World range it may be more restricted, as, for example, in the Atlas Mountains of Morocco, where it is largely confined to stream valleys and forests at altitudes between 1200 m and 1800 m; in Nepal, it is found at elevations of 2500 m to 4800 m.

In the Americas, the "house wren superspecies" (see Systematics) occupies many of the ecological niches exploited by the Northern Wren in the Palearctic Region, especially highly modified landscapes such as wood edges, well-vegetated suburban areas and regenerating abandoned farmland. The Southern House Wren, being unable to tolerate unbroken forest, does not occur over much of Amazonia, but it rapidly colonizes suitable clearings when they appear. Over the remainder of the continent, this species occupies a remarkable range of habitats, from quite highly urbanized situations to montane areas and arid regions with dry bushland, from sea-level up to 4000 m. In the Falkland Islands, the isolated Cobb's Wren (*Troglodytes cobbi*), obviously closely related to the mainland house wrens, has adapted to a harsh environment consisting of moorland and tussac grass; unlike any other troglodytid species, it has learnt to forage among seaweed on tidal shores, and it does in fact occur at higher densities in places where territories actually abut the sea. In contrast to the house wrens, the group of montane *Troglodytes* wrens occurring from southern Mexico southwards to northern Argentina is much more specific in its habitat requirements. This group, comprising the Mountain, Santa Marta (*Troglodytes monticola*), Ochraceous, Rufous-browed and Tepui Wrens, is usually restricted to various forest types, always in uplands and often at considerable altitude, in the case of the Santa Marta Wren up to 4800 m. Similar habitat, that of bamboo thickets in *páramo* and sub-*páramo*, is required by the appropriately named Timberline Wren.

Bewick's Wren often co-exists with, and perhaps suffers from competition from, the Northern House Wren in eastern North America. Here, it has benefited from European colonization, as semi-open habitat was created by the clearing of climax forest for farmland. In western North America, it occupies a very wide variety of habitats, including *chaparral* brushland, cactus-dominated scrub and riparian woodland, some of which are unsuitable for house wrens.

Forming a group of four closely related species, the wood-wrens are found in forested land from Mexico south to Bolivia. Notwithstanding their great morphological and behavioural similarities, they have developed distinct habitat requirements and only rarely occur together. The White-breasted Wood-wren (*Henicorhina leucosticta*) inhabits wet lowland broadleaf forest, mostly below 1500 m, whereas the Grey-breasted Wood-wren lives in humid mountain forest, usually above 1500 m, and extending up to *páramo* edge at 3800 m in Costa Rica. The Bar-winged Wood-wren (*Henicorhina leucoptera*) is found very specifically in a few high-altitude forests, usually very impoverished, with stunted trees and heavy ericaceous undergrowth, on leached quartzite soil, a habitat which it sometimes shares with the previous species. The fourth species, only recently distinguished as a separate species from the Grey-breasted Wood-wren (see Systematics), is the Munchique Wood-wren, which has hitherto been recorded at 2250–2640 m in extremely wet, stunted cloudforest on the Pacific slope of the Colombian Andes. It is ecologically sharply separated from the two neighbouring subspecies of the Grey-breasted Wood-wren, one of which lives at lower elevations on the same slope, while the other occurs on the drier eastern slopes of the Munchique massif. Although all three taxa can be seen within a distance of 1 km in some areas, no two of them have ever been found together.

The genus *Cyphorhinus* contains three species which, in appearance and habits, seem to be evolving convergently with the terrestrial antbirds, the habitat of which they frequently share.

Bathing in wrens is an obscure subject that receives little attention in literature, but it does seem to occur in species, such as the ***Carolina Wren****, that inhabit relatively humid regions. Desert wrens, by contrast, spend much of their lives without water, and even when it is available they apparently make use of it infrequently. Instead, they are enthusiastic dust-bathers, this habit having been reported in a wide variety of wrens and in a range of moist and arid habitats.*

[*Thryothorus ludovicianus*, High Island, Texas, USA. Photo: Rob Curtis/ The Early Birder]

All occur in wet forest with extensive undergrowth. One, the Chestnut-breasted Wren (*Cyphorhinus thoracicus*), is a montane form, found in wet upland forest and cloudforest, often with a luxuriant growth of mosses and epiphytes. The other two, the Song Wren (*Cyphorhinus phaeocephalus*) and the Musician Wren (*Cyphorhinus aradus*), are lowland species, inhabiting humid forest and second growth with an extensive understorey, or *várzea*, from sea-level to 1000 m.

In the Andes, from Colombia southwards to northern Bolivia, the four species in the genus *Cinnycerthia* are very similar to one another not only in appearance but also in habitat requirements. All are found in wet mountain forest with a luxuriant understorey, usually between 1500 m and 3500 m, and often in association with thickets of *Chusquea* bamboo or in areas with extensive wet mosses growing epiphytically on tree boles and low branches. This genus as a whole does not tolerate extensive habitat modification.

The two *Odontorchilus* species are unusual among wrens in that they feed mostly in the forest canopy. As a consequence, both are restricted to areas of suitable forest, usually those which have not undergone much human modification. The Tooth-billed Wren (*Odontorchilus cinereus*) is a lowland species, found in tropical Amazonian forest below 500 m, while the Grey-mantled Wren (*Odontorchilus branickii*) lives in humid montane upper-tropical and subtropical forest of the Andes from Colombia south to Bolivia. The latter lives at 1400–2200 m on the Amazonian drainage, but can be observed as low down as 800 m on the Pacific slope.

The large wrens in the genus *Campylorhynchus* have succeeded in colonizing some habitats which are denied to smaller members of the family. No other troglodytid genus has been so successful in arid areas of Mexico and the south-western USA, although several other small insectivorous birds from different families, such as the Verdin and the gnatcatchers, have managed to exploit very arid landscapes. The Cactus Wren (*Campylorhynchus brunneicapillus*) occurs in a number of different types of desert, although always with the proviso that there be spiny cacti, such as prickly-pear (*Opuntia*) or various species of cholla (*Opuntia*), in which to nest. In the absence of such cacti, as, for example, in uniform stands of mesquite bushes (*Prosopis*), the Cactus Wren is generally absent. Cactus Wrens adapt quite well, albeit at a lower density, to highly degraded and disturbed habitats, including such areas as gravel pits and junkyards, so long as sufficient suitable vegetation remains for foraging and nesting.

Several other members of the genus, such as the Fasciated (*Campylorhynchus fasciatus*) and Boucard's Wrens (*Campylorhynchus jocosus*), also specialize in semi-arid habitats, although none has been able to exploit true desert to the same degree as has the Cactus Wren. A number of species, such as the Grey-barred Wren (*Campylorhynchus megalopterus*), are found at higher altitudes in Middle America, when their habitats include pine and pine-oak forest. The Rufous-naped Wren (*Campylorhynchus rufinucha*) occurs mostly on the drier Pacific slope, where it is frequently associated with bull's-horn acacias (*Acacia collinsii* and *A. cornigera*). These trees are host to aggressive symbiotic ants of the genus *Pseudomyrmex*, which provide the nesting wrens with vicarious protection from predators such as white-faced capuchin monkeys (*Cebus capucinus*) (see Breeding). In other parts of Middle and South America, species of *Campylorhynchus* have adapted to much more humid forest, where they may specialize in foraging in epiphytes, plant forms that are generally absent in arid areas. Troglodytids occurring in such humid biotopes include the White-headed Wren (*Campylorhynchus albobrunneus*) and the Band-backed Wren, although, in areas where the two are sympatric, the former tends to be found in the wetter habitats. The Band-backed Wren is, in fact, a very adaptable species, occurring in a wider range of habitats than does any other member of the genus; it inhabits humid forest at sea-level in Mexico and Guatemala, palm groves, wet epiphytic and drier pure oak forest at intermediate altitude and, at 3000 m, cypress (*Cupressus*) forest. It can also tolerate substantially disturbed habitat, such as forest clearings and clumps of trees bordering farmland.

General Habits

Among the different groups of wrens there is a considerable diversity of habits. The great majority of the species are found in forest of various types or at forest edges, mostly in tropical areas. These are complex biotopes, with several different ecological niches, the exploitation of which by different troglodytid

Although most wrens are birds of shady nooks, they are not averse to soaking up some sun. This ***Northern Wren*** *has chosen a sunlit tree stump on which to splay its wings and erect the plumage of its upperparts, from nape to rump. The lower photograph shows a* ***Southern House Wren****, similarly prostrated, although in this instance it is sunning itself on level ground. This type of spread-eagled, fluffed-up posture is typical of sunbathing wrens, as well as other passerines, and presumably maximizes the surface area of plumage directly struck by sunlight.*

*This **Banded Wren** is roosting in a low bush, with its body feathers fluffed up and its head tucked into its scapulars for insulation. While this is a common nocturnal posture for wrens, many species prefer to roost inside cavities, or even inside "roosting nests" built specially for this purpose. Cavity roosting is probably commonest in the temperate zone, where wrens maintain body temperatures on frozen winter nights by roosting communally, with scores of individuals sometimes sleeping inside tree holes or nestboxes.*

genera has given rise to quite diverse behavioural patterns. Several groups of wrens keep on or close to the ground. The most highly terrestrial are the *Microcerculus* nightingale-wrens, which spend most of their time on the forest floor, walking with a mincing gait, constantly teetering the tail in the manner of an Ovenbird (*Seiurus aurocapilla*). Nightingale-wrens fly only infrequently, and they are rarely caught in mist-nets, as they simply walk underneath them. In both behaviour and external appearance they are obviously converging evolutionarily with a group of small formicariids, the antpittas, the habitat of which they share. Almost equally terrestrial are the *Cyphorinus* wrens, which forage on or near the forest floor and which, again, share many morphological characteristics with the unrelated terrestrial antbirds.

Wrens enjoy a reputation for furtiveness. Indeed, the majority of species are relatively difficult to observe, as they readily disappear into dense vegetation at the slightest disturbance. The *Microcerculus* wrens have developed this behaviour to a fine art and can be extraordinarily difficult to see for even the most patient watcher. By contrast, the large wrens of the genus *Campylorhynchus* are raucous and boisterous extroverts, frequently singing from exposed posts, in suburban areas even from the tops of lampposts, and generally acting in a rambunctious and uninhibited fashion, travelling in noisy groups that are very easy to locate. In terms of general behaviour, however, most members of the family fall somewhere in between these two extremes. Species such as Sumichrast's Wren can be very secretive, but frequently are overcome by a sense of curiosity that impels them to emerge in order to sneak a look at the intruder. Without their loud and persistent songs, many wren species, especially those inhabiting dense tropical forest, would go largely undetected.

The wrens living in temperate climates tend to be solitary or to occur in pairs, the young associating with their parents for only a limited period of time. Among tropical genera the situation is more variable. The genus *Cinnycerthia* is notably gregarious. The Rufous Wren (*Cinnycerthia unirufa*), for example, occurs in parties of up to 20 individuals, more than can be accounted for by an extended family, and frequently joins mixed flocks with other species. Several other tropical wrens occur in mixed flocks, as typified by the two *Odontorchilus* species, the Tooth-billed and Grey-mantled Wrens, which frequently associate with mixed parties of tanagers (Thraupidae), becards (*Pachyramphus*) and other canopy-dwellers. Similarly, the Stripe-throated Wren (*Thryothorus leucopogon*) routinely occurs in mixed flocks of antwrens (Thamnophilidae) and other species, whereas several of its congeners, such as the Plain-tailed Wren, apparently never do so. Some species routinely follow swarms of army ants (see Food and Feeding). For species with co-operative nesting strategies, notably the tropical members of the genus *Campylorhynchus*, groups of blood-relatives associate and act collaboratively to defend the nest and rear the young (see Breeding).

A few troglodytids, such as the Marsh Wren, will sing at night, especially in moonlight, but generally wrens are strictly

The wrens are perhaps best known and best loved for their songs. Being oscine passerines, they possess a complex syringeal structure and the ability to learn extensive repertoires, and therefore some of them produce vigorous and varied outpourings, while others are hauntingly musical. The least varied and least musical songs in the family, however, are produced by members of the genus Campylorhynchus. *The song of the **Cactus Wren**, for instance, is a harsh, rhythmical series of "jar-jar-jar" notes, a familiar sound in semi-deserts of the southern USA and northern Mexico.*

diurnal. Most members of the family roost in cavities or in nests. Multiple nest-building during the breeding season is common among wrens, in some cases, as in the Marsh Wren, to an extraordinary degree, leaving numerous surplus nests for roosting. Some species, however, build nests for specific use as roosting sites. These include many of the *Campylorhynchus* wrens. Cactus Wrens, for instance, build nests throughout the year, and the juveniles may make tentative efforts at nest-building within days of fledging, with serious construction by ten weeks, obviously long before there is any chance of the youngsters themselves breeding. Wood-wrens, too, construct special roosting nests. In the case of the lowland-dwelling White-breasted Wood-wren, these are quite different from the breeding nest, being of very flimsy construction, and often with little effort at concealment; they are usually placed higher up in forks of slender saplings, so that a predator climbing to the nest cannot avoid shaking the support and alerting the occupant. In contrast, the Grey-breasted Wood-wren, living in the colder highlands, builds a thick-walled, well-insulated and snug roosting nest. White-bellied Wrens (*Uropsila leucogastra*) also build two types of nest, one a flimsy, thin-walled construction that is presumably intended for roosting only.

Many wrens roost as family groups, or the female sleeps with the young. Juveniles may then roost alone, sometimes, as with the Cactus Wren, in nests not of their own construction. Communal roosting also occurs among Northern Wrens. In this case, the birds forage as individuals during the daytime, gathering together only at dusk, the incentive being mutual body-heat conservation during long, cold nights. Northern Wrens frequently roost in cavities, usually with up to ten individuals together, but up to 96 have been found in one site in Europe and 31 in North America. In roosting aggregations of this kind, the wrens position themselves in layers, and the individuals in each layer hold the head pointing inwards, so that a rough circle is formed.

One extraordinary type of behaviour, found among many wrens of different genera and in totally different habitats, is the destruction of the eggs and, sometimes, the young of other birds, sometimes of conspecifics but very frequently those of other species. Both the Giant Wren of southern Mexico and the Bicoloured Wren (*Campylorhynchus griseus*) of northern South America have acquired the local dialectal name of "*chupahuevo*", meaning literally egg-sucker, apparently owing to a propensity of these wrens to enter chicken coops and attack the eggs therein.

Other troglodytids have developed egg destruction to a much greater degree than an occasional raid on a hen-house. In temperate North America, the Northern House Wren can be extremely destructive of other species. House wrens will enter the nests of other cavity-using species, such as the Carolina Chickadee (*Poecile carolinensis*), the Tufted Titmouse (*Baeolophus bicolor*) or the White-breasted Nuthatch (*Sitta carolinensis*), and either pierce the eggs or throw them out. Not all of the wren's aggression, however, is directed at cavity-nesters; species such as the Chipping Sparrow (*Spizella passerina*) may also be victimized, and quail (Odontophoridae) eggs experimentally placed in open nests in Northern House Wren territories may be attacked. The destructive effect of this troglodytid on other avian species has been observed for more than a century, and gave rise to a superbly vitriolic paper by a certain A. Sherman, published in the *Wilson Bulletin* of 1925, entitled "Down with the House Wren boxes". Sherman documented in great detail the crimes of the "felonious House Wren", prophesying that "if no steps are taken to stop his unrestricted breeding it is safe to predict the time will come when all true bird lovers will wring his neck as cheerfully as they now wring the neck of the pestiferous English Sparrow". Her solution was that persons who put up nestboxes used by these wrens should take them down again, so that "a kind Providence need not protect his memory from the just execrations of future generations". In one interesting instance observed by Sherman, a Northern House Wren entered a building where there was a preserved shrike (*Lanius*) nest with blown eggs; the wren pitched the eggs out on to the floor. On being replaced, the eggs were again tossed out by the wren on a second raid, by which time they were a little the worse for wear.

There is circumstantial evidence that nest predation by house wrens may have been heavily implicated in the decline of Bewick's Wren in eastern North America. In most areas, the appearance of the one coincided with the disappearance of the other. Certainly, the Northern House Wren has a substantial impact on the Prothonotary Warbler (*Protonotaria citrea*) in Canada, where this cavity-nesting parulid is considered endangered (see Status and Conservation). In southern Ontario, nest

*Like all of his kind, this male **American Rock Wren** has about a hundred different syllables in his repertoire. Each of his songs consists of one of these syllables repeated three or four times, sometimes with a different syllable appended. During a bout of singing, one series is followed after a short pause by another series, usually based on a different syllable. This cycle is repeated, often for long periods in the breeding season. The resultant pattern and cadence of notes is distinctive, drawing attention to this solitary songster, drably dressed but vociferous, in the sunbaked screes and boulder falls of his desert home.*

[*Salpinctes obsoletus obsoletus*, San Bernardino, California, USA. Photo: Brian E. Small]

*A male **Marsh Wren** perches atop a cat-tail, or bulrush, and gives full vent to his vocabulary, with head held high and cocked tail aquiver. In springtime, in the wetlands of North America, this is a familiar sight, just as the associated hurried gurgling chatter is a common sound. Common it may be, but the codes encrypted into the song of the Marsh Wren are only beginning to be deciphered. One major discovery is that two types of singers exist. From the Great Plains eastward, males have repertoires of roughly 30-60 different songs, whereas, from the Great Plains westward, they sing well over 100 songs apiece. These differences are reflected in song-control centres of the forebrain, western males devoting about 50% more brain space to learning sounds. These same males produce songs full of harsh, grating sounds contrasting with loud tonal notes, while the songs of eastern males are simpler, softer, more liquid. In all, it seems fairly clear that two lineages are involved, and that these are probably worthy of treatment as separate species, a contention supported by assortative breeding in the overlap zone, and the results of DNA analysis. But what factors underlie these differences in repertoire size? One idea is that marshes tend to be smaller in the west, and richer in food, so that wren populations are denser, resulting in decreased territory size and increased polygamy. By boosting male–male competition, and amplifying the effects of sexual selection, marshland ecology may have driven the evolution of large repertoires in western birds.*

[*Cistothorus palustris*, Rocky Mountains, Montana, USA. Photo: John Winnie Jr/DRK]

Another Cistothorus *species, the* ***Sedge Wren****, is equally voluble in defending its territory and advertising for mates. Males in some populations have impressive repertoires of 300-400 songs, which they usually deliver from prominent perches. Preliminary studies suggest that North American birds improvise their dry staccato songs, whereas birds from Central and South America rely more heavily on mimicry and produce more liquid phrases. At the moment, the Brazilian bird pictured here is lumped with relatives as far away as Canada, but further work will probably result in the subdivision of this polytypic taxon into three separate species.*

[*Cistothorus platensis polyglottus*, Serra da Canastra, Minas Gerais, Brazil. Photo: Edson Endrigo]

predation by the wrens is one of the major causes of nesting failure among the warblers.

Although egg predation by Northern House Wrens has attracted the most attention by virtue of the species' close association with humans, other, non-cavity-nesting troglodytids, notably the marsh wrens in the genus *Cistothorus*, are also well known as predators of eggs. In eastern North America, the Marsh Wren frequently attacks the eggs of Red-winged Blackbirds (*Agelaius phoeniceus*), as well as those of species up to the size of the Least Bittern (*Ixobrychus exilis*). Intraspecific egg destruction also occurs; females have been seen to kill the chicks of wrens in adjacent territories and to throw them out of the nests. Marsh Wrens can even be caught in traps baited with small eggs. Furthermore, incubating females of the Marsh Wren may show considerable hostility towards their mates, doubtless in order to protect their own eggs; these are unusually thick-shelled, perhaps as a defence against attack. Marsh Wren predation may have a significant negative effect on the breeding success of Red-winged Blackbirds, which, for their part, are very aggressive towards wrens. In western North America, a similar state of mutual hostility exists between Marsh Wrens and Yellow-headed Blackbirds (*Xanthocephalus xanthocephalus*); the blackbirds may destroy wren nests in order to prevent a brooding female from returning to her eggs. In Colombia, Apolinar's Wren appears to have an equivalent mutually hostile relationship with the local icterid, the Yellow-hooded Blackbird (*Chrysomus icterocephalus*).

The Sedge Wren in North America exhibits the same behaviour towards marsh-dwelling icterids and may have a significant adverse effect on their populations. Sedge Wrens have been seen to attack the eggs of species as large as the Cinnamon Teal (*Anas cyanoptera*), but without being able to penetrate the shell. Several other troglodytids, such as the Plain Wren in the genus *Thryothorus*, have been seen to prey on other species' eggs or young, and additional observation and fieldwork would doubtless reveal that this behaviour is quite general.

A number of explanations have been advanced for the phenomenon of egg predation by wrens. In some cases the eggs may be wholly or partially eaten, but frequently they are not; eggs are not, therefore, a significant food source. Intraspecific egg destruction may be a useful way of reducing competition for food resources at the period of maximum demand, and it may be relevant that Marsh Wrens, for example, sometimes nest at very high densities with tiny territories. This explanation, however, is less plausible when applied to interspecific predation involving large unrelated species such as the Yellow-headed Blackbird. In the case of the cavity-nesting house wren, the act of destroying the nests of other cavity-nesting species may, in the long run, ensure a supply of nesting sites for the wrens; the latter, being migratory, arrive and commence nesting later than do some resident victims such as the Carolina Chickadee or the Tufted Titmouse. Perhaps significantly, the non-cavity-nesting Northern Wren appears not to prey on eggs. On the other hand, the highly predatory marsh wrens are also non-cavity-nesters.

The behaviour and general habits of the Donacobius resemble those of the mockingbirds more than they do those of the wrens, a fact that, prior to recent DNA investigations, was used by some authors to argue that this species belongs in the family Mimidae (see Systematics). This is a noisy, extroverted bird, usually occurring in small groups of up to four, blood-related individuals. Pairs perform ritualized mutual displays, with much flirting and wagging of the long tail, which is held such that the conspicuous white tips are on show. A more intense form of display involves the adoption of a hunched-back posture, with the head and tail held down, the throat grossly distended, and sometimes with the wings drooped to reveal the conspicuous white flash on the primaries. Both sexes sing. During mutual song sessions, the pair-members may sit close to one another, waving the long tail rhythmically from side to side, with the inflatable yellow throat patch distended. As the Donacobius seems to form long-term pair-bonds, breeds co-operatively and has a rather extended breeding season, it is somewhat difficult, if not impossible, to distinguish between possible breeding displays and general social activity.

For many troglodytids living in arid conditions, water-bathing is not an option. Indeed, even when water is available, the American Rock Wren and the Canyon Wren have not been observed to indulge in this activity, preferring instead to dust-bathe. Cactus Wrens, too, habitually dust-bathe, but they will bathe in water when it is present, even visiting suburban birdbaths for that purpose. Marsh Wrens, but not Sedge Wrens, have been seen to bathe in swamp water. Curiously, water-bathing has not been reported for Northern House Wrens, although both this species and the

Carolina Wren do dust-bathe. Bewick's Wren bathes in both water and dust. There are a few reports of sun-bathing. Carolina Wrens have been seen to lie in the sun with the eyes half-closed, the wings and tail partially spread, and the feathers of the head, back and rump raised. The Northern Wren and Southern House Wren are others recorded sun-bathing.

Most wren species have been seen to preen, head-scratching being of the indirect type, with the foot lifted over the wing. Allopreening is apparently rare among troglodytids, although it has been observed for a few species.

Aggressive behaviour by wrens is generally associated with territoriality and breeding. Threat displays usually involve the fanning of the wings and the drooping and partial spreading of the tail, while pointing the bill at the object of aggression. Actual physical combat, however, is uncommon. Typically, two individuals will fly vertically upwards for a short distance, while flapping the wings into each other, grasping each other's feet and sometimes pecking. Occasionally, such efforts are directed against other species. American Rock Wrens, for example, have been seen to attack Northern House Wrens which were attempting to pilfer nesting material from their nest, and have also been observed to attack the much larger Western Kingbird (*Tyrannus verticalis*).

Voice

The Troglodytidae include some of the finest and most appreciated singers among all birds. The Northern Wren, for example, heard throughout the Holarctic Region, is appreciated for the long duration of its song and for the degree of expressiveness contained within its singing. This species' songs range from barely audible whispered ones, given while courting a female, to songs delivered with a truly surprising vehemence for so tiny a bird. It is the songs of wrens that define certain habitats throughout much of the New World. Examples are the cascading, sweet liquid whistles of the aptly named Canyon Wren, heard throughout canyons in western North America, the rhythmic "char char char char" of the Cactus Wren in the deserts of the south-west USA and northern Mexico, the unmistakable gurgling of Marsh Wrens, inseparably linked with cat-tail and bulrush marshes from the Pacific seaboard across to the Atlantic coast, the "tea-kettle tea-kettle tea-kettle" song of the Carolina Wren in the Deep South of the USA, and similar striking songs and duets of other *Thryothorus* wrens throughout Central and South America.

Although most wrens bear English names that helpfully allude to their distinctive plumages, or to the habitat or geographical area in which they are found, some have escaped such mundane appellations and have been given names drawing attention more to their vocal abilities. Thus, two of the *Microcerculus* species are known as nightingale-wrens and another as the Flutist Wren, while the Central American subspecies *luscinia* of the Southern Nightingale-wren (*Microcerculus marginatus*) is generally referred to as the Whistling Wren; and two of the three *Cyphorhinus* species are the Song Wren and the Musician Wren. Given the appealing qualities of these songsters, it is no surprise that they have attracted considerable attention, both aesthetically and scientifically.

Most members of the family achieve their remarkable songs by learning, the young birds imitating the songs of adults in the population. This was nicely demonstrated in a study of Bewick's Wrens undertaken by Kroodsma in the north-west USA. In the Willamette Valley of Oregon, where Bewick's Wrens are resident, a young male stays with his parents until four or five weeks of age, and then sets out to find a territory of his own. By eight weeks of age, he will probably already be on his own territory, one that he will retain for the rest of his life. There, the youngster begins to practise singing; his first attempts are only scratchy, continuous jingles, but his efforts gradually improve, and within a few weeks he is already singing what are clearly attempts at imitations of the songs of adult males around him. The young male perfects his songs during the autumn and over the winter, and by the following spring has acquired the songs of his immediate neighbourhood, as those are the ones that he must use in order to function there. Although he was capable of imitating his father's songs before dispersing, all of these were eventually rejected and replaced with the songs that he needed at his permanent breeding location.

This learning process is easily demonstrated also in laboratory experiments, as with Marsh Wrens. If a ten-day-old Marsh Wren is removed from the nest and hears no songs over the next year, he sings "nonsense" songs, songs that are unrecognizable

*For so tiny a bird, the **Northern Wren** produces a remarkable amount of noise! The song of the male, performed in forests and gardens across much of the Northern Hemisphere, is a lusty, ringing series of trills and modulated notes. The sequence lasts several seconds and is almost impossibly complex. That such a vigorous and piercing refrain could issue from a 9-cm bird weighing 6 g has always seemed nothing short of miraculous. A wren in full song cocks and quivers his tail, turns slowly from side to side, and seems to vibrate with single-minded effort. Unlike so many tropical wrens, the female never sings.*

[*Troglodytes troglodytes troglodytes*, Germany. Photo: Gertrud & Helmut Denzau]

*One of the most mesmerizing of avian songs is performed by the **Musician Wren**. It consists of slow, clear, whistled phrases, with halting cadence and innovative switches in pitch, repeated with minor variation before moving on to a novel motif. It is perhaps the most enchanting sound of the Amazonian understorey. Musical sections are often interspersed with brief gurgling churrs, especially when the bird is agitated. The song is sometimes described as an antiphonal duet, but it often seems to be the product of a single bird. How much the female contributes to the main phrase, or to the churring, is a topic for further study.*

[*Cyphorhinus arada interpositus*, Alta Floresta, Mato Grosso, Brazil. Photo: Edson Endrigo]

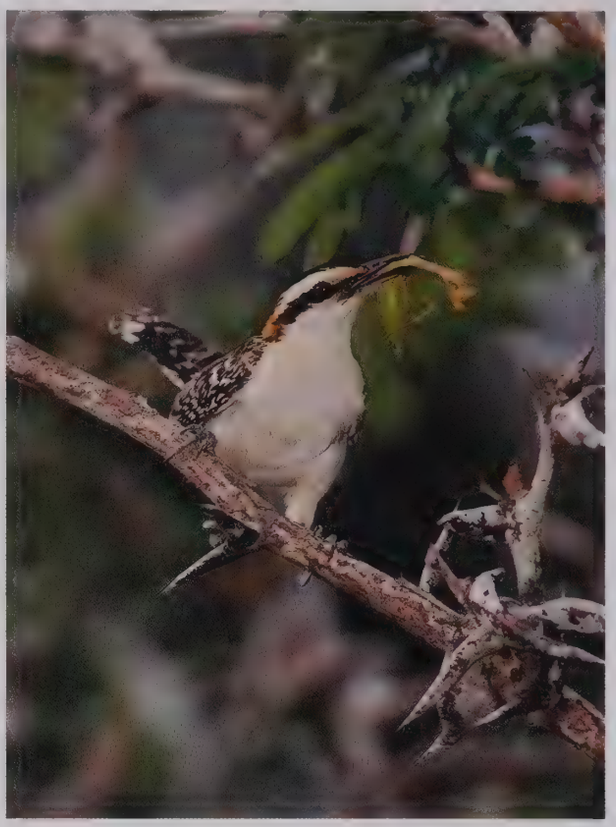
as to species. If he is allowed to hear some Marsh Wren songs over loudspeakers, however, he attends to the minutest of details in those songs, imitating them with remarkable precision. In the laboratory, males can begin to imitate songs broadcast from loudspeakers when they are as young as 15 days of age, with a peak of learning ability when between 25 and 40 days, and perhaps a secondary peak ending around day 60; little to no learning of additional songs occurs after 75 days. More realistic learning experiences can be achieved by allowing a juvenile to learn songs from an adult, singing male, and the sensitive phase for learning can then be extended well beyond 75 days, to the following spring, at a time when a migratory yearling male would establish his first breeding territory. Flexibility in where and when to learn is necessary for these wrens, as some nestlings hatch in the period after the adults have stopped singing for the year, and those nestlings must delay much of their learning until the following spring.

Most wrens probably learn their songs in this fashion, whereby young birds disperse to a breeding location and learn their songs there. One of the best forms of evidence for this is vocal dialects, in which the songs of the wrens vary over short geographical distances. Songs of Bewick's Wrens, for example, change gradually over distance, and sometimes change abruptly at discontinuities in habitat, so that the songs in a father's neighbourhood are different from those in the neighbourhood where his young male offspring establishes a territory. Songs of Marsh Wrens, and the sequences in which individuals use them, vary from one marsh to another, as J. Verner found in the 1970s. Similarly, Kroodsma recorded that songs of American Rock Wrens at a site in eastern Oregon were different from those uttered by the species at another locality only 160 km away. In Europe, the songs of Northern Wrens can differ over very short distances, a small lake being enough of a barrier that songs on one side are different from those on the other. Likewise, among Carolina Wrens in the USA, it was found that songs changed rapidly over a 145-km transect; most versions were heard at only a single locality, and most songs in the wren repertoires changed abruptly at dispersal barriers.

The one known exception to this process of precise song imitation and the formation of song dialects involves the North American population of the Sedge Wren, which is closely related to, yet so different from, the Marsh Wren. A nestling Sedge Wren, when taken into the laboratory and exposed to songs of adults of its species, imitates none of those songs. Instead of copying songs from the loudspeakers or from other young birds nearby, he improvises a sizeable repertoire of unique songs, such that few, if any, of the songs that he perfects are like those of others of the species. Consistent with this style of song development is the evidence from wild-living individuals in North America, where neighbouring males also have unique repertoires of songs. In ef-

*The antiphonal duet of the **Donacobius**, easily observed in the swamps and lakesides of South America, is impressive both acoustically and visually. The male's song is a rather manic whiplash sound ("who-it, who-it, who-it"), often given solo, but just as often accompanied by the female's rhythmical lower-pitched sizzling. Singing birds fluff their throat plumage, revealing a bizarre patch of bare, inflatable, yellow skin at the sides of the neck, recalling a prairie-chicken* (Tympanuchus). *Even more dramatically, duetting pairs often perch prominently side-by-side, girating their tails in unison.*

[*Donacobius atricapilla atricapilla*, Mamirauá Reserve, Amazonas, Brazil. Photo: Luiz Claudio Marigo]



fect, Sedge Wren songs are like snowflakes, as no two seem to be exactly alike, but each is instantly recognizable as being the song of a Sedge Wren because all songs are built on the same principle, a few introductory notes followed by a dry, staccato trill, "cut-cut-cut-trrrrrrrrrrrrr".

Why the North American Sedge Wren seems to differ from all other troglodytids in its style of song development may perhaps be explained by its unique reproductive biology. Individuals that are ringed at one location early in the season, in the northernmost part of the range, typically leave there during mid-season, presumably going elsewhere to breed; as these wrens often arrive to breed at lower latitudes, such as Nebraska, Indiana and Kentucky, during July and August, it appears that they make a stopover to nest on their migratory route back to the coast of the Gulf of Mexico. These Sedge Wrens are rather nomadic, and not at all site-faithful. They rarely return to the same breeding location in successive years; in one unpublished study, S. Johnson found that, of 300 individuals, only one returned to breed at the site where it had nested in the preceding year.

The uniqueness of these North American Sedge Wrens is highlighted by a brief survey of other *Cistothorus* wrens, based largely on the investigations of Kroodsma and colleagues. In Costa Rica and the Falkland Islands, other populations of the Sedge Wren are sedentary, and neighbouring males imitate songs from one another, creating song dialects over relatively short distances. In Brazil, neighbouring male Sedge Wrens answer each other with identical songs, such behaviour being possible only if the birds learn their songs from each other. Similarly, the Merida Wren (*Cistothorus meridae*) of the Venezuelan Andes and the globally threatened Apolinar's Wren of Colombia are sedentary and, again, neighbouring males learn each other's songs, as evidenced by the readily documented song dialects of these species. Interestingly, the recently described subspecies *hernandezi* of Apolinar's Wren not only has a more varied repertoire of song types than the nominate form, but also lives in small groups in which several individuals, of both sexes, sing communally. In North America, too, populations of the Marsh Wren are typically sedentary or, if migratory, individuals are highly site-faithful, returning annually to the same marsh.

It is likely that the unparalleled movement patterns among the North American Sedge Wrens have co-evolved with a reduced emphasis on song imitation. Local communities of birds are highly ephemeral, with individuals staying together just long enough to raise one family. They then move on to the next breeding location, either in the same year or in the following year. There is little time or opportunity to relearn large vocal repertoires at each breeding location; indeed, as the repertoire of a single male can number up to 300 different songs, it is perhaps impossible to accomplish such a feat twice in each breeding season. The solution for these Sedge Wrens is to improvise or in-

Species in the genus Campylorhynchus *have a slightly broader dietary spectrum than that of most wrens: they remain chiefly insectivorous, but without being restricted to smaller invertebrates. This* ***Rufous-naped Wren*** *has caught a large mantid, and others in the genus are known to eat scorpions, or even small vertebrates such as lizards or frogs on occasion. These bulky, co-operative wrens also consume a certain amount of non-animal food, predominantly fruit, berries and seeds, with up to a fifth of the diet made up of this type of vegetable matter.*

[*Campylorhynchus rufinucha*, Santa Rosa National Park, Costa Rica. Photo: Marie Read]

Unlike its larger relatives, the ***Northern House Wren*** *has a tiny bill and its intake of food is almost purely invertebrate. It forages low down in tangled vegetation, where it finds and consumes a range of small bugs, caterpillars, grasshoppers, beetles and spiders. Vegetable matter figures only peripherally, making up less than 2% of the diet. It is also a notorious egg vandal, routinely destroying the clutches of other species, without ever seeming to eat the contents. In the case of cavity-nesters, this curious behaviour might relate to competition for nest-sites, but in other cases it is harder to explain.*

[*Troglodytes aedon*, south-west Ohio, USA. Photo: Dave Maslowski/ Maslowski Productions]

Bewick's Wren *forages mainly on the ground and in low vegetation, thriving on an almost exclusively invertebrate intake. An analysis of stomach contents in Californian birds revealed that 31% of the diet was made up of bugs* (Hemiptera)*, 21% beetles, 17% bees and wasps, 12% caterpillars, butterflies and moths, and the remainder was made up of various other arthropods. A very small quantity of vegetable matter is eaten, mostly in winter.*

[*Thryomanes bewickii*, Rio Grande Valley, Texas, USA. Photo: Tom Vezo]

vent songs, using some shared rules for generating species-typical songs. The result is that, no matter what the geographical origin of each singing individual, and no matter where he has been on his travels, he will instantly be recognized, both by other males and by females, as a Sedge Wren.

Geographical patterns in songs can be the first clues to the evolutionary history of the wrens that sing them. In Costa Rica, for example, F. G. Stiles discovered a sharp transition zone in the songs of nightingale-wrens, leading to the formal recognition of two species, the Northern Nightingale-wren (*Microcerculus philomela*) and the Southern Nightingale-wren. Farther north, in Mexico, the songs of two allopatric *Hylorchilus* populations were found by H. Gómez de Silva to be sufficiently distinct to warrant species status for both, as Sumichrast's Wren and Nava's Wren (see Systematics). In the Neotropics, likewise, careful listening to wood-wrens in Colombia led S. L. Hilty to suggest that the birds living at especially high altitudes represented a new species, as their songs were different from those of the wood-wrens throughout the rest of Colombia. In 2003, this high-elevation form was officially recognized as a new species, the Munchique Wood-wren (see Systematics). The songs of North American Sedge Wrens vary little, if at all, geographically, revealing what must be one large evolutionary unit in North America. In contrast, local dialects conceal these evolutionary groups to some extent in Central and South America, but major geographical differences in songs, from Costa Rica to Brazil and to the Falkland Islands, surely represent different evolutionary groups, which are perhaps, as suggested by M. T. Traylor in 1988, worthy of species status.

Another example in North America is that of the Marsh Wren populations, which almost certainly consist of two species (see Systematics), not one as currently recognized. From the Atlantic coast east to the central Great Plains one style of singer is found, and from the central Great Plains west to the Pacific another kind, and the differences between the two in behaviour are striking. The songs of western males are highly diverse, with harsh and grating sounds contrasting with loud tonal notes; those of eastern males are more liquid, without the harshness, and far less diverse. Western males introduce their songs with short, sharp "click" notes, whereas eastern males begin with a nasal buzz. In addition, western males have much larger song repertoires, containing an average of perhaps 150 different songs, far more than the 30 to 50 songs in the repertoires of eastern males, and western males race through their repertoires much faster than do eastern males. These differences in vocal repertoires are reflected in the song control centres of the forebrain, too, with western males devoting about 50% more brain space to controlling their much larger song repertoires. The extra brain space in western birds is not generated because the birds learn more songs, but, rather, it seems to be part of a

The ***Canyon Wren*** *is an exclusively insectivorous species. Its bill is especially fine and decurved, its cranium is flattened and its tarsi are relatively short. These adaptations allow it to delve deep into crevices in rocks, and even to clamber inside narrow nooks and fissures, techniques it uses to glean spiders, beetles, bugs, ants and termites from their hiding places. It has also been observed to pilfer paralysed invertebrates from the nests of mud-dauber wasps.*

[*Catherpes mexicanus conspersus*, Anza-Borrego Desert State Park, California, USA. Photo: François Gohier/ Ardea]

*The **Plain-tailed Wren** is an Andean species, pairs and small bands of which rove in sprawling patches of* Chusquea *bamboo at high altitudes. So rarely does it show itself for more than a few seconds that almost nothing is known about its foraging ecology. This photograph of a mist-netted individual, temporarily incarcerated in a photographic tent, provides one of the few clues regarding its insectivorous habits.*

[*Thryothorus euophrys euophrys*, Río La Plata, Carchi, Ecuador. Photo: Doug Wechsler/ VIREO]

genetic programme that generates sufficient brain space so that large repertoires can be learned.

Furthermore, many of these behavioural and neural differences are based on genetic differences between eastern and western birds, as nestling males taken from eastern and western populations behave differently when they experience the same laboratory environment. Juveniles from western North America still imitate about three times as many songs as do eastern ones, and the western individuals also allocate more brain space for controlling those larger repertoires. In the laboratory, western males also race through their repertoires faster than do the eastern males. The western males are simply more proficient at learning the larger repertoires than are the eastern birds, and these differences in ability are due to genetic differences that have evolved in the two respective groups since they diverged from their common ancestor. One possible explanation for the escalation in vocal behaviour among western Marsh Wrens is that territories in the west are often smaller, so that competing males are singing more closely together, and males are also more polygynous, so that the stakes in the singing game are higher. With these smaller territories, a small marsh reaches lek-like proportions, and prospecting females can choose from among all of the competing males, a situation that may have promoted the evolution of especially large repertoires and complex singing behaviour.

Just how complex these aspects of vocal behaviour are is revealed by Verner's study of western Marsh Wrens. At Turnbull National Wildlife Refuge, in eastern Washington state, he found that neighbouring males have essentially the same repertoires of about 115 different songs, but they have learnt not only the songs, but also the sequences in which to use them. As the wrens countersing from neighbouring territories, they often answer each other with identical songs, not just once, but many times in succession; there is frequently a community effect, too, as other males within earshot are often heard to echo the same song. The possibilities for interactions are intriguing, as a male can respond to a neighbour with the song that he just sang, or jump ahead one song in the standard sequence, or give a song that is well removed from that particular sequence. The response choice that a male makes, or perhaps is allowed to make, may well signal important information to other individuals listening to this exchange, information that may indicate the relative prowess of the two singers. When a tape recorder plays a standard sequence of song within a territory, for example, a male routinely jumps ahead in the sequence, so that the tape recorder "sings" a particular song type *after* the resident male. It is possible that, by refusing to follow the recorder, the male signals his dominance to this simulated intruder.

As already intimated (see also Systematics), the eastern and western populations of the Marsh Wren almost certainly represent two separate species, and a similar situation prevails with the Northern Wren. The songs of males of the latter species in western North America consist of brief notes delivered at breakneck speed, so that human ears hear little more than a high-pitched blur. In contrast, eastern songs are far less complex; they are delivered more slowly, contain fewer notes, and have fewer notes per unit time. Repertoire sizes, too, differ, eastern males having an average of only two relatively simple songs apiece, whereas western males have perhaps a dozen basic songs, from which countless permutations are generated. Moreover, the non-learnt call notes differ, western Northern Wrens having a sharp, high-pitched note and eastern ones a lower-pitched, richer note. Predictably, perhaps, the songs of this species in the Old World, from Britain east to Japan, are different again. In tonal quality and organization, they are most like those of the wrens from eastern North America. Repertoires in Eurasia consist typically of six or seven songs, each given in a constant, repeatable fashion, much like the singing of eastern Nearctic wrens.

As the esteemed tropical biologist A. F. Skutch pointed out in 2001, we know far more about the few "odd" wrens that have invaded the north-temperate zone than we do about the 50 or so that have remained in the New World tropics. In the tropics, the vocal behaviour of troglodytids can be very different.

One immediately noticeable difference between the wrens in the north-temperate zone and the tropical wrens is that females in the tropics sing far more. In the case of the two house wrens, for example, females in North America sing occasionally in at least one well-studied population, in Wyoming, although perhaps not in some other populations; these Northern House Wrens are polygynous. In contrast, females of the Southern House Wren, which are monogamously paired to their males, sing far more regularly throughout the tropics. Females of the related Socorro

*A study of diet in the **Cactus Wren** showed that 17% of its intake was vegetable matter, a higher proportion than in other members of the family, although few have received detailed study. As it happens, the bulk of this figure was made up of a single item: cactus seeds. In the upper image, a foraging individual is visiting the ripe fruit of a saguaro* (Carnegiea gigantea)*, where, unlike several other vertebrates, it does not seem to target the soft flesh, but merely collects the abundant seeds. By eating this item in considerable quantities, and defecating at least some of them elsewhere, the Cactus Wren is the only troglodytid that can claim a significant role in the dispersal of plants. Cactus seeds are clearly an important food supply in the arid landscapes of the southern USA and northern Mexico, but this does not diminish the fact that 83% of the diet consists of animal matter, including small frogs and lizards, spiders, ants, wasps, grasshoppers, and lepidopterans, as seen in the lower photograph. Some individuals, rather ingeniously, have learnt to prise squashed insects from car radiator grills.*

[*Campylorhynchus brunneicapillus couesi*, Arizona, USA. Above, photo: Dave Maslowski/ Maslowski Productions.

Below, photo: Konrad Wothe]

Although there is virtually nothing on record about wrens drinking, the habit is possibly widespread in the family. As with bathing, it seems likely that wrens living in arid landscapes make less use of water than wrens of relatively humid habitats, even when water is available. Thus, the ***Carolina Wren****, a common bird in moist woodlands of eastern North America from south Canada to north Mexico, is more likely to visit water habitually than are its relatives from drier habitats to the west. How much it drinks, however, is difficult to judge. This individual may be visiting an autumn pool to drink, to bathe or to forage, but the picture tells only part of the story.*

[*Thryothorus ludovicianus ludovicianus*, south-west Ohio, USA. Photo: Dave Maslowski/ Maslowski Productions]

Wren (*Troglodytes sissonii*), confined to the island of that name off western Mexico, also sing. Among the *Cistothorus* wrens, females of the temperate-zone Marsh Wren and Sedge Wren do not sing, but those of the two Andean species do; female Merida Wrens emit a simple trill as their mates sing a more complex, whistled song, and female Apolinar's Wrens utter a prolonged trill that slowly rises and falls in pitch, the male then chiming in with a briefer, more complex song. In southern Mexico, Sumichrast's Wren, in the genus *Hylorchilus*, exhibits similar vocal differences between the sexes: the female's song is less complex than that of the male, being a dry, staccato chatter, much like that of a male Cactus Wren, whereas her mate's song is a rich series of descending whistles.

These differences between temperate and tropical representatives of a genus are especially pronounced among the *Thryothorus* wrens. Only one of these, the Carolina Wren, reaches North America, and the male of that species has a repertoire of 40 or so loud, rich songs; the female, in contrast, utters a simple rattle, typically in response to her mate's song during aggressive encounters with other wren pairs. In the tropics, however, female *Thryothorus* wrens often have songs that are just as complex as are those of the males. The songs of both sexes of the Rufous-and-white Wren (*Thryothorus rufalbus*), for example, consist of a series of pure whistles gradually or abruptly accelerating in tempo, with the female's song slightly higher in frequency than the male's; a male and a female often sing simultaneously, the songs overlapping in time but less so in frequency. In the Black-bellied Wren, too, male and female songs are an equally complex series of rich whistles, often overlapping in time, but that of the the female again perhaps a little higher in frequency. Most impressive among these *Thryothorus* wrens are those species, such as the Buff-breasted Wren (*Thryothorus leucotis*), in which the male and female sing such a tightly co-ordinated duet that their respective roles are indistinguishable, unless one happens to be standing between the two singers.

Careful study of one of these duetting species, the Bay Wren, has revealed how and, to some extent, why the sexes engage in such duets. R. N. Levin found that males and females duet precisely, even when they first meet, thereby dispelling the previously held notion that it would take time, in a long-term monogamous pair-bond, for such precision to be learnt. Rather, it seems that the birds follow some general rules that enable this precision, regardless of which particular song type each contributes. Further, a lone female or a lone male can maintain the territory by itself, dispelling still another idea, namely, that the duet is needed for joint territory defence. It is the female that begins each duet, the male then joining her, and it seems therefore to be the male's behaviour, not that of the female, that makes the joint singing a duet. Perhaps this is because the male can in this way announce to other males in the neighbourhood that this particular female is taken; in other words, he is employing "acoustic mate-guarding".

Equally enlightening is the way in which territorial males and females sing and respond to songs. A paired male responds strongly to both male and female song, as if territorial towards both sexes. When he becomes unpaired, he increases his singing substantially, just as do most unpaired songbird males, and he then responds more strongly to female song than to male song, suggesting that his abundant songs serve to attract a mate. A female that becomes unpaired, however, does not change her singing rate, and lack of a male song accompanying her clearly signals that she is unpaired. Whether she is unpaired or not, she responds strongly to songs of other females but not to those of males, suggesting that she uses her songs in order to defend her territory against other females.

Ongoing studies of another *Thryothorus* species in Costa Rica, by L. E. Molles and S. L. Vehrencamp, illustrate the diverse singing styles within this genus. In the case of the Banded Wren, males are the primary singers, and a typical repertoire consists of about 20 different songs. Females, too, sing, and their songs are of the same general form as those of the males, but of lower amplitude; a female occasionally sings jointly with her mate during a territorial dispute. As with some other troglodytids, such as the Sedge Wren and the Marsh Wren, males sing vigorously at dawn and switch to new song types more at that time than they do later in the morning. Among these wrens, the rate of singing and the frequency with which a male switches to a new song type may signal important information to listeners about his mood, but the exact rules for conveying the appropriate information are not necessarily the same for all species.

What appears to be one of the most complex duets is that of the Canebrake Wren (*Thryothorus zeledoni*), a species restricted

Unlike most Campylorhynchus *wrens, the* ***Cactus Wren*** *is monogamous. Pairs stay together for long periods, with little or no emphasis on courtship display, complex song or duetting. Instead, for much of the year, they breed. Once the female begins to lay in one nest, the male sets out to construct the next. When the first brood fledges, the female completes this second nest and lays a clutch in it. This cycle is repeated until conditions become unfavourable. As a result of their methods, each pair of Cactus Wrens is able to embark on anything from three to six breeding attempts annually, only two or three of which are likely to be successful.*

[*Campylorhynchus brunneicapillus couesi*, Green Valley, Arizona, USA. Photo: Tom Vezo]

to the Caribbean slope of Central America. A study of this wren was recently undertaken in north-east Costa Rica by N. I. Mann and others, who captured and individually colour-ringed 24 territory-holding adults. Blood samples were analysed to enable these to be sexed. The researchers found that the duet of this species consisted of three main components, each one distinctive in structure. The male had a repertoire of very brief rapid phrases and the female had a repertoire of different, slightly longer phrases. In addition, the male had a second, separate repertoire of somewhat longer, higher-frequency phrases, each containing 4–6 elements; each duet was almost invariably introduced by one of these. Thus, a typical duet would consist of the male's introductory phrase followed by a very fast and highly co-ordinated alternation of female and male phrases. In a very few instances, the male's introductory phrase, which he also used as a solo song, was omitted. The Canebrake Wren is often considered conspecific with the Plain Wren, although it differs vocally and in plumage. Interestingly, Mann and colleagues' preliminary data on the nominate race of the Plain Wren, inhabiting the Pacific slope of Costa Rica, appear to suggest that this has a song pattern similar to that of the Canebrake Wren.

Vocalizations include more than singing, of course, and the members of this family have extensive repertoires of calls as well. Partly because wren songs are often so striking, the calls of these species have been studied relatively infrequently. The most thorough study in this respect has been done with the Stripe-backed Wren (*Campylorhynchus nuchalis*), a co-operative breeder (see Breeding) that occurs in Venezuela and Colombia. J. J. Price found that, in co-operative family groups, young males learn their repertoires of calls from adult males, and young females learn their calls from adult females. As a result, males in the same "patriline" have nearly identical call repertoires, no matter whether the young male stays at home or disperses to another group, and all females within a "matriline" have identical repertoires, too, but the calls are different from those of the males. This form of vocal tradition thus provides clues as to both sex and kinship, and studies using playback have shown that the males can readily distinguish male relatives from non-relatives. These wrens provide a rare example of individuals being able to recognize their kin on the basis of learnt vocal cues, and these cues undoubtedly prove useful in helping them to keep track of close kin within and among family groups, thereby enabling complex social relationships among individuals in this co-operative breeder.

Many wrens have short tails which are prominently displayed during song bouts or social interactions. Whether this signal contains any information is unclear, but some evidence has been found in support of the idea that males with the shortest tails are particularly attractive to females. The male ***Marsh Wren*** *is a classically stubby-tailed wren, and proud of it. He is also polygamous. One Canadian study found a skewed sex ratio of only 0·65 males per female, with 10 unmated males, 53 monogamists, 48 bigamists and 9 trigamists. In Georgia, however, only 5% of males had more than one partner, suggesting that rates of polygamy are regionally variable.*

[*Cistothorus palustris palustris*, Dryden Lake, New York, USA. Photo: Marie Read]

Food and Feeding

Arthropods make up the bulk of the food items eaten by most troglodytids. Among the different wren genera, however, there is

Nest-building by males is a recurrent feature in wrens. The ***Carolina Wren*** *is fairly typical in that the bulk of the building process is undertaken by the male, although sometimes he merely brings material and the female adds it to the structure. As with most wrens, the outer layers of the nest are constructed with dead plant matter, usually leaves, strips of dry bark and thin stems. Other, non-vegetable items are sometimes interwoven, including string, horsehair and snakeskins. If the nest is selected for breeding, a soft lining is added.*

[*Thryothorus ludovicianus ludovicianus*, Appledore Island, Maine, USA. Photo: Marie Read]

considerable variation both in the food and in the techniques used as a means of acquiring it.

There is a substantial body of data on the diets of most of the North American wren species, as well as that of the Northern Wren in Europe, derived from examination of stomach contents of specimens. It should be borne in mind, however, that studies of stomach contents were typically undertaken in one geographical location and were often quite limited in scope; hence, published results may not be entirely representative of the diet of a species throughout its range, or even throughout the year. Broadly speaking, invertebrates of many kinds form most or all of the food of this family. For example, American Rock Wrens take such prey as locusts and grasshoppers (Orthoptera), earthworms (Oligochaeta) and grubs, and Canyon Wrens consume spiders (Araneae), beetles (Coleoptera), bugs (Hemiptera), planthoppers (Homoptera), ants (Hymenoptera), termites (Isoptera) and similar prey, ranging in length from 2 mm to 12 mm, while Bewick's Wrens feed on bugs, beetles, bees and wasps (Hymenoptera) and caterpillars. The Northern House Wren eats caterpillars, grasshoppers, beetles, leafhoppers (Cicadellidae) and spiders, among others, and the Northern Wren's diet includes such items as grasshoppers, earwigs (Dermaptera), beetles, spiders, woodlice (Isopoda) and the like. Northern House Wrens are known to favour slower-moving prey, such as spiders and bugs, rather than such insects as flies (Diptera), the capture of which would be more challenging. This species has been seen also to take calcareous matter, such as mollusc shells, and to feed such inorganic items to its young, presumably as a calcium supplement at a time when it is needed for bone growth. Larger, vertebrate prey is occasionally found in stomachs. The American Rock Wren, for example, will take young lizards. It is of interest to note, incidentally, that neither the latter species nor the Canyon Wren appears to drink, even when water is freely available.

Vegetable matter does figure to a minor extent in the diets of some of the smaller North American troglodytids. For instance, Bewick's Wren takes some vegetable matter, especially in winter, while the Northern Wren has been observed to eat berries, including elderberries (*Sambucus*) and blueberries (*Vaccinium*), as well as some seeds and even seaweed.

The large wrens of the genus *Campylorhynchus* have a dietary spectrum that is wider than that of smaller troglodytids. Most members of this genus eat substantial quantities of vegetable matter, such as cactus seeds. The only one which has been studied in any great depth is the Cactus Wren; in one case, 17% of the diet of this species consisted of vegetable matter. *Campylorhynchus* wrens also take relatively large prey, such as lizards and frogs, and one of the Spanish names for Boucard's Wren, "*Matraca Alacranera*", implies that this species eats scorpions (Scorpiones). As previously mentioned (see General Habits), the Giant and Bicoloured Wrens are known in local Mexican and Colombian dialects as "*chupahuevo*", meaning egg-sucker, although whether they actually eat hens' eggs or merely vandalize them is not known. Bicoloured Wrens can also be quite destructive to soft fruit, such as mangoes.

This ***Bicoloured Wren*** *has pulled a strip of bark from a branch for its nest, a domed structure with a narrow side entrance, usually over 3·5 m above the ground. To save the effort involved in building, second-hand nests are readily adopted, as long as they are domed. The nests of* Pitangus *or* Myiozetetes *tyrant-flycatchers are ideal, and the pendant structures built by thornbirds* (Phacellodomus) *are sometimes used. In most populations of this wren co-operative breeding is the norm, and nests with helpers are significantly more successful than unassisted nests.*

[*Campylorhynchus griseus griseus*, Guyana. Photo: Flip de Nooyer/ Foto Natura/FLPA]

Wrens probably build more nests per annum than any other birds. This is not because they nest in greater numbers, or produce exceptional numbers of broods, but because of the phenomenal effort they invest in constructing supplementary nests. Many wrens build simple nests for roosting, and in some the male seems positively addicted to filling every suitable nook in his territory with a half-built potential nest. Multiple nests are a common feature in the ***Marsh Wren****, for example, males of which sometimes build twenty skeleton nests in a season, using dry strips of reeds. As in other wrens, females inspect the handiwork of males and select a single site for breeding, adding finishing touches and a soft lining to the chosen nest. The individual pictured here (almost certainly a female) is collecting cat-tail down for this very purpose. Skeleton nests may take two days to build, and require a considerable investment of energy. Despite the costs involved, the construction of multiple nests might be adaptive on several levels, not least because back-up nests are useful in the event of nest predation or destruction. It is also possible that an assortment of "decoy" nests is enough to confuse or discourage predators, and it has even been suggested that females choose their mates on the basis of nest-building prowess, preferring the most prolific males.*

[*Cistothorus palustris palustris*, Dryden Lake, New York, USA. Photo: Marie Read]

The Campylorhynchus *wrens build bulky globular nests. That of the* ***Rufous-naped Wren*** *is made from grass and plant fibres, with an upward-directed tunnel entrance at one side, leading into a central chamber lined with feathers and down. The whole structure is situated 1·5–10 m above the ground, where it is often highly visible. It is usually placed out of reach in a cactus or thorn bush, or adjacent to an active wasp nest, in order to deter predators. The nest pictured here is lodged in an acacia tree, a site that provides dual protection: if a capuchin monkey* (Cebus) *wants to steal the nest contents it must navigate not only the acacia's vicious thorns, but also, typically, the aggressive ants that live on and in the tree. These ants have painful stings and they rally to attack any mammal careless enough to trespass in their tree. For good reason, then, the Rufous-naped Wren preferentially sites its nests in those trees occupied by the most hostile ants! The* ***Stripe-backed Wren*** *is not known to adopt such clear-cut anti-predator strategies, but often places its similar nests at the tips of narrow branches, where they are difficult for predators to reach. In this case, the outer structure of sticks and bulky twigs is the creation of a thornbird* (Phacellodomus), *illustrating the opportunistic appropriation of abandoned arboreal nests so common in* Campylorhynchus *wrens. When nests of other species are borrowed, the wrens dispense with an outer layer, and simply stuff the existing cavity with a lining, often copiously, as this photograph shows.*

[Above: *Campylorhynchus rufinucha*, Playa Tambor, Costa Rica. Photo: Antonio Cortizo.

Below: *Campylorhynchus nuchalis nuchalis*, Hato El Cedral, Venezuela. Photo: François Gohier/ Ardea]

For many of the Neotropical wren species, the data on prey items are very scanty and, in many cases, few relevant observations are available. Furthermore, the notes on stomach contents accompanying specimens frequently contain unhelpful and vague generalizations, such as "insects", "insect parts" and the like. As a result of the more meticulous work of A. Wetmore in Panama and of F. Haverschmidt in Suriname, the diets of most species in these two countries are known in better detail. According to the rather limited information published, the diet of the tropical *Thryothorus* wrens encompasses a very great variety of arthropods. These comprise many orders of insects, including lepidopteran larvae, ants, bugs, grasshoppers, cockroaches (Blattodea) and dipteran flies, as well as other groups, among them spiders, woodlice, centipedes (Chilopoda) and millipedes (Diplopoda). So far as is known, vegetable matter, usually in the form of seeds, is a very minor component in the food of these species. The sole North American member of this genus, the Carolina Wren, will also take small invertebrates, including lizards, tree-frogs and young snakes.

In its unique sawgrass habitat in western Cuba, the Zapata Wren has learnt to exploit a more varied range of food resources, including fairly large lizards of the genus *Anolis*, seeds, lichen, snail eggs, slugs and a wide variety of invertebrates. By contrast, the marsh-dwelling *Cistothorus* wrens are more purely insectivorous, although in mid-winter, with snow on the ground, the Sedge Wren in extreme southern South America does eat seeds. Snails have not been recorded as being consumed by any troglodytids with the single exception of Sumichrast's Wren, in the diet of which they may figure quite prominently.

The food of the Donacobius consists almost entirely of invertebrates, mostly gleaned from leaf surfaces, but also taken in flight. Recorded prey items of this species include beetles, hymenopterans, orthopterans, neuropterans and arachnoids.

The feeding techniques of wrens also exhibit considerable variation and adaptation to different habitats. The members of many genera spend most of their time in foraging in the lower levels of dense vegetation, where they examine leaves for prey or rummage in leaf litter. *Henicorhina*, *Thryothorus* and *Troglodytes* are typical examples of such unobtrusive wrens. Nevertheless, the various species have differing habits. Some, such as the Coraya Wren, routinely feed quite high up in trees, whereas the Rufous-and-white Wren specializes in foraging in leaf litter and is rarely seen far from the ground. The only wrens which might be described as canopy feeders are the two species in the genus *Odontorchilus*, the Tooth-billed and Grey-mantled Wrens, which are regularly found 30 m or more above the ground in the upper levels of tropical and subtropical forest.

Some tropical species have developed a technique employed by antbirds and many other Neotropical birds, that of following swarms of army ants, opportunistically snapping up invertebrate prey flushed from otherwise secure hiding-places by the insects. Typical in this respect are the terrestrial *Cyphorhinus* wrens, such as the Song and Musician Wrens, which bear a superficial resemblance to some of the formicariid antbirds. Others include the Sooty-headed Wren in the genus *Thryothorus* and, at least where its range overlaps that of army ants, in southern Mexico, the White-bellied Wren in *Uropsila*. The lowland White-breasted Wood-wren is also a typical ant-follower, but its relative, the highland Grey-breasted Wood-wren, is not, as it is altitudinally separated from army ants. Not unexpectedly, the degree of association with army ants varies. Some species, such as the Riverside Wren, will join swarms briefly, before losing interest and foraging elsewhere.

Northern Wrens are somewhat unusual within the family in that they have been seen to prey on tadpoles and tiny fish, by wading into shallow water and actually immersing the head as they search for these food items. They have also been observed while attending the European badger (*Meles meles*), much in the manner of Cattle Egrets (*Bubulcus ibis*) following livestock, and catching prey disturbed by the mammal's foraging activities. The rock-dwelling wrens, the Canyon, Sumichrast's and Nava's Wrens, have developed special anatomical features, such as a long, decurved bill, a flattened skull and widely splayed legs, which enable them to forage deeply into crevices in rock faces. In addition, Canyon Wrens will often sally forth briefly from high rock walls to seize insects flying nearby. Classic flycatching behaviour, involving the mid-air pursuit of flying insects, is uncommon among the members of this family, although Northern Wrens may occasionally practise this method of foraging.

Most terrestrial wrens are very secretive, the two nightingale-wrens obsessively so, feeding only in places where they are well hidden. The Wing-banded Wren (*Microcerculus bambla*) appears to specialize in finding prey in rotten logs lying on the forest floor, where it vanishes for several seconds inside cavities in hollow fallen tree trunks. *Campylorhynchus* species, on the other hand, are anything but furtive. The Cactus Wren, for example, frequently feeds on the ground well in the open, even sometimes on suburban lawns.

Several troglodytids have developed opportunistic feeding strategies. Carolina Wrens, especially during the winter months, come to feeding stations, where they are especially fond of suet. They have also been seen to take sunflower seeds and to crack them open in the manner of a nuthatch, by wedging the seeds into a cranny and hammering them with the bill. Canyon Wrens may pilfer the paralysed spiders with which mud-dauber wasps (*Scelifron cementarium*) provision their nests, while the White-bellied Wren will steal prey from spiders' webs. On Guadalupe Island, off Baja California, the local subspecies *guadeloupensis* of the American Rock Wren, restricted to that island, has learnt to frequent slaughterhouses, where it feeds on flies attracted to the offal. Another example of opportunism concerns the Cactus Wren. In suburban situations in the American South-west, some individuals of this species have discovered that the squashed insects on the radiators of cars are a reliable source of conveniently pre-cooked protein.

Breeding

Among different groups of wrens there exist a number of breeding features and strategies that are quite unusual in passerines.

All Thryothorus *species build globe-shaped nests with side entrances. The nest of the* ***Banded Wren*** *is fairly typical, being shaped like an old-fashioned chemical retort hung in the crotch of a tree. It has an entrance-tube sloping downwards on one side of the support and a nest-chamber on the other.* Thryothorus *wrens tend to nest fairly low down, usually less than 3 m up and often very close to the ground. This species deters predators by building its nest in irritating nettle-bushes, next to the pendant nests of wasps and hornets, or in bull's horn acacias* (Acacia collinsii *and* A. cornigera). *These trees, pictured here, are inhabited by aggressive ants which provide vicarious protection from many types of egg thief.*

[*Thryothorus pleurostictus ravus*, Santa Rosa National Park, Costa Rica. Photo: Marie Read]

In common with other Campylorhynchus *wrens, the* ***Cactus Wren*** *builds a large, conspicuous, pouch-shaped nest, with a side entrance leading to an inner cavity. The materials most frequently used for the outer layers are grass and plant fibres, while the nest-chamber is lined with softer items such as feathers and down. Artificial material is incorporated when available: in this case the nest seems to have been reinforced with waste paper, and decorated with lengths of blue thread, black thread and cotton wool. To discourage predators, the most inaccessible locations are selected. The heart of a cholla cactus* (Opuntia), *for example, seems unlikely to receive unwelcome visitors.*

[*Campylorhynchus brunneicapillus couesi*, Arizona, USA. Photo: David Hosking/ FLPA]

These include polygamy, usually in the form of polygyny but also, more rarely, polyandry, as well as co-operative breeding and an extraordinary degree of multiple nest-building. It should, however, be admitted that there are major gaps in our knowledge of the breeding biology of the Troglodytidae. Indeed, for more than a quarter of the tropical wrens, not even has the nest been described, and detailed studies of the breeding strategy exist for only a few species.

The fact that wrens build more than one nest in a single season has been well known for many years. In England, for example, many decades ago, every bird-nesting schoolboy was familiar with the phenomenon of the "cock's nests" of the Northern Wren. The degree of multiple-nesting varies greatly among wren genera, apparently not occurring at all in some, but reaching an extraordinary degree in the *Cistothorus* marsh wrens, and a peak in the Marsh Wren itself. Male Marsh Wrens may, in the course of a season, construct up to twenty separate nests. From among these the female will then choose a suitable one, which she then completes, or she may even, apparently, induce the male to build yet more. It takes the male perhaps two days to build a candidate nest, but it can require eight days for both sexes to complete the nest that is to be used for breeding. Given the very substantial resources demanded of the male for this construction bonanza, there must be a major payback in evolutionary terms. The precise nature of this is, however, a matter of considerable debate. Certainly, in the event of a disaster befalling a breeding nest, it is obviously advantageous to have a half-completed back-up nest at hand. In a cat-tail marsh, where it is not easy to conceal a nest, the presence of numerous "decoy" nests may confuse a predator, and it is perhaps significant that the Sedge Wren, which nests in more tangled vegetation where concealment is easier, builds only half as many surplus nests as does the Marsh Wren. It has been suggested that the sheer vigour of a male's nest-building activities may indicate to the female his breeding fitness. Surplus nests are also useful for roosting, but why would twenty such nests be required? Probably, no single hypothesis completely explains the phenomenon. The building of additional nests for roosting is widespread among the members of this family. In the case of some species, such as the White-breasted Wood-wren, the Riverside Wren and the White-bellied Wren, the dormitory nests are slighter in construction and more poorly concealed than are the breeding nests, and the roosting nest of the Plain Wren, for example, is so flimsy that the bird can make an emergency exit by bursting out through the back wall.

For a number of genera, among them *Odontorchilus*, *Hylorchilus* and *Microcerculus*, there is no documented evidence that multiple nests are built, although this may be due to a lack of observation. Many *Thryothorus* wrens build dormitory nests but not, apparently, multiple breeding nests. One species, the Carolina Wren, a debatable member of this genus (see Systematics), occasionally builds spare nests in the breeding season. By way of contrast, the constructing of multiple nests appears to be standard in the genus *Troglodytes*, at least for those of its members which have been adequately studied. In Europe, Northern Wrens build half a dozen or more nests in each breeding season, although the number is smaller in western North America, as it is also, evidently, in the case of island populations of this species. Similarly, male Northern House Wrens construct multiple nests and, indeed, throughout the breeding season, they seem incapable of resisting the temptation to drop a few twigs into suitable cavities, often to the discomfiture and annoyance of the rightful owners. Among the *Campylorhynchus* species, the Rufous-naped Wren in El Salvador builds at least eight nests for each one actually used for breeding, at least some of the remainder serving as roosting sites. In Arizona, USA, the male Cactus Wren habitually starts to construct a second nest while his mate is incubating the first clutch; after this brood has fledged and become independent, the female will join in the completing of the second nest, which is immediately used for the rearing of a further brood.

Detailed study, with individually marked birds, is required in order to establish whether a wren species is routinely polygamous. In view of the paucity of such studies with regard to the species not occurring in Canada and the USA, it is not surprising that reproductive strategies are known for only a few of the tropical members of the family. In North America, on the other hand, extensive investigations have revealed that *Cistothorus* wrens are frequently polygynous. In one Canadian study of Marsh Wrens, undertaken in Manitoba, a total of 120 males consisted of ten bachelors, 53 monogamists, 48 bigamists and nine trigamists, suggesting an unequal sex ratio of about 0·65 males for each female. In contrast, a study in Georgia, in the south-east USA, revealed only 5% bigamous males. Being mated to a bigamist has

*The **Northern House Wren**, one of the best-known members of the family, is a cavity-nester. It lives commensally with man, and in line with this association it often nests in artificial sites, such as nestboxes, holes in walls, or cavities in sheds. Natural sites include the disused nests of orioles, swallows, kingfishers, and, as this photograph proves, those of woodpeckers. Wherever the cavity, and whichever its original excavator, male wrens pile up a large foundation of coarse twigs, leaves, bark and other material, on top of which females add a cup, and a lining of hair, wool and feathers. Cavity-nesting wrens do not build a roof over their nest.*

[*Troglodytes aedon*, Ontario, Canada. Photo: Arthur Morris/ Birds as Art]

Unlike most Campylorhynchus *species, the* ***Thrush-like Wren*** *regularly nests inside tree cavities, or holes in eaves. It is not a true cavity-nester, however, as it merely uses large apertures and always builds a roof over its nest. Moreover, most nests are not sited in cavities at all, but in the crotches of palms or the upper branches of trees. In these cases, the design is more typical of the genus: a disorganized dome of twigs and grasses with an outside ante-chamber and an inner breeding chamber. In their zeal, these boisterous wrens often collect odd materials to incorporate in their constructions, and thus some nests are festooned with snakeskins and scraps of plastic.*

[*Campylorhynchus turdinus hypostictus*, Serra dos Carajás, Pará, Brazil. Photo: Luiz Claudio Marigo]

The most interesting aspect of the reproductive behaviour of the ***Sedge Wren*** *is its nomadic nesting strategy. The race* stellaris, *pictured here, breeds between May and September every year, but in different regions the nesting period is concentrated at different times. This is apparently because northern birds breed first, then migrate to marshes further south, where they breed again. As a corollary of this mid-season, between-brood, migratory tendency, breeding birds are often so highly clumped as to appear colonial. The nest is a typical globe-shaped structure with a side entrance, located low down in sedges and tall grasses.*

[*Cistothorus platensis stellaris*, Pickering, Ontario, Canada. Photo: George K. Peck]

its disadvantages. For instance, female Marsh Wrens with promiscuous mates tend to receive short shrift from the partner when it comes to providing care for the nestlings, and are frequently left entirely to their own devices. Polygyny occurs also among Sedge Wrens, although less frequently than is the case with the related Marsh Wren. Female Sedge Wrens mated to an already mated male tend to nest later, to lay fewer eggs and to rear fewer young when compared with females in a monogamous relationship, and they rarely attempt a second brood; furthermore, their nestlings tend to weigh less than do those of monogamous parents, no doubt because they receive less food.

Polygamy is known to occur in those species of *Troglodytes* which have been studied. In western European populations of the Northern Wren, about half of the males are polygynous, although polygyny is apparently rarer among the North American races of this species. Substantial levels of polygyny have, however, been discovered in some populations of the Northern House Wren, especially in situations where surplus nest-sites are available. Secondary females tend to be less successful in rearing young than are primary ones, the latter having the help of the male in the feeding of nestlings. Notwithstanding this, some female Northern House Wrens seem preferentially to choose an already mated male, even when surplus bachelor males are available. Presumably, in those cases, the advantage of passing on one's own genes in combination with the genes of a particularly fecund male outweighs the reduction in the absolute number of offspring produced. In contrast to its northern relative, the Southern House Wren appears to be only rarely polygamous. In one detailed study of this species in Colombia, no instances of polygamy were observed, although, in a Panamanian study, both the active displacement of the male of a mated pair by an intruding male and the opportunistic taking-over of a bereaved female were recorded.

In an interesting study of Northern House Wrens that utilized nestboxes at the University of Wisconsin–Milwaukee Field Station, N. E. Poirier and colleagues found that mate-switching during a single breeding season was fairly common. Although this was initiated by the male, it was not correlated with his paternity of the first brood. It was found that males were more likely to change partner when unmated females were nearby. Such males generally started to advertise for a new mate during the incubation stage or the early part of the nestling stage at their first nest, and they successfully paired with a different female during and just after the nestling period. As mate-switching males sired more or less the same number of young as did males that stayed with the same partner, they appeared not to benefit directly from switching mates. Of the females that were deserted, on the other hand, half did not find a second mate during the breeding season and thus incurred a reproductive cost.

Co-operative breeding by birds is a more common phenomenon than was previously believed, having been documented for a number of different, unrelated avian families. Typically, it involves the assistance of individuals other than the mated pair in defending territories against conspecifics, in rearing young and in defence against predators. The "helpers at the nest", to use the phrase coined by Skutch, are usually blood relatives of the primary breeding pair. By enhancing the survival of that pair's young, the helpers also ensure the propagation of their own genes, albeit in a more diluted manner. Among the troglodytids, co-operative breeding reaches its most developed form in some of the tropical members of the genus *Campylorhynchus*. In the Stripe-backed Wren of Venezuela and Colombia, breeding groups can contain up to 14 individuals, consisting of a dominant breeding pair and numerous assistants, which are mainly the pair's offspring from previous broods. Several group-members may sing, and all may participate in defensive activities against, for example, Shiny Cowbirds (*Molothrus bonariensis*); the two dominant individuals, are, however, the only breeders and are the most persistent singers. All members of a group may assist in the rearing of the young, and breeding success is strongly correlated with the number of assistants available. The young wrens usually remain with their natal group for up to a year, after which all females, and the majority of males, disperse to nearby groups, thus reducing the potential for incest. Vacancies in large groups are much sought after and are the subject of much competition; small

*The domed nest of the **Marsh Wren** is built of thin strips of leaves and grass. It is about 18 cm high, 12 cm wide, and typically sits about a metre above water (or high-tide) level. Through a side entrance a cavity is reached, and this is lined by the female with fine leaves, cat-tail down, and feathers. The difficulty of concealing these bulky structures provides one explanation for the male's habit of constructing numerous nests: the wealth of unused sites may throw a predator off the scent. While this dilution effect could be a positive by-product of having multiple nests, it seems unlikely to explain the evolution of the male's industrious behaviour, which, in all likelihood, stems from a suite of factors. In any case, breeding nests can be distinguished from non-breeding nests, with practice, by the presence of a small sill below the entrance-hole. This sill seems to retain the eggs within the cavity, preventing them from rolling out in high winds.*

[*Cistothorus palustris palustris*,
Long Island,
New York, USA.
Photo: Tom Vezo]

Over the years, one of the strongest arguments against placement of the ***Donacobius*** *amongst the wrens has been that its nest, a very deep, cup-shaped structure, lacking a side entrance, and built mainly by the female, is unparalleled within this family. The female incubates the eggs alone, but both sexes provision the young, often assisted by one or two closely related helpers. Interestingly, adults have been reported dipping their underparts in water so that the brood is cooled during hot weather, and the nestlings' mouths are pink with three black spots, a pattern almost unique in South American passerines.*

[*Donacobius atricapilla atricapilla*, Minas Gerais, Brazil. Photo: Anita Studer]

groups, on the other hand, may have difficulty in filling vacancies. Individuals joining adjacent groups initially have a low rank within that group, but later rise to a senior breeding status.

The Fasciated Wren of western Ecuador and Peru has been less intensively studied than has its close relative the Stripe-backed Wren, but it appears to have a well-developed co-operative breeding strategy, with groups of up to ten individuals for each breeding pair, the young of one year remaining to assist with nesting in the next year. Conventional, unaided pairs do also exist, however. As for other members of the genus *Campylorhynchus*, the degree of co-operative breeding varies both among species and within a given species. In a Venezuelan study, for example, two different populations of Bicoloured Wrens had quite different strategies. In one population, only 15% of nests had a helper, and then only a single one, whereas more than half of the nests in the other population had assistants, often several of them and of both sexes. Some other *Campylorhynchus* species show some degree of co-operative breeding, but the strategy seems to be less pronounced in the more northerly species. The Cactus Wren, resident in the southern USA and the northern half of Mexico, is essentially a conventional breeder. On rare occasions juveniles of one brood have been seen to bring food to a subsequent brood, but this seems to be exceptional.

Of particular interest is the reproductive behaviour of the recently described subspecies *hernandezi* of Apolinar's Wren, which differs from the nominate race in indulging in classic co-operative breeding, with group defence of the territory but only one pair nesting. This appears to be the first report of this reproductive strategy, as opposed to polygamy, for the genus *Cistothorus*.

Finally, co-operative breeding has been suspected also for the Peruvian Wren (*Cinnycerthia peruana*). In this case, the variable amount of white feathering on the face of adults may indicate social and breeding status.

With the exception of the cavity-nesting species, and disregarding the atypical Donacobius, all wrens build an enclosed, roofed nest with a side entrance. In the genera *Henicorhina*, *Cistothorus*, *Troglodytes*, *Campylorhynchus*, *Thryorchilus* and *Ferminia*, and in some *Thryothorus*, the general nest form is an ovoid ball made from grass, rootlets and fibres and with a hole at the side. In the case of the Marsh Wren, the breeding nests are distinguished from surplus or dummy nests by the fact that they have a sill at the entrance, which prevents the eggs from rolling out in windy conditions. The female usually lines the nest with finer material, hair and feathers. In other troglodytid genera, the nests are more elaborate in form, often with an entrance tube pointing downwards. That of the White-bellied Wren, in the monotypic genus *Uropsila*, is a beautifully woven structure resembling an old-fashioned chemical retort, with an ovoid nesting chamber and downward-pointing entrance tunnel. Some *Thryothorus* species, such as the Happy and Sinaloa Wrens, build a similar type of two-part nest, often draped over a twig so that the breeding chamber is on one side and the entrance on the other. A similarly shaped nest, suspended over a twig, is made by the Peruvian Wren, but the nests of the other three members of the genus *Cinnycerthia* have not been described. Likewise, the nest of the Song Wren, the best-known member of *Cyphorhinus*, is boomerang-shaped, an untidy structure of coarse roots and leaf skeletons placed over a thin branch.

Cavity-nesting wrens do not build a roof over the nest. Males of both the Northern House Wren and the Southern House Wren fill the nesting cavity almost completely with coarse twigs, or even with such items as bits of rusty wire, before the female, after adding more twigs, builds a cup and lines this with hair, wool and feathers. Information on the nests of the four *Microcerculus* species is scanty, but those described are open structures made from dead leaves.

The crevice-nesting Canyon Wren constructs an open cup of wool, hair and feathers on a base of twigs and moss. Frequently, extraneous matter is included. One especially larcenous Canyon Wren in California regularly pilfered an extraordinary collection of loot from a nearby office, to the total of 600 paper clips, 500 pins, 100 matches and such other miscellaneous sundries as pennibs, screws and similar odd items. The American Rock Wren, also a crevice-nester, has the peculiar habit of building a nest foundation of pebbles. The expenditure of energy for this is by no means trivial; one nest of this species, the only member of the genus *Salpinctes*, had 2·2 kg of pebbles, the equivalent of 120 times the 18-g body weight of the wren itself, with the largest pebble, at 6 g, weighing almost a third of the bird's own weight. The evolutionary advantage of this major expenditure of energy is obscure; curiously, similar behaviour is exhibited by the Black Wheatear (*Oenanthe leucura*), an inhabitant of rocky slopes in

Spain and Morocco. The Thrush-like Wren (*Campylorhynchus turdinus*) of central South America also frequently includes extraneous objects in its nest, a habit which has given rise to local legend in Bolivia (see Relationship with Man).

In certain cases, the form of the nest is dependent on the selected nest-site. Thus, the Carolina Wren usually builds a domed nest, but in totally enclosed sites, such as nestboxes, it may reduce or omit the roof. Bewick's Wrens, too, will build either an open nest or a domed one according to circumstances.

There is much variation in nest-sites among the Troglodytidae, and sometimes even among members of the same genus. Most wrens nest in vegetation of various kinds, the *Thryothorus* and some *Troglodytes* species typically in dense brush, *Cistothorus* and *Ferminia* in grasses and rushes, and *Campylorhynchus* in various bushes and cacti. Other species are cavity-nesters. In North America, for example, the Northern House Wren relies heavily on artificial sites, both nestboxes and such incidental locations as cavities in sheds, but it also uses natural cavities such as woodpecker (Picidae) holes and a variety of other sites; the latter include old nests of paper wasps (*Polistes*), from which the wren first removes some of the interior structure, and the riverbank burrows of Belted Kingfishers (*Megaceryle alcyon*), the mud-bottle nests of Cliff Swallows (*Petrochelidon pyrrhonota*) and the pendent nests of Northern Orioles (*Icterus galbula*). The petrophilous wrens, those in the genera *Salpinctes*, *Catherpes* and *Hylorchilus*, nest in rock crevices, while the Southern Nightingale-wren, in *Microcerculus*, utilizes the disused burrows of other species, either in sandy banks or in old termite (Isoptera) nests.

Several members of the family have learnt to place their nests in naturally defended sites. A prime example is that of the Cactus Wren, which makes little effort to conceal its nests, instead building them in the savagely spiny cholla cactus, which acts as an effective deterrent to such predators as raccoons (*Procyon lotor*) and ring-tails (*Bassaricus astutus*). Some other troglodytids nest in spiny bromeliads or nettles. Several species, in different genera, routinely site their nests in places where they can obtain vicarious protection, by hostile insects, from such mammalian predators as monkeys. Thus, the Sinaloa and Happy Wrens frequently build in bushes next to the nests of hornets (*Vespa*). In the American tropics, there exists a curious symbiotic relationship between ants of the genus *Pseudomyrmex* and bull's-horn acacia trees. The ants nest in the hollow acacia thorns and feed on nectar and small nutritious corpuscles, called "Beltian bodies", provided by the tree; in return for this board and lodging, the ants defend the trees against predatory insects and, further, even remove weeds from the ground around the trunk of emerging plants. Bull's-horn acacias thus represent a very hostile environment, one where the ants are in effect "kept by the acacia as a standing army" and savagely attack the unwary intruder. Several wrens have learnt to capitalize on this, by siting their nests in such trees. The White-bellied Wren in Guatemala almost invariably nests in acacias, and in Costa Rica the Rufous-naped Wren goes even further, actively seeking out trees with the most aggressive ants and defending them against birds of other species. Wrens building in such secure locations appear to make little effort to conceal their nests. In contrast, the Bicoloured Wren, which does not routinely build in ant-inhabited trees, hides its nests much more effectively. Although the presence of wrens' nests would seem to confer no obvious advantage either on the tree or on the ants, the birds and their young are not molested by the insects.

The Troglodytidae exhibit considerable variation not only in nest-sites, but also in egg colour and in clutch size. Egg colour can vary within a genus, and sometimes even within a species. In the genus *Thryothorus*, some species lay immaculate white eggs or, more rarely, pale blue, bluish-green or deep sky-blue ones, while the eggs of other species are whitish or buff-white with a variable amount of brown or cinnamon speckling or blotching. Similar variation occurs in the genus *Campylorhynchus*: the eggs of the majority of its members are whitish with speckles or blotches of various shades of brown, but those of the Stripe-backed and Band-backed Wrens are plain white. In the case of the Cactus Wren, even different subspecies lay distinctive eggs, *affinis* in southern Baja California having paler eggs than those of the races in coastal California, and inland races having egg markings that are more brightly coloured. Similarly, the Sedge Wren lays white eggs in most parts of its huge range, but in Tierra del Fuego the local race *hornensis* lays speckled eggs, and an Aleutian race of the Northern Wren, *meligerus*, has white eggs, in contrast to the heavily marked eggs of other subspecies. A further example of intraspecific variation is provided by the Marsh

*The **Moustached Wren** is an abundant and familiar bird across a large swathe of South America, but there is almost nothing on record about its nesting behaviour. Its nest and eggs have apparently never been described, and it is not clear whether it breeds co-operatively. This is a wonderful example of the mismatch of scientific attention focused on temperate and tropical birds, the latter having been largely ignored until recently. We might speculate that, like most wrens, it feeds its nestlings a diet of insects (indeed, this individual is carrying a hymenopteran for its brood), but clarification of the simple aspects of its breeding biology can only result from studies in the field.*

[*Thryothorus genibarbis genibarbis*,
Alagoas, Brazil.
Photo: Anita Studer]

In most well-studied wrens the female broods alone, but both parents feed the young large numbers of insects. The ***Northern Wren*** *is no exception. The eggs of this species are tiny, and the clutches it lays are correspondingly large, ranging from three to nine eggs, with five to eight eggs being entirely normal. Even larger clutches (up to 17 eggs) have been recorded, but these are probably the result of two females laying in one nest. Even so, normal clutches hatch into a lot of hungry mouths, and this keeps both adults busy for 14–19 days.*

[*Troglodytes troglodytes troglodytes*, Navalmoral de la Sierra, Ávila, Spain. Photo: Juan Manuel Hernández]

Wren, the eggs of which are usually chocolate-coloured or brown, spotted with darker brown, but some individuals appear to lay clutches of white eggs. Sometimes, single white eggs also appear in a clutch.

There is a general tendency among passerines for clutch sizes to be smaller in tropical regions than they are in temperate ones, while tropical species, perhaps as a means of compensating for this low fecundity, have longer breeding seasons and, often, more broods. This principle seems to hold for most troglodytids, and, indeed, is sometimes apparent even within one species. Thus, the wood-wrens, the *Microcerculus* wrens and the *Cyphorhinus* wrens, among other tropical species, lay only two eggs. The clutches of many tropical members of the genus *Thryothorus* often consist of only two or three eggs, whereas the Happy and Sinaloa Wrens, temperate representatives of the same genus in northern Mexico, usually lay five. For the Cactus Wren, the normal clutch in Arizona is of three to five eggs, rarely up to seven, but the same species in Baja California usually lays just two eggs. Similar variations are found in other species, representing several genera. Frequently, as demonstrated by the Northern Wren and the American Rock Wren, island subspecies have smaller clutches than those of their mainland counterparts.

Wrens are usually multi-brooded, insofar as the local climate allows. In temperate regions, with a constrained breeding season, there is a rush to launch one brood successfully before starting another one. Parental care of the fledged young tends, therefore, to be of short duration in North America and Europe, while in many tropical species the family-members remain together as a feeding party for several months after leaving the nest. This doubtless enhances the survival rates of offspring and thereby compensates for smaller clutches. An exception to this general tropical strategy is provided by the Southern House Wren. Athough the clutch size of this species is small when compared with that of the closely related Northern House Wren, the Southern House breeds rapidly and frequently, one female in Colombia having been observed to raise as many as seven broods in a period of just 17 months.

Incubation of the eggs seems to be the duty exclusively of the female. In some cases, she may be fed on the nest by the male, although in polygynous species, such as the Marsh Wren, she usually receives lamentably poor provision. Incubation periods tend to be longer among the larger species than among the smaller ones. For example, the Cactus Wren sits for up to 23 days and other *Campylorhynchus* species for 17–20 days, whereas the duration can be as short as 12 days for the American Rock Wren and the Canyon Wren. The incubation period of the small wood-wrens, however, is usually 18–20 days. The nestlings are generally fed by both parents, but in the case of polygynous species the contribution of the male may amount to little or nothing. Among the co-operative breeders, on the other hand, a variable number of helpers assist with brood-feeding.

In the tropics, the young wrens frequently associate with their parents for a prolonged period after fledging, in some cases for almost a year. Parental feeding of the fledglings is probably limited to a much shorter period, but with many species the parents and juveniles remain together as a family unit for months on end. It is easy speculate how such associations may evolve into the co-operative nesting behaviour so typical of the tropical *Campylorhynchus* wrens; after all, if the time is not right for the individual to reproduce, the next best option for it to propagate its own genes is to enhance the survival of its own siblings, even those of different broods.

Interestingly, in Costa Rica, young Southern House Wrens of one brood have been observed to assist in the feeding of their parents' subsequent broods, even though this behaviour seems to be rare for this *Troglodytes* species. Among temperate members of this genus, such as the Northern House Wren or the Northern Wren, parental care of fledged young is of short duration, usually lasting for no more than two weeks, after which the juveniles are left on their own. One could speculate that, for migratory species, the necessity of building up fat reserves prior to migration could have a greater survival benefit in terms of "the selfish gene" than does the enhancing of the survival of one's siblings.

The domed nest form of most wrens and the cavity-nesting habit of the remainder appear to provide these birds with some protection from parasitic species. Nevertheless, brood parasitism is a significant factor in reducing the nesting success of certain troglodytids. In some parts of the USA, up to 25% of Carolina Wren nests fail as a result of parasitism by the Brown-headed Cowbird (*Molothrus ater*). In the Neotropics, the Shiny Cowbird is generally the main culprit in this respect, although it is not a major problem for troglodytids in this region. On the other hand,

The nests of the ***Northern Wren*** *are located in a variety of sites, frequently in dense vegetation but also in cavities and crevices. Favoured spots include ivy-covered trunks and walls, and the tangled roots of fallen trees, but in truth the range of locations is so broad that it is difficult to identify preferences. Wherever they breed, they lodge their nests in well-concealed sites, and leave a tiny aperture for their comings and goings, thereby minimizing predation. Another hazard usually avoided is that of brood parasitism. Old World cuckoos* (Cuculus) *and New World cowbirds* (Molothrus) *sometimes lay in the nests of Northern Wrens, but rarely. They are probably kept at bay by the closed structure and narrow entrance to the nest itself. Indeed, it is not impossible that domed nests evolved in wrens not only in response to predation but also to brood parasitism. Either way, they seem to have proved a rather effective deterrent.*

[*Troglodytes troglodytes*. Photo: Stephen Dalton/ NHPA]

two *Thryothorus* species, the Rufous-and-white and Buff-breasted Wrens, are frequent victims of the American Striped Cuckoo (*Tapera naevia*) in South America, and the Northern Wren in Europe is occasionally parasitized by the Common Cuckoo (*Cuculus canorus*).

Finally, the nesting habits of the Donacobius exhibit several interesting features, formerly used by taxonomists to argue for this species' inclusion in or, paradoxically, its exclusion from the Troglodytidae. This is a co-operative nester, at least in situations where it occurs at high density. The breeding unit varies from simply the nesting pair alone to groups of up to four individuals. The nest is an open cup, quite unlike that of any other member of the family, and is built in vegetation, often over or at the edge of water. Over most of its range, which extends from east Panama across to the east coast of Brazil and southwards, east of the Andes, to north-east Argentina, the Donacobius lays a clutch usually of two eggs, but in Brazil frequently of three. The eggs, purplish-white and covered by heavy purplish blotches, are incubated by the female alone, for a period of about 16–18 days. A curious habit of the adults is that of cooling the nestlings by wetting them with water brought on the adults' breast feathers. The breeding success of this species is correlated with the amount of help available; pairs without helpers are usually able to rear only one chick to fledging, whereas those with helpers can succeed in raising two or three young. In contrast to most wrens, the Donacobius appears to be single-brooded.

Movements

The great majority of wren species appear to be very sedentary. In other words, not only is the species found in a particular location throughout the year, but probably the very same individuals are present there in all months. After leaving the family group, the juveniles will disperse, probably in a random manner, until they encounter a vacant territory. In the case of the co-operatively nesting Stripe-backed Wren, the young of both sexes remain with the breeding group for a year or so, after which all females and the majority of males disperse to breed with nearby groups; the distance in terms of linear displacement may, however, be very short.

Most tropical wrens appear to be sedentary even when faced with major climatic fluctuations, such as the wet and dry seasons of Central America and northern South America. In a few cases, some altitudinal movement appears to occur, although the data are scanty and the precise nature of the movement not clearly understood. For example, the Merida Wren seems to vacate some habitats during the rainy season, and in El Salvador the Rufous-and-white Wren occurs in winter at sea-level in thickets of the palm *Bactris subglobosa*, a habitat known locally as "*huiscoyol*", whereas it is not found below 300 m in the summer. At the northern edge of its range, in the Sierra Madre of Mexico, the Happy Wren migrates vertically, but no such movements have been noted farther south in its range.

When one moves into temperate zones, however, it is noticeable that troglodytids become increasingly less sedentary. The North American populations of the Sedge Wren, for instance, are totally migratory, with no overlap at all between the breeding range, which extends from Saskatchewan east to Quebec and south to Kentucky and Pennsylvania, and the non-breeding range, mainly in the coastal states from Virginia south to north-eastern Mexico. These North American populations are also unique in that they are nomadic during the breeding season, abandoning some areas and, later in the same season, appearing in others. In contrast, the Sedge Wrens in Middle America, from the highlands of southern Mexico southwards to Costa Rica, seem to be entirely sedentary. In South America, too, the Sedge Wren populations, which may perhaps represent two separate species (see Systematics), are similarly non-migratory; here, the southernmost subspecies, *hornensis*, experiences very harsh conditions during the austral winter, although the type specimen of this taxon was taken on a ship "twenty leagues south-east of Cape Horn", suggesting that some movement may occur at times.

A similar distinction in the movements of different populations is exhibited by the Marsh Wren complex of taxa. Those summering in the vast area from northern Alberta eastwards to New England are entirely migratory, spending the winter months along the Atlantic seaboard from New York south to Mexico, whereas the subspecies breeding in coastal habitat in the eastern USA are either partial migrants, in the north, or sedentary. In some coastal marshes in the southern-eastern USA, the Marsh Wren populations present in winter are a mixture of sed-

Both sexes of ***Marsh Wren*** *generally provision the brood, but not so polygamous males, which are somewhat negligent of their parental duties. Nestlings are nurtured intensively for 13–15 days, receiving a wide variety of insects along the way, in this case a fairly large aquatic species, perhaps a newly emerged dragonfly. After fledging, young wrens may be fed by one or more parents for another couple of days or so, but they achieve full independence very rapidly.*

[*Cistothorus palustris palustris*, Dryden Lake, New York, USA. Photo: Marie Read]

entary local breeders and winter visitors from farther north. A totally sedentary race is found in central Mexico. Vagrant Marsh Wrens have been recorded in Bermuda and Cuba, illustrating this species' ability to cross large expanses of open water.

In western North America, the American Rock Wren is partially migratory. It vacates the northern portion of its range, from British Columbia south to Colorado, in winter, whereas the species is present throughout the year in the remainder of the western USA and in Mexico; again, disjunct populations from south Mexico south to Costa Rica are totally sedentary. The American Rock Wren is a notable vagrant, stray individuals turning up, usually in October and November, in various places across eastern North America, from Newfoundland and New Jersey south to Louisiana and Florida. The Canyon Wren, on the other hand, appears to be much more sedentary. Although it does undertake some altitudinal movements in the northern parts of its range, occurrences of vagrants are fewer, and in localities closer to the breeding area.

A very limited partial migration takes place in the case of Bewick's Wren, the eastern populations of which are more mobile than are the western ones. Carolina Wrens are essentially sedentary, but they do crop up extralimitally, sometimes in locations well removed from the breeding range. Of over 500 recoveries of individuals of this species ringed in North America, only 31 had made any movement at all, and only three demonstrated significant displacement, having covered distances of, respectively, 250 km, 150 km and 75 km. Extralimital movements made by the Carolina Wren may involve wandering by juveniles in their first season.

The two *Troglodytes* species breeding in North America are strongly migratory. For the Northern House Wren, a large body of data has been amassed from recoveries of ringed birds, and this information allows a detailed analysis of movements; for no other wren species in the Americas are there adequate data for such studies. The Northern House Wren is totally migratory; apart from a small area of southern California, there is no part of its range where it occurs in all months of the year. Individuals ringed on the breeding grounds in coastal eastern North America appear to winter in Florida. Inland breeders, from east of the Appalachians, migrate on a broad front to non-breeding quarters extending mostly from Texas eastwards to Georgia and Florida, those from the eastern part of the breeding range tending to winter farther east than do those from more westerly areas; there are, however, a few recoveries demonstrating strong longitudinal displacements, as, for example, from Ontario south-west to as far as Texas. Northern House Wrens breeding on the Great Plains and the Prairie Provinces of Canada, in contrast, have a strongly south-eastern orientation of migration. There are no significant recoveries of house wrens ringed in western North America. This species has occurred as a vagrant in western Cuba, the Bahamas, Newfoundland, and as far north as Churchill, in the Canadian province of Manitoba.

The Southern House Wren, incidentally, is essentially sedentary over most of its vast range, although it displays a remarkable ability to appear in small isolated patches of suitable habitat when these are created by human activity. The populations in extreme southern South America, however, are truly migratory, leaving southern Tierra del Fuego during the austral winter. The precise whereabouts of their non-breeding quarters are not known, and no information on their movements is available from any ringing studies.

For the other *Troglodytes* wren of the Nearctic, the Northern Wren, the situation is more complex. The bulk of the breeding range, from northern British Columbia across southern Canada to Newfoundland, is vacated after the breeding season, when the wrens migrate to a wintering range that extends from New England south to Florida, Texas and north-eastern Mexico; the species occurs in all months in southern Ontario and the Appalachian chain, but it is not certain that it is the same individuals that are present there throughout the year. Western North American populations may be partially migratory or sedentary. The numerous endemic subspecies of the Aleutian chain and the Pribilof Islands are known to be totally sedentary, and those breeding in the region from Alaska south through northern California appear to be so. In southern California and Arizona, however, the species does occur in winter but is absent in the summer months.

In the Old World, the Northern Wren again comprises a mixture of sedentary and migratory populations. The species leaves most of Scandinavia and north-western Russia after breeding, as it appears unable to tolerate winter conditions north of the –7°C

Towards the end of the nestling period, an adult ***Northern Wren*** *arrives at the nest every few minutes with a billful of prey. When this frantic provisioning finally bears fruit, and the nestlings fledge like a stream of fluffy balls spilling from the tiny entrance, it often seems incredible that so many could fit, never mind survive and grow, in such a small and firmly constructed cavity. Once out of the nest they are fed for a further 9–18 days before becoming totally independent.*

[*Troglodytes troglodytes hiemalis*, Thunder Bay, Ontario, Canada. Photo: Wayne Lankinen/ DRK]

There is a relationship between latitude and several forms of breeding data in wrens. Clutch size in the ***Northern House Wren****, for example, increases with latitude, while the number of broods decreases. Northern birds suffer lower temperatures and a shorter insect emergence. Perhaps predictably, therefore, they often only manage a single brood per year, this becoming two broods further south, while birds in the southernmost reaches of the range are regularly triple-brooded.*

[*Troglodytes aedon aedon*, Pennsylvania, USA. Photo: Joe McDonald/ Auscape]

isotherm. In western Europe, from Iceland south to the Mediterranean Basin, and from the south Baltic region south to Poland and the Ukraine, the Northern Wren occurs throughout the year, as it does also in north Africa, Turkey, Cyprus, the Caucasus and northern Iran. Isolated island populations, such as those on the Faeroes and St Kilda, are also sedentary. Farther east, in the Himalayan region, eastern China, Japan and Taiwan, it is likewise observed in all months. The breeding grounds in northern China and eastern Siberia, including Kamchatka and Sakhalin Island, are vacated in winter, although the species is resident on the Commander Islands, east of Kamchatka.

Whereas there are, unfortunately, no worthwhile ringing data for the Northern Wren in North America, a substantial number of ringing recoveries exists in Europe. Individuals breeding in Norway have been encountered in winter in the region from northern Germany south to Belgium; wrens from Sweden and the Baltic area tend to have a generally, but not exclusively, south-western orientation, with recoveries reported from Hungary westwards, all the way to south-western France and eastern Spain. Northern Wren movements in Britain seem to be of two distinct types. The first is a short-distance movement of up to 50 km, and is essentially random in orientation, while the second is longer, up to 250 km, and with a markedly north-south orientation between summer and winter and the reverse heading in spring. A number of wrens that had been ringed at locations on the south coast of England have been recovered in France, including several in the south of that country. These may well have involved individuals that were already on migration when they were caught for ringing, since it is obvious that the vast bulk of British Northern Wrens, which are subspecifically distinct from mainland European ones, do not leave the British Isles.

Observations of birds striking tall buildings, TV towers, lighthouses and similar structures at night, or being found dead in the morning at such places, indicate that all migratory troglodytid species in North America and Europe migrate nocturnally. This can occasionally lead to considerable mortality (see Status and Conservation).

It is worth mentioning here that the Donacobius, almost certainly not a "true" wren (see Systematics), appears to be a very sedentary species. In one study in Peru, in which birds were individually marked, there was no evidence of any movement between patches of suitable habitat that were separated by a distance of only 2 km.

Relationship with Man

In crass economic terms, wrens have little impact on human beings. Their habitats, whether they be forest, scrubland, marsh or desert, rarely impinge upon agriculture. Apart from a few records of the larger *Campylorhynchus* wrens attacking soft fruit, the members of this family seldom interact, for good or ill, with farming. There is the possibility that, in certain geographically restricted cases, various wren species may make a modest contribution to local economies in terms of attracting birdwatching visitors. If arrangements for such small-scale tourism were handled properly, species such as the Zapata Wren of Cuba could doubtless bring in minor amounts of hard currency from visiting ornithologists, and a little employment for local people, without further endangering the species itself. Any such economic benefit, however, will always be indeed modest; wrens are, after all, neither lions nor elephants.

In contrast to the minimal economic interaction between the Troglodytidae and humans, the role of wrens in folklore and legend is extraordinarily widespread and pervasive. This is especially true of the Northern Wren in Europe. It is odd that a small, brown, inedible bird should be so important in the folklores of so many diverse cultures. Indeed, in western Europe, among passerines, probably only the European Robin (*Erithacus rubecula*) figures more prominently. Doubtless, this is due in some measure to the loudness of its song. Certainly, the songs of the members of this family make them difficult to overlook. In Canada, for example, the name for the Northern House Wren in the Ojibway language of Ontario translates literally as "he who makes a lot of noise for his size".

One common feature in many different cultures is the recognition of the wren as the "King of the Birds". In a number of European languages, as diverse as Dutch, Classical Greek, Polish, Romanian and Lithuanian, among others, the vernacular name for the Northern Wren implies royalty. One example is the Ger-

*The nest of the **Canyon Wren** is unusual. It is an open cup of wool, hair and other material, with a base of coarser twigs, built by both sexes in a shady recess or rocky crevice, but also frequently in ruined buildings and other artificial sites. Some individuals incorporate artificial debris into the structure, an inexplicable habit taken to extremes by the nest-building pair in California which pilfered 100 matches, 500 pins and 600 paper clips, plus a collection of similar junk, from a nearby office.*

[*Catherpes mexicanus*, Kickapoo Cavern State Park, Texas, USA. Photo: George K. Peck]

man *Zaunkönig*, meaning "king of the fence". Elsewhere, however, the mantle of royalty seems to have been taken over by the even smaller *Regulus* kinglets, which, for example, are known in France and Spain respectively as *roitelet* and *reyezuelo*.

How did the tiny wren become the birds' king? One legend, widespread among several European cultures, tells of a contest among the birds for the throne; the one which could fly the highest would inherit the crown. As might be expected, this was the eagle. As the eagle, exhausted and incapable of further climbing, was about to call down to the unsuccessful claimants below to proclaim his triumph, the wren, which had concealed itself among the eagle's back feathers or, in some versions, under his wing, popped out and flew a few feet higher. The origin of this widespread legend is obscure, but it may have come from one of Aesop's fables, since lost. Aesop himself probably acquired many of his fables from Indian sources, although, curiously, an almost identical legend is found among the Canadian Ojibway people.

An obviously related legend, again widespread in western Europe, involves the bringing of fire, or light, to the world by the wren. This entailed a flight to the heavens from which the wren returned successfully, but with all of his feathers burnt off. In gratitude, all except one of the birds agreed to give the wren one of their own feathers so that he could clothe his nakedness. The single exception was the owl, which maintained that he had none to spare. As punishment for his stinginess, the owl was for ever thereafter condemned to a solitary life; harassed by small birds during the day, and spending the nights alone in the dark forest, making forlorn and mournful hooting noises. A variation of this story identifies the robin as the fire-fetcher, although in Breton legend it was Hell, not Heaven, that provided the fire. In eastern Europe, the fire-bringer was the swallow.

A remarkable tradition, formerly practised in much of western Europe, was the wren hunt. Typically, this took place on St Stephen's day, or Boxing Day, 26th December, although in some locations it happened on Christmas Eve, on Christmas morning, on the Epiphany, or "Twelfth Night", or even on St Valentine's Day. Basically, groups of young boys would catch wrens and attach them to decorated poles, a holly bush (*Ilex*) or, in Wales, a house adorned with ribbons. The unfortunate bird would then be paraded by a procession of boys and young men in strange and fantastic garb, some dressed as women, sometimes with blackened faces and carrying wooden swords; in Ireland, the parade took place to the accompaniment of doggerel verse and the music of flutes and the *bodhrán*, a traditional drum. The young participants then went from door to door, soliciting modest funds and treats. In the Isle of Man, the wren would sometimes then be interred with due solemnity and respect, to the sound of dirges sung in the now extinct Manx language. Wren-hunting occurred widely in the British Isles, not only in the Celtic areas but also in such counties as Suffolk and Surrey, as well as in parts of France. The tradition seems to have been strongest, however, in southern Ireland and the Isle of Man. Manx fishermen carried wren feathers with them to sea as protection against shipwreck, while in Scotland fisherfolk scattered wren feathers into the wind in the belief that this would enable them to predict the profitability of the herring (*Clupea harengus*) harvest.

The origins of the wren hunt are obscure. According to one legend, the wren betrayed St Stephen as he was trying to escape from jail, thereby causing his martyrdom. There are several Irish legends. In one of these, the wren was cursed by St Moling for eating the holy man's pet fly. In another, a wren (presumably a Protestant wren!) was blamed for warning King William of Orange's sleeping forces of a stealthy Irish attack, by jumping up and down on a drum; most interestingly, exactly the same story existed seven hundred years earlier, but in this case it was somnolent Danes who were aroused. In all probability, the origins of the tradition date back to early or pre-Christian times. In Celtic mythology, for example, the wren was the king of the oak tree and the symbol of the Old Year, while the robin represented the New Year, hence the symbolic dispatch of the wren at a time close to the winter solstice.

In the New World, wren mythology seems to be less extensive or, in cultures lacking the written word, perhaps simply unrecorded. According to Cherokee legend, the wren closely observes women in labour, rejoicing in the birth of a girl but loudly lamenting the appearance of a boy, who will grow up to hunt the wren. In Suriname, the haunting and arresting song of the Musician Wren is reckoned to be a bad omen for hunters. In contrast, the Southern Nightingale-wren is considered to be a good talisman for deer-hunters in Brazil, although, to be effica-

*As with many cavity-nesters, nest hygiene is of paramount importance to the **Northern Wren**. This individual is carrying away a faecal sac in an act of cleanliness which is likely to increase survivorship, both for itself and its offspring. The broods of this species are so large that adults leave carrying a faecal sac almost every time they visit the nest, at least in the latter stages of the nestling period. Failure to do this would result in a dangerously fouled and malodorous cavity, and a nest entrance advertised with white excrement, features that would not only attract predators, but increase the likelihood of disease.*

[*Troglodytes troglodytes pacificus*, Queets, Olympic National Park, Washington, USA. Photo: Rob Curtis/ The Early Birder]

cious for this purpose, the bird must be captured on a Thursday or Friday during a period when the moon is waxing. The habit of some species of incorporating human artefacts in their nests (see Breeding) has led to a number of superstitious beliefs. The Thrush-like Wren, for example, frequently includes extraneous objects in its nest and, according to local legend in Bolivia, if one loses a banknote, one should examine all the local wren nests to ascertain whether the thrifty birds have incorporated it into their own nest structures.

Finally, there is the curious fact that, in the Creole languages of the West Indies, the Southern House Wren is endowed not with royalty, but also with divinity. On English-speaking islands it is called "God-bird" and on French ones "*Oiseau Bon Dieu*", while in Suriname it is known as "*Gadofowroe*".

Broadly speaking, wrens are looked upon with some affection by the general public. This is presumably due largely to their small size. This may perhaps have been in the minds of the members of the German Union for Nature Conservation when they selected the Northern Wren as the "Bird of the Year" for 2004. That body stated that the Northern Wren, although not threatened, is a symbol of a natural, diverse environment that must be maintained and protected.

*Wherever the **Northern Wren** is a garden bird, which happens to be the case across much of its range, it is known by affectionate nicknames. A veritable "troglodyte" with fearless and inquisitive habits, it seeks secluded cave-like niches for its nest, a search that regularly leads into man-made structures, especially garden huts and tool sheds. Pairs breed in an astounding variety of locations, including empty plant pots and the pockets of hanging coats. If an old teapot or a rusty kettle is lodged in ivy for wrens, they take to it cheerfully, as they do to wooden nestboxes. Indeed, large numbers of wrens sometimes roost communally in natural or artificial sites during severe weather; in one instance, 96 wrens were seen to emerge from a single roost.*

Status and Conservation

The fate of different troglodytids at the hands of man is very varied. Some species have greatly benefited from human activity, whereas others have suffered sorely. In North America, the clearing of continuous climax forest during the period of European settlement created the forest-edge habitat suitable for the Northern House Wren and Bewick's Wren, while artificial structures provided secure nesting sites, allowing for major expansions in the range of both species. In the USA, Northern House Wrens colonized western West Virginia by the late 1800s, North Carolina by the 1920s and South Carolina by the 1940s. Bewick's Wren had expanded into West Virginia by 1834, Pennsylvania by 1843, Georgia by 1854, Ohio by 1879 and New Jersey by 1890, and had reached southern Ontario, in Canada, by 1898. In contrast to the house wren, however, Bewick's Wren has suffered major declines in the eastern part of its range and now occurs only in isolated pockets east of the Mississippi; it has been proposed that the race concerned, *altus*, be listed as Endangered. The reasons for this major decline are not entirely clear, but one plausible explanation is the well-documented nest destruction by Northern House Wrens (see General Habits). The latter may, in fact, represent a conservation problem under some circumstances. In Canada, the cavity-nesting Prothonotary Warbler is confined to southern Ontario, the entire population totalling fewer than two dozen pairs. Its nesting success is adversely affected on a substantial scale by Northern House Wrens, being significantly higher in areas without these nest-destroyers. The wrens cause nesting failure by puncturing and sometimes throwing out the warbler's eggs, attacking nestlings and perhaps adults, and dropping twigs into nest-cavities already occupied by the warblers. The decline of Bewick's Wren in eastern North America seems to have coincided with the expansion of the range of the Northern House Wren. Although the attributing of the disappearance of Bewick's Wren to the Northern House Wren's activities may be a facile explanation of a more complex phenomenon, the evidence is suggestive.

The two *Cistothorus* wrens of North America have rather specialized habitat requirements, the Marsh Wren occurring in reeds, rushes and grasses over water and the Sedge Wren in damp sedgy meadows. Since Europeans settled in North America, Marsh Wren habitat has been extensively destroyed as wetlands have been drained for agriculture and other purposes. The species' total population has doubtless declined substantially, but it remains common or abundant in suitable habitat, which in some areas is now expanding as a result of the building of artificial water impoundments. It is probable that the Sedge Wren was helped by the creation of habitat through human clearances; this wren may also breed in weedy rice fields, although these are discouraged in modern farming practices. Nevertheless, Sedge Wrens are regarded as threatened in several US states. In Canada, breeding-bird surveys over the decade 1991–2000 indicate a slow population increase.

*The range of the **Wing-banded Wren** spans much of Amazonia from the Guianas to south-east Peru. Across this huge expanse it is sympatric with the Southern Nightingale-Wren* (Microcerculus marginatus)*, but it is almost always rarer than its congener, perhaps because it is more strongly tied to undisturbed forests. Its patchy distribution notwithstanding, the extent of its occurrence is too large to permit its inclusion in any threatened category, or even the holding bay of Near-threatened. Like the other* Microcerculus *wrens, it nests in cavities: only two nests have so far been described, both built some 2 m up in vacated burrows, probably initially excavated by jacamars (Galbulidae).*

[*Microcerculus bambla bambla*, Iwokrama, Guyana. Photo: Doug Wechsler/ VIREO]

No species of wren has become extinct in historical times, but several give cause for concern, and a number of subspecies have indeed disappeared. Of these, the race *exsul* of the American Rock Wren, restricted to the island of Isla San Benedicto in the Revillagigedo Group, off western Mexico, became extinct in the most spectacular fashion in 1952, when its island home catastrophically erupted. A few wrens survived the initial eruption, which also killed tens of thousands of nesting seabirds, and lingered for a few months, but all ultimately perished. All other extinctions have been caused by man, usually by the sadly familiar practices of habitat destruction and the introduction of alien predators. Two island subspecies of Bewick's Wren have been lost: *brevicauda* was one of several Guadelupe endemic taxa that vanished from that island, off Baja California, prior to 1892, and *leucophrys*, of San Clemente Island, California, became extinct by, probably, 1986. In the West Indies, the Martinique race of the Southern House Wren became extinct about 1900. Two other races of that species, *guadeloupensis* on Guadeloupe and *mesoleucus* on St Lucia, are hovering on the brink, if they have not already gone over it; the first was believed to be extinct, but a tiny population was rediscovered in 1969 and 1973, and the second still persisted, in very small numbers, in 1984. No recent information is available for either subspecies. On some other islands, such as Dominica, the local races of the Southern House Wren remain common. Given the ability of this species, over most of its range, to adapt to or, indeed, to benefit from human-wrought changes, the loss of some of the races is perhaps unexpected. It can doubtless be ascribed to the typical vulnerability of naive island populations to introduced predators, in these instances predominantly mongooses (Herpestidae).

Populations of some island races of the Northern Wren fluctuate, at times plummeting to alarmingly low levels. In Scotland, for example, the subspecies *fridarensis*, confined to the 7·6 km² of Fair Isle, between the Shetlands and the Orkney Islands, has numbered as few as ten singing males, but it rapidly bounced back to three or five times this level. When the taxon *hirtensis* was first described on St Kilda, the westernmost of the Outer Hebrides, in 1884, it was initially considered to be a new species; this unleashed a frenzy of collecting, with single skins fetching a guinea or more, the equivalent of £1.05 in modern British currency, which was at that time a huge sum of money for an impoverished local Gael. Notwithstanding this, *hirtensis*, now treated as a subspecies of the Northern Wren, was probably never in danger, mainly because of the physical inaccessibility of much of the population, and nowadays it typically numbers more than 200 pairs. At the eastern edge of the Northern Wren's Palearctic range, the subspecies *mosukei* on the Izu Islands, south of the Japanese mainland, is considered endangered, while the subspecies *orii* recently became extinct on the Daito Islands, about 800 km south of Kyushu.

Several troglodytid species are confined to islands of various sizes, but, in contrast to the sad condition of the West Indian races of the Southern House Wren, all of them should survive. The Cozumel Wren (*Troglodytes beani*) is restricted to the Mexican island of that name, where it is generally both abundant and tolerant of moderate habitat modification. Off the other, western coast of Mexico, in the Revillagigedo Archipelago, are the much smaller islands of Clarión and Socorro, each with an endemic wren. Because of the small size of their respective ranges, the Clarion Wren (*Troglodytes tanneri*) is classified by conservationists as Vulnerable and the Socorro Wren is considered to be Near-threatened. Both islands have suffered substantial habitat changes following the introduction of such animals as goats and cats, but the wrens appear able to tolerate this environmental alteration. This situation contrasts with that of the Socorro Mockingbird (*Mimodes graysoni*), which is in a very sorry state and is listed as Critical. Fortunately, the archipelago is now a biosphere reserve, and efforts are being made to remove alien species.

In the Falkland Islands, the endemic Cobb's Wren was probably widespread throughout prior to human settlement, but it has since retreated to offshore islands in the face of habitat destruction and the introduction of cats and rats (*Rattus*). Although classified as Vulnerable owing to its restricted range, it has an estimated population of 4000–8000 pairs, spaced over more than thirty islands of between 5 ha and 3000 ha, and does not seem to be in any real danger. Accidental introduction of either cats or rats to any of these islands, however, would almost certainly result in the disappearance of the local wren population. Efforts are currently being made to exterminate alien predators on several of the more suitable islands.

*The **Superciliated Wren** is a Tumbesian endemic, restricted to seasonally arid landscapes in southwest Ecuador and northwest Peru. Dry forests in this region are being damaged at a tremendous rate, triggering the inclusion of this species in the Near-threatened category. Nonetheless, it escapes red-listing because it thrives in scrubland and hedgerows, as well as in taller forests, and its population is therefore relatively large and stable.*

[*Thryothorus superciliaris baroni*, Chaparri Ecological Reserve, Lambayeque, Peru. Photo: Heinz Plenge]

Most of the conservation worries concerning troglodytids refer to Central and South American members of the family. No fewer than four species of concern occur in Colombia, a country in which an almost permanent state of severe civil unrest is not conducive to conservation efforts in remote regions. The species at the most serious and most immediate risk is Niceforo's Wren (*Thryothorus nicefori*), which was described in 1945 from a small area near Bucaramanga and was then not seen again until 1989, when one pair was observed. It appears to be dependent on acacia scrub, a habitat which is highly disturbed by burning, overgrazing and clearance for agriculture. Niceforo's Wren is presently classified as Critical.

Apolinar's Wren, "officially" listed as Endangered, is restricted to tiny patches of habitat in Colombia, where recent study has revealed the existence of two separate populations. These are currently treated as representing subspecies, but each is perhaps deserving of full species status (see Systematics). The nominate race is found only in reedbeds around a number of high-altitude lakes. Unfortunately, many of these are in heavily populated areas in the departments of Cundinamarca and Boyacá, and much suitable habitat has been lost in recent years. Populations of 50 or so pairs exist at Laguna de Tota, in Boyacá, and at Laguna de Fúquene, in Cundinamarca; the species apparently still persists in some locations around Bogotá, and the type specimen was, in fact, collected only about 6·5 km from the capital city. Some of the breeding habitat of this taxon lies within national parks, but, given the current state of civil unrest in Colombia, park status may be no guarantee of protection. Recent estimates of the total population of the nominate race are in the region of 250 adults, justifying for this taxon a classification of Critical. A further cause for concern with this race involves a growing incidence of brood parasitism by the Shiny Cowbird, the local population of which appears to be increasing. The other subspecies of Apolinar's Wren, *hernandezi*, has so far been found in just two small locations. Its population density at these seems to be quite high, and the sites themselves do not appear to be under immediate threat. It is possible that this race may occur also at other places with suitable habitat, but, because of concerns over security, it has not yet been possible to investigate these. In view of the tiny currently known range of *hernandezi*, it is suggested that it be afforded the conservation category of Vulnerable.

Although the Santa Marta Wren is not "officially" listed as globally threatened, it has a very limited total range, being confined to higher levels in the massif of Santa Marta, in north Colombia; notwithstanding the supposedly protected status of much of its range, which is encompassed within a national park, habitat destruction, including overgrazing, burning and forest-cutting, continues apace, suggesting that the species should be designated as, at best, Vulnerable. The recently discovered Munchique Woodwren (see Systematics) has a very small range in the western Andes of Colombia. At first, this range was thought to amount to less than 100 km² in an area suffering habitat destruction, and talk was that the species should be placed in the Critical category. However, very recently a new population has been found

*The **Bar-winged Woodwren** is found in the mountains of northern Peru, on either side of the River Marañón, and it also occurs in southernmost Ecuador in the Cordillera del Cóndor. Due to this relatively circumscribed distribution, it qualifies as a Restricted-range species, but it is not thought to be in any immediate threat of extinction. Indeed, forests within its altitudinal range are still fairly intact, largely because they contain few commercial timber species, and stand on infertile soils. As such this wren remains rather common at several sites.*

[*Henicorhina leucoptera*, Abra Patricia, San Martín, Peru. Photo: Jon Hornbuckle]

***Cobb's Wren** is an insular offshoot of the "House Wren complex". It was once abundant on the Falkland Islands, but the arrival of man and his commensals, notably cats and rats, prompted a population crash. It is now restricted to 30 or more uninhabited offshore islands, where it is thought to number between 4000 and 8000 individuals. Although it seems to be secure, further accidental introductions of mammalian predators could eliminate some crucial populations, and it is therefore listed as Vulnerable. Efforts are currently being made to eradicate alien mammals from a number of suitable islets.*

[*Troglodytes cobbi*, Falkland Islands. Photo: Hanne & Jens Eriksen]

some 350 km to the north; here, the bird seems to be common, and much of the unprospected intervening area supports apparently suitable habitat, so the prospects are improving. The Merida Wren of the Venezuelan Andes, despite its very restricted range, does not appear to be at any risk.

The two members of the Mexican genus *Hylorchilus* might almost be regarded as island species in that they live only in forest growing on isolated outcrops of karst limestone. Whether they ever occurred in the intervening non-karst areas is something of a moot point, since these have been largely deforested for agriculture. Both species are the subject of some concern. Sumichrast's Wren seems to be in the better shape. Although its total range is encompassed in an area of only 6000 km², in only a small proportion of which it is actually present, a total of twelve separate populations has been located. In some of these it is found at the very high density of one pair per hectare, and it is able to exploit very small patches of habitat, some as tiny as 0·5 hectares. In addition, it tolerates a degree of habitat disturbance. Sumichrast's Wren is currently considered Near-threatened, the greatest threats facing it being the cutting of forest for firewood and quarrying. Nava's Wren is classified as Vulnerable, with suggestions that it should be upgraded to the conservation category of Endangered. It appears to be less tolerant of habitat disturbance than is its congener. Some parts of its range are protected, but the viability of both species can be guaranteed only by further land protection, either by direct acquisition for reserves or through long-term agreements with landowners.

Farther south, in El Salvador, the local subspecies *nannoides* of the Rufous-browed Wren is now restricted to a protected area of 600 ha on Volcán Santa Ana. Here, its population is estimated to number no more than about 4000 individuals.

The unique Zapata Wren, confined entirely to small areas of the Zapata Swamp, in south-western Cuba, is a source of very serious concern. It is currently classified as Endangered, and at one point it was feared that it was already extinct. Recent observations, however, suggest a population in the region of 120–140 pairs. The main threats to this species appear to be destruction of its habitat by fires and predation by introduced mongooses. Currently, management plans for the Zapata Swamp are in place, with the aim of preserving this and several other endemic species.

Twenty-one troglodytids, including five of the six globally threatened ones, are restricted-range species. Of the non-threatened species in this category, it is believed that their small geographical ranges would render them vulnerable in the event of major habitat destruction. In southern Mexico, for instance, the Giant Wren is restricted to a narrow coastal strip of the state of Chiapas. It seems to be abundant in parts of this small range, and to be able to co-exist well with present land uses, but any change in its environment could cause problems for this distinctive wren.

*The **Zapata Wren** has always been restricted to drier areas of the Zapata swamp, in the Caribbean island of Cuba, where it favours savanna-type habitat with sawgrass* (Cladium jamaicense), *rushes, and a few bushes to use as songposts. The total population has recently been estimated at 120-140 pairs, quite extensively but patchily distributed throughout the swamp. Given the fact that so few individuals survive, and the continuing threat of grass-burning, the species is treated as Endangered. Fortunately, its status has generated a considerable amount of interest and a conservation project is under way.*

[*Ferminia cerverai*, Zapata, Cuba. Photo: Albert Masó]

***Niceforo's Wren**, one of the least known members of the family, is quite possibly close to extinction. It was described on the basis of seven specimens taken in 1945, but went unseen thereafter until 1989, and is now classed as Critical. It occurs in a highly restricted area around San Gil, Santander, Colombia, where it is apparently unable to tolerate recent changes in land use. Much of its natural habitat has been converted to coffee plantations, or is overgrazed by cattle and goats. Surveys are needed to clarify its current status, but also to assess its validity as a species separate from the Rufous-and-white Wren* (Thryothorus rufalbus).

[*Thryothorus nicefori*, near San Gil, Santander, Colombia. Photo: John S. Dunning]

On the Caribbean coast, the Yucatan Wren (*Campylorhynchus yucatanicus*) occupies an even smaller range, some of which is protected by national parks. This, however, is no justification for complacency, as the Yucatán Peninsula is currently undergoing extensive development for resorts. As a further example, the Bar-winged Wood-wren, already listed as Near-threatened, occurs in very limited areas on high mountains in southern Ecuador and northern Peru, where it is confined to stunted forest on impoverished soils. This choice of habitat, unattractive for human exploitation, is probably the species' best guarantee for survival. Also highly restricted in Peru is the Inca Wren, which does, however, seem to be common in suitable areas.

Although many members of the family have large geographical ranges, these are becoming increasingly fragmented. This is especially true of species which rely on lowland tropical forest and have limited tolerance of change, such as the Northern Nightingale-wren, large segments of the former habitat of which have been deforested. While such species may be abundant in areas where suitable habitat still remains, their populations as a whole have exhibited substantial declines in recent years. The future health and viability of these forest-reliant species will obviously depend on the capacity of the human population to reverse the present rate of habitat destruction in Central and South America.

Apart from habitat loss and degradation, there appear to be few threats to troglodytids. As mentioned previously (see Movements), non-resident populations of wrens migrate during the night-time. These nocturnal movements can at times involve certain hazards, chief among which is probably the risk of flying into stationary structures such as lighthouses, TV towers and various tall buildings. Observations suggest that, under certain weather conditions, Northern House Wrens, Marsh Wrens and Sedge Wrens in North America and Northern Wrens in Europe can suffer substantial numbers of casualties as a consequence of hitting tall obstructions in the dark. The level of mortality due to such accidents, however, is extremely minimal in terms of the total population of the species concerned.

Natural deaths resulting from starvation during prolonged periods of harsh weather can be more serious, sometimes depressing populations for several years. Nevertheless, wrens are generally capable of recovering to their former strength within a relatively short length of time.

PLATE 35

inches 4

cm 10

Genus *CAMPYLORHYNCHUS* Spix, 1824

1. Boucard's Wren

Campylorhynchus jocosus

French: Troglodyte de Boucard **Spanish**: Cucarachero del Balsas
German: Harlekinzaunkönig
Other common names: Boucard's Cactus-wren

Taxonomy. *Campylorhynchus jocosus* P. L. Sclater, 1860, Oaxaca, Mexico.
Has been thought by some to form a superspecies with *C. yucatanicus* and *C. brunneicapillus*. Sometimes treated as conspecific with *C. gularis*, but the two are quite distinct in appearance and probably occupy slightly different ecological niches. Monotypic.
Distribution. SC Mexico (S Puebla, S Morelos, Guerrero and Oaxaca).

Descriptive notes. 17 cm; 23·8–29·8 g. Has dull white supercilium, dull blackish eyestripe, dark grey ear-coverts; crown dark chocolate-brown, nape rufescent, shoulders blackish with whitish longitudinal streaks, back reddish-brown with scattered black and white spots; rump dull rufescent brown, rectrices grey-brown with dull blackish-brown bars, outer ones with whitish tips; primaries and secondaries blackish-brown with pale buff bars; chin and throat white, underparts white with conspicuous black spots, flanks buffy with diffuse darker bars; eye red-brown; bill blackish, pale bluish-grey base of lower mandible; legs greyish-slate. Sexes similar, spots on underparts of female tend to be smaller than male's. Juvenile has markings on back less well defined, throat speckled, underparts dull greyish with spots duller and more diffuse. Voice. Song a series of grating notes repeated up to a dozen times, also a harsh rapid chatter; sexes sing in duet.
Habitat. Dry or arid forest, sometimes with giant cacti. Arid subtropical scrub, also pine–oak (*Pinus–Quercus*) forest and oak scrub; mostly 800–2500 m, occasionally as low as 600 m. Can tolerate considerable disturbance of habitat.
Food and Feeding. Both animal and vegetable matter; insects and other invertebrates, also cactus seeds, etc. Whether or not it eats scorpions (Scorpiones), as implied in one Spanish vernacular name, is not known. Forages from ground level up to tops of cacti and trees; less often on ground than *C. brunneicapillus*.
Breeding. Nests with eggs in mid-Jun and early Jul in Oaxaca; nest-building observed in Apr, and pre-juvenile mid-Jul; probably single-brooded. Nest domed, with side entrance. Eggs 3–4, whitish with dense speckles of brown and grey; no information on incubation and fledging periods; apparently, individuals other than the two parents sometimes assist at nest. One recorded instance of parasitism by Brown-headed Cowbird (*Molothrus ater*).
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Confined to small area in S Mexico, mostly in states of Oaxaca and Guerrero. Fairly common in some parts of range, less so in others. Able to tolerate substantial human modification of habitat, provided that sufficient scrub and bushes remain.
Bibliography. Anon. (1998b), Arizmendi & Márquez (2000), Binford (1989), Blake (1953), Farley (1994), Forcey (2002), Friedmann (1971), Hellmayr (1934), Howell & Webb (1995), Hunn *et al.* (2001), Peterson, Escalona *et al.* (2003), Ramírez & Ramírez (2002), Ridgway (1904), Rowley (1984), Selander (1964).

2. Spotted Wren

Campylorhynchus gularis

French: Troglodyte tacheté **German**: Bartzaunkönig **Spanish**: Cucarachero Manchado
Other common names: Spotted Cactus-wren, Mexican Wren

Taxonomy. *Campylorhynchus gularis* P. L. Sclater, 1861, Bolaños, Jalisco, Mexico.
Sometimes treated as conspecific with *C. jocosus*, but the two are quite distinct in appearance and probably occupy slightly different ecological niches. Considerable individual variation in some characters (e.g. degree of spotting on underparts), but differences appear insufficiently constant to warrant separation of distinct races. Monotypic.
Distribution. Mexico, in two disjunct populations separated by unsuitable habitat: in W, from SE Sonora S to N Michoacán and W México; in E, from SW Tamaulipas S to Hidalgo.

Descriptive notes. 17 cm; 28·3–31·0 g. Has whitish supercilium, brown lores and eyestripe, buffish-white ear-coverts; crown chestnut-brown, shoulders and back rufescent brown marked with dull black and buffy white; primaries and secondaries barred dark brown, buff and grey-brown; rectrices grey-brown, barred darker; chin, throat and chest off-white, narrow blackish malar stripe, chest side with conspicuous blackish spots; belly and lower flanks buffy, diffusely barred darker; eye reddish-brown; bill blackish above, pale bluish-grey below, yellowish base; legs greyish-slate. Sexes similar. Juvenile is very different, has crown unmarked dull black, upperpart markings more diffuse, chest unspotted pale buff. Voice. Song a series of harsh churring notes, or a series of unmusical gurgling phrases. Call a gruff "cheh-cheh-cheht".
Habitat. Varied. Oak and pine–oak (*Pinus–Quercus*) woodland, usually of a fairly dry nature, also mixed stands of leguminous shrubs and cacti; in Sonora, rocky slopes with palms. 800–2500 m; locally to 3000 m in Colima.
Food and Feeding. Little information. Diet mostly invertebrates, but some vegetable matter such as cactus seeds taken. Has been seen to take small lizards. Forages actively in small groups, on or near ground, occasionally higher, to c. 15 m; seeks food in bark crevices and among rocks, also in clumps of epiphytes.
Breeding. Largely unknown. Nests in Sonora in Jun. Nest domed, with side entrance; one in Sonora was located on underside of dead palm frond. Clutch size unknown, but up to four fledglings seen together; eggs undescribed; no information on incubation and fledging periods. One recorded case of parasitism by Brown-headed Cowbird (*Molothrus ater*).
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Abundance varies; quite sparse and uncommon in some areas, and very common in suitable habitat in others.
Bibliography. Anon. (1998b), Arizmendi & Márquez (2000), Edwards & Martin (1955), Farley (1955, 1994), Gaulden (1996), Hellmayr (1934), Howell & Webb (1995), Hutto (1980, 1987), Lea & Edwards (1950), Ridgway (1904), Russell & Monson (1998), Selander (1964), Webster (1958), Zimmerman & Harry (1951).

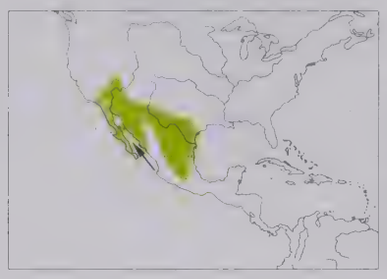
3. Yucatan Wren

Campylorhynchus yucatanicus

French: Troglodyte du Yucatan **German**: Yucatanzaunkönig **Spanish**: Cucarachero Yucateco
Other common names: Yucatan Cactus-wren

Taxonomy. *Heleodytes brunneicapillus yucatanicus* Hellmayr, 1934, Río Lagartos, Yucatán, Mexico.
Has been thought by some to form a superspecies with *C. jocosus* and *C. brunneicapillus*. Sometimes regarded as a race of latter, but differs significantly in plumage, voice, behaviour and nest form. Monotypic.
Distribution. N coast of Yucatán Peninsula from approximately Celestún E to El Cuyo (mostly in Yucatán state, marginally N Campeche), in E Mexico.

Descriptive notes. 18 cm; 31–40 g. Has off-white supercilium, dark brown eyestripe, ear-coverts finely streaked brownish-grey; crown blackish-brown, shoulders and back dark brown with longitudinal white streaks; primaries and secondaries conspicuously barred off-white and dull blackish-brown, with greater and lesser upperwing-coverts barred dull black and off-white; tail barred blackish-brown and dull grey-white; chin, throat and chest off-white with fine longitudinal streaks, heavier on chest; lower flanks diffusely barred, undertail-coverts barred dull blackish; eye red-brown; bill grey-black, pale greyish-horn base of lower mandible; legs dark grey. Sexes similar. Juvenile has all markings less well defined, bars on wing-coverts buffy, eye brownish. Voice. Song a series of 4–5 repeated notes, e.g. "chick che-wa chooo" etc, quite distinct from that of *C. brunneicapillus*; duetting by both sexes common. Call a harsh growl.
Habitat. Coastal scrubland with scattered bushes 3–6 m in height, sometimes with *Opuntia* cacti; also, less commonly, in areas such as bushy edges of pastures. Extends only a few km inland.
Food and Feeding. No data on diet available. Forages in pairs and family groups, on ground and in low vegetation.
Breeding. Season probably Mar–May or later. Nest built by both sexes, an ovoid ball of grass with side entrance, usually c. 2–3 m above ground in bush; nest less spherical than that of *C. brunneicapillus*, and not sited preferentially in cactus; multiple nests probably constructed and used for roosting. Eggs undescribed; incubation and fledging periods unknown.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in the Yucatán Peninsula Coastal Scrub EBA. Common or abundant in undisturbed prime habitat, less so in marginal habitat such as brushy field edges; seems able to tolerate some disturbance. Occurs in several protected areas, i.e. Ría Celestún, San Felipe and Río Lagartos National Parks. Would be highly vulnerable to extensive coastal development such as has occurred very intensely on E coast of Yucatán Peninsula; so far, much of the species' range has not attracted too much development of this type, but any shift in the focus of holiday-resort development from the Cancún–Playa del Carmen axis to coastal areas farther N & W could be very damaging.
Bibliography. Anon. (1998b), Arizmendi & Márquez (2000), Ceballos & Valdelamar (2000), Hellmayr (1934), Howell & Webb (1995), Klaas (1968), Paynter (1955), Selander (1964), Tramer (1974), Wheatley & Brewer (2001), Zimmerman (1957).



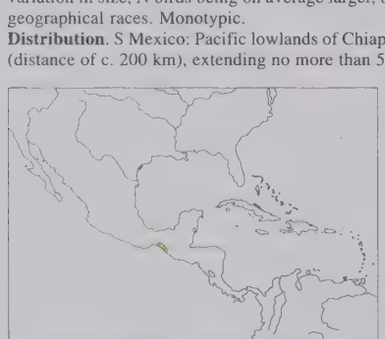
4. Cactus Wren

Campylorhynchus brunneicapillus

French: Troglodyte des cactus **German**: Kaktuszaunkönig **Spanish**: Cucarachero Desértico
Other common names: Northern Cactus Wren

Taxonomy. *Picolaptes brunneicapillus* Lafresnaye, 1835, California; error = Guaymas, Sonora, Mexico.
Has been thought by some to form a superspecies with *C. jocosus* and *C. yucatanicus*. Sometimes regarded as conspecific with latter, but differs significantly in plumage, voice, behaviour and nest form. USA and N Mexican population sometimes referred to as race *anthonyi*, but name *couesi* has priority. Eight subspecies recognized.
Subspecies and Distribution.
C. b. couesi Sharpe, 1882 – S USA (S Nevada, SW Utah, S Arizona, S New Mexico, S Texas) and NW & NC Mexico (N Sonora, N & E Chihuahua, N Coahuila).
C. b. sandiegense Rea, 1986 – extreme SW USA (coastal S California) and NW Baja California.
C. b. bryanti (Anthony, 1894) – W coast of Baja California (between 31° N and 29°30' N).
C. b. purus (van Rossem, 1930) – both coasts of Baja California between c. 29° N and 25° N.
C. b. seri (van Rossem, 1932) – Tiburón I, in Gulf of California.
C. b. affinis Xántus de Vesey, 1860 – S Baja California (S from 25° N).
C. b. brunneicapillus (Lafresnaye, 1835) – NW Mexico (C Sonora S to N Sinaloa).
C. b. guttatus (Gould, 1837) – C Mexican plateau from Nuevo León S to Michoacán and Hidalgo.

On following pages: 5. Giant Wren (*Campylorhynchus chiapensis*); 6. Bicoloured Wren (*Campylorhynchus griseus*); 7. Rufous-naped Wren (*Campylorhynchus rufinucha*); 8. Thrush-like Wren (*Campylorhynchus turdinus*).



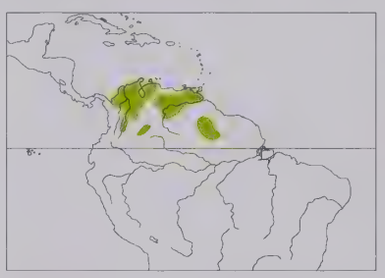
Descriptive notes. 18–19 cm; 33·4–46·9 g. Nominate race has supercilium white, ear-coverts streaked dark grey and white, crown unmarked chocolate-brown with rufescent tinge, nape brown with white streaks, back and rump grey-brown with white and black streaks; primaries and secondaries strongly barred blackish and off-white; rectrices with brownish-black and pale grey-brown bars, outer ones tipped white; chin white, throat and upper chest heavily marked with black on whitish background, belly whitish with darker streaks, flanks and lower underparts ochraceous buff; eye reddish-brown; bill dull blackish, base of lower mandible paler greyish; legs brown or pinkish-brown. Sexes similar. Juvenile has no white streaks on nape or back, black markings on chest less prominent, eye muddy grey-brown. Race *couesi* is larger than nominate, posterior underparts paler; *sandiegense* is less rufescent on crown; *bryanti* is darker and browner above than nominate, with conspicuous white streaks on rump and scapulars; *purus* has almost pure white underparts, little buff on flanks; *seri* has less cinnamon-buff on underparts than nominate, wider abdominal spotting; *affinis* has pale underparts with black markings reduced, distinct white bars on all rectrices except middle pair; *guttatus* is more grey, duller than nominate, with less conspicuous white markings on upperparts. Voice. Song a series of harsh "jar-jar-jar" notes. Alarm a low buzz, also a repeated staccato "tek".
Habitat. Semi-desert of various vegetational types, including Sonoran and Chihuahuan Deserts. Requires the presence of spiny cacti such as prickly pear or cholla (*Opuntia*); absent from pure stands of creosote bush (*Larrea mexicana*) without such cacti. Sea-level to 1400 m in Arizona, more sparsely to 2000 m in New Mexico and C Mexican plateau.
Food and Feeding. Mostly animal matter, including hymenopterans (ants, wasps), grasshoppers (Orthoptera), spiders (Araneae) and other arthropods, also small frogs and lizards. Some vegetable matter, including cactus seeds, also taken. Forages low in vegetation or on ground; turns over ground debris, also stones and larger rocks, to locate prey hidden beneath; moves rapidly on ground. Some individuals learn to pry squashed insects from car radiator grills.
Breeding. Egg-laying from Feb, less often Jan, in USA (Arizona), later at high elevations; up to six broods may be attempted, usually only two or three succeed. Nest large and conspicuous, pouch-shaped, with side entrance leading to retort-shaped cavity, built of grass and fibres and lined with feathers, some artificial material sometimes incorporated when available; usually located in spiny cactus, sometimes in other bush, rarely in artificial situation such as in cavity in eaves; nests for roosting built throughout year. Eggs 3–5, rarely up to 7, in N, usually only 2 in race *affinis* (in Baja California), buffy-pinkish with fine brown or reddish-brown speckles, some geographical variation in egg colour, e.g. tending to be dark in *sandiegense*, considerably paler in *affinis*; incubation by female alone, period c. 16 days (up to 23); chicks fed by both sexes, very rarely also by other individuals, fledging period in Arizona 19–23 days; male starts to build second nest while female is laying first clutch, she assists in completing it as soon as first brood is fledged, and shortly thereafter lays second clutch in it.
Movements. Almost entirely sedentary; of 126 recoveries of ringed individuals, only one showed any movement, and all others were found at, or very close to, initial ringing site. No occurrences outside normal range, apart from one bizarre record in Canada (Saskatchewan).
Status and Conservation. Not globally threatened. Generally common to abundant over much of its range. Has shown itself to be adaptable; can survive well in very degraded or modified habitats (e.g. in open industrial sites, junkyards and the like), so long as some suitable vegetation, especially spiny cacti, remains.
Bibliography. Anderson (1934a, 1934b), Anderson & Anderson (1957, 1959, 1960, 1961, 1962, 1963, 1965, 1973), Anon. (1998b), Antevs (1946), Austin (1974), Baicich & Harrison (1997), Bailey (1922), Bancroft (1923, 1930, 1946), Bent (1948), Blake (1953), Contreras (1997), Crooks *et al.* (2001), Facemire *et al.* (1990), Farley (1994), Guzmán *et al.* (2001), Hellmayr (1934), Howell & Webb (1995), Marr (1981), Marr & Raitt (1983), Mearns (1902), Milton *et al.* (1998), Parkes (1986), Phillips *et al.* (1964), Price *et al.* (1995), Proudfoot *et al.* (2000), Rea & Weaver (1990), Ricklefs (1966, 1967, 1968, 1975), Ricklefs & Hainsworth (1967), Ridgway (1904), Root (1988), Rowley (1935), Russell & Monson (1998), Selander (1964), Small (1994), Smith (1970), Udvardy (1963), Wapple & Smith (1982), Wolford (1969), Zink *et al.* (2001).

5. Giant Wren

Campylorhynchus chiapensis

French: Troglodyte géant **German**: Riesenzaunkönig **Spanish**: Cucarachero de Chiapas
Other common names: Giant Cactus-wren, Chiapas Wren

Taxonomy. *Campylorhynchus chiapensis* Salvin and Godman, 1891, Tonalá, Chiapas, Mexico.
Sometimes considered conspecific with *C. griseus*, but very widely separated geographically. Some variation in size, N birds being on average larger, but differences insufficient to warrant naming of geographical races. Monotypic.
Distribution. S Mexico: Pacific lowlands of Chiapas, from about Puerto Arista S to Puerto Madero (distance of c. 200 km), extending no more than 50 km inland.



Descriptive notes. 20–22 cm; 43·4–57 g. Has prominent buff or whitish supercilium, black eyestripe, black crown, nape and shoulders; upperparts unstreaked bright chestnut-brown, rectrices dark chestnut-brown with conspicuous white subterminal band on all but cenral pair; flight-feathers greyish-black, secondaries edged chestnut and obscurely barred, upperwing-coverts rufous-brown; ear-coverts, chin, throat and chest white, belly and vent buff; eye reddish-brown; bill black above, grey with paler base below; legs pale slate-blue to greyish-brown. Sexes similar. Juvenile resembles adult, but underparts less pure white. Voice. Repeated rhythmic hollow phrases, chortling and rollicking; sexes sing in unison. Various grating and harsh churring calls.
Habitat. Variety of bushland, including such areas as farmyards modified by human activity, bushy fence rows and hedges; ideal habitat includes groves of guanacastes (*Enterolobium*) or mangoes (*Mangifera*) with denser patches of trees, and with bull's-horn acacias (*Acacia collinsii*) for nesting. Sea-level to 300 m.
Food and Feeding. No information recorded. Diet probably largely invertebrates. Feeds on or near ground, rarely at a great height, and is thus ecologically separated from *C. rufinucha*, which tends to feed in smaller branches; inspects fallen dead trees and bases of living trees. Has been seen to enter chicken coops, apparently attacking eggs therein.
Breeding. May–Jul; possibly double-brooded. Some evidence of multiple helpers at nest. Nest a bulky roofed structure c. 25–35 cm in diameter, circular entrance at side, built of straw, weed stems, pieces of vine etc., situated 3–4 m up and with little effort at concealment, frequently in bull's-horn acacia; latter has a symbiotic relationship with aggressive *Pseudomyrmex* ants, which attacks intruders but do not molest this species' nest. One clutch recorded, of 3 eggs, light buff with heavy mottling of brown; no information on incubation and fledging periods.
Movements. Apparently entirely sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in the North Central American Pacific Slope EBA. Frequently common or abundant within its small range; in prime habitat, groups found spaced at intervals of c. 100–150 m. Most of existing range is heavily modified by agriculture; the species seems to be very tolerant of such disturbance, provided that adequate hedgerow and bushes remain.
Bibliography. Anon. (1998b), Blake (1953), Brodkorb (1939), Ceballos & Valdelamar (2000), Howell & Webb (1995), Peterson *et al.* (1998), Ridgway (1904), Selander (1955, 1964), Skutch (1940, 1960, 1976).

6. Bicoloured Wren

Campylorhynchus griseus

French: Troglodyte bicolore **German**: Brauenzaunkönig **Spanish**: Cucarachero Currucuchú
Other common names: Bicoloured/Guyanian Cactus-wren

Taxonomy. *Furnarius griseus* Swainson, 1838, savannas of Guyana.
Sometimes considered conspecific with *C. chiapensis*, but very widely separated geographically. Five subspecies recognized.
Subspecies and Distribution.
C. g. albicilius (Bonaparte, 1854) – N Colombia and NW Venezuela (Macaraibo Basin, Falcón, Lara, W Trujillo).
C. g. bicolor (Pelzeln, 1875) – upper Magdalena Valley and W slope of E Andes in Santander and Boyacá (Colombia).
C. g. minor (Cabanis, 1851) – lowlands of N Venezuela (Cojedes and Apure E to Sucre and Monagas, S to N Bolívar) and E Colombia (Meta).
C. g. pallidus Phelps, Sr & Phelps, Jr, 1947 – N Amazonas, in Venezuela.
C. g. griseus (Swainson, 1838) – E Venezuela (NW Amazonas, NW Bolívar), SW Guyana and extreme N Brazil (Roraima).

Descriptive notes. 21–22 cm; 37–46·5 g. Nominate race has off-white supercilium contrasting with dark brown eyestripe; crown and nape dark chocolate-brown, back paler chocolate-brown; primaries and secondaries as back but with numerous darker bars; rectrices brownish-black with conspicuous white subterminal band on all but central pair, broadest on outer feathers; throat and entire underparts white; eye brown; bill black, grey base of lower mandible; legs slate-grey. Sexes similar. Juvenile has back greyer and less rufescent than adult, cap mottled grey-brown, underparts grey-white. Race *albicilius* is deeper rufous than nominate; *bicolor* is similar to previous, but less bright rufous on rump; *minor* is smaller, with blackish-brown nape and upper back; *pallidus* has back much more grey, less rufous, than nominate, with darker crown. Voice. Song a series of multiple loud gurgling notes, 2–5 per phrase, with harsh grating undertone, female song slightly different and invariably including a trill; marked geographical variation in song type, race *albicilius* in particular differing from e.g. *minor*; pair-members sing individually or in duet, or in choruses with three or more individuals singing simultaneously. Calls varied, mostly harsh and grating.
Habitat. Scattered bushland, of varied nature. In Colombia, race *bicolor* occurs in arid thorn-scrub with cacti, but other races in quite humid areas. Absent from both completely forested areas and completely open areas. Sea-level to 2100 m in Colombia, to 1600 m in Venezuela.
Food and Feeding. Mostly invertebrates; significant amounts of vegetable matter also taken, including berries, and reported as destructive to fruit such as mangoes. According to local Colombian tradition, enters hen-houses and preda
tes eggs. Forages in trees and palms, also on ground.
Breeding. Jan–Mar and May–Aug in Venezuela. Co-operative breeder, although extent to which this occurs highly variable, in some populations majority of nests have one or more helpers, in others only 15%; helpers are blood-relatives (frequently brothers or sisters) of nesting pair. Nest a domed structure with small side entrance, made of grass and fibres, placed 3·5 m or more above ground and well concealed in tree or palm; old domed nest of other species, e.g. tyrannid (of genus *Pitangus* or *Myiozetetes*), or pendent one, e.g. of Rufous-fronted Thornbird (*Phacellodomus rufifrons*), also used. Eggs 3–5, buff or cinnamon, speckled with brown; incubation by female alone, period 17 days; chicks fed by both sexes, and by helpers when present, for c. 17 days in nest and up to 30 days after fledging. Nests with helpers up to three times more successful than those without, enhanced success due to better defence of nest.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Frequently common or abundant. Able to tolerate substantial modification of habitat, provided that sufficient bushes remain; for example, can co-exist with agricultural practices such as ranching.
Bibliography. Austad & Kerry (1986), Austad & Rabenold (1986), Chapman (1917), Darlington (1931), Delacour (1923), Friedmann (1948), Haffer (1975), Haydock (1998), Haydock *et al.* (1996), Hellmayr (1934), Hilty (2003), Hilty & Brown (1986), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Miller (1947), Phelps & Phelps (1947), Rabenold *et al.* (1988), Ridgely & Tudor (1989), Selander (1964), Sick (1993, 1997), Snyder (1966), Thomas (1979).

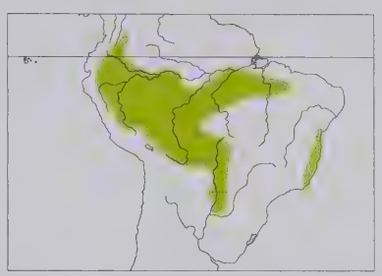
7. Rufous-naped Wren

Campylorhynchus rufinucha

French: Troglodyte à nuque rousse **Spanish**: Cucarachero Nuquirrufo
German: Rotnacken-Zaunkönig

Other common names: Rufous-naped Cactus-wren; Sclater's Wren (*humilis*); Hooded Cactus-wren, Rufous-backed Wren (*capistratus* group)

Taxonomy. *Picolaptes rufinucha* Lesson, 1838, Veracruz, Mexico.
Some authors divide races into three informal groups: *humilis*; nominate; and the four remaining southernmost subspecies. Races *humilis* and *nigricaudatus* intergrade in S Mexico (Chiapas). Six subspecies recognized.
Subspecies and Distribution.
C. r. humilis P. L. Sclater, 1856 – W Mexico (Colima E to W Chiapas).
C. r. rufinucha (Lesson, 1838) – E Mexico (Veracruz and adjacent N Oaxaca).
C. r. nigricaudatus (Nelson, 1897) – S Mexico (Chiapas) and W Guatemala.
C. r. castaneus Ridgway, 1888 – interior of Guatemala E to Honduras and Nicaragua.
C. r. capistratus (Lesson, 1842) – Pacific coast of El Salvador and Nicaragua S to NW Costa Rica.
C. r. nicoyae A. R. Phillips, 1986 – Nicoya Peninsula, in NW Costa Rica.



Descriptive notes. 15–19 cm; 28·9–31·8 g. Unmistakable over most of range. Nominate race has white supercilium, blackish lores and eyestripe; crown blackish, nape and back chestnut-brown, shoulders with black and white longitudinal streaks; primaries and secondaries and their coverts prominently barred blackish and brown; rectrices grey-brown with diffuse darker barring, prominent whiter tips on outermost three feathers runs into mgreyish-brown; chin and throat white, weak black malar stripe, chest pale buffy white with small round brownish-black dots, belly buff-white, diffuse blackish bars on flanks; eye red-brown; bill dark horn, paler at base; legs bluish-grey. Sexes similar. Juvenile is like adult, but supercilium buffy white, markings on back more diffuse, rufous of back duller. Race *humilis* has no streaks on shoulders, variable rufous-brown crown with dusky feathers centres, spots on underparts reduced or absent; *nigricaudatus* has blackish rectrices, unspotted underparts; *capistratus* has paler chestnut back than previous, light brownish-grey bars on central rectrices; *castaneus* is similar to last, but with much less variegated back markings; *nicoyae* is smaller, with anterior supercilium and side of chest strongly washed with brown. Voice. Song a prolonged series of rich chortling phrases, usually 3–8 notes, interspersed with harsher chatters; sexes duet. Calls short and harsh.
Habitat. Arid and semi-arid areas with dry scrub (especially with *Opuntia* cactus), including areas substantially modified by human activity; less commonly in mangroves and in lower levels of cloudforest. Occurs from sea-level to 1200 m in Mexico, to 1400 m in El Salvador and to 800 m in Costa Rica.
Food and Feeding. Feeds predominantly on invertebrates, especially small insects, spiders and so on; probably also takes some vegetable matter, including berries. Habitually forages in pairs or small groups, usually in low vegetation; sometimes seeks food on verandahs or even actually inside buildings.
Breeding. Season mid-Mar to Jul, mostly Apr–Jun, in El Salvador; probably single-brooded. Nest built by both sexes, a bulky globular structure of grass and plant fibres, upward-directed tunnel entrance in one side, leading into central chamber lined with down and feathers, nest of race *humilis* more highly domed; usually 1·5–10 m above ground in cactus or thorn bush, occasionally in artificial site such as roof eaves, or in pendent nest (relined) of species such as Spot-breasted Oriole (*Icterus pectoralis*); in Costa Rica and doubtless other areas, deliberately sites nest in acacia (*Acacia*) harbouring symbiotic aggressive stinging ants (e.g. of genus *Pseudomyrmex*), choosing tree with the most hostile ants, also frequently close to wasp nest and thereby gaining vicarious protection against nest-predatory monkeys; numerous nests for roosting built throughout year. Clutch size 3–6 (usually 4–5) in El Salvador, usually 4 in Costa Rica, eggs white or buffy white with speckles or blotches of brown, lilac or blackish; no information on incubation and fledging periods; young may be fed by helpers other than parents, presumably related birds.
Movements. Apparently entirely sedentary.
Status and Conservation. Not globally threatened. Common or abundant in many parts of its range. Appears able to tolerate substantial habitat modification, provided sufficient bushes and cacti are left.
Bibliography. Anon. (1998b), Arizmendi & Márquez (2000), Binford (1989), Blake (1953), Dearborn (1907), Dickey & van Rossem (1938), Flaspohler & Laska (1994), Hellmayr (1934), Howell & Webb (1995), Hutto (1992), Joyce (1990, 1993), Komar & Domínguez (2001), Land (1970), Lowery & Dalquest (1951), Monroe (1968), Rowley (1966), Selander (1964), Slud (1964, 1980), Stiles & Skutch (1989), Young *et al.* (1990).

8. Thrush-like Wren

Campylorhynchus turdinus

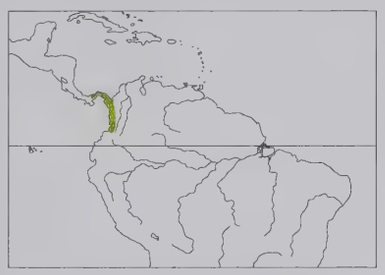
French: Troglodyte grivelé **German**: Drosselzaunkönig **Spanish**: Cucarachero Turdino
Other common names: Thrush-like Cactus-wren; Plain-breasted Wren (*unicolor*)

Taxonomy. *Opetiorhynchus turdinus* Wied, 1821, Rio Catolé, Bahia, Brazil.
Sometimes considered conspecific with *C. albobrunneus*, but has totally different vocalizations. Proposed race *aenigmaticus* (from SW Colombia) of latter sometimes included with present species; probably a hybrid form. Three subspecies normally recognized.
Subspecies and Distribution.
C. t. hypostictus Gould, 1855 – SE Colombia and E Ecuador E across Brazil to R Tocantins, S to E Peru and N Bolivia.
C. t. unicolor Lafresnaye, 1846 – lowlands of E Bolivia and adjacent Brazil, N & C Paraguay and extreme N Argentina (E Formosa).
C. t. turdinus (Wied, 1821) – E Brazil (Maranhão, and Bahia S to Espírito Santo).

Descriptive notes. 20·5 cm; 39 g. Nominate has supercilium and lores whitish or pale greyish, ear-coverts mottled grey-brown; crown dull-scalloped blackish-grey, shoulders and back similar with broader scalloping; lower back and rump blackish-grey, obscurely barred buffy grey; primaries and secondaries barred dull blackish and brown, rectrices dull blackish-brown; chin, throat and chest dull white, chest with conspicuous blackish spots; flanks buffish-grey with diffuse darker bars; eye pale orange-rufous; bill blackish above, ivory below; legs dusky grey. Sexes similar. Juvenile duller, spots on chest reduced and less well marked. Race *hypostictus* similar to nominate, but more heavily and extensively spotted below; *unicolor* is very different, underparts with few or no spots, upperparts grey with little brown tinge, supercilium more obvious. Voice. Song a loud, cheerful chortling, often prefaced by a series of harsh scratchy notes; both sexes sing.
Habitat. Humid forest, including *várzea* and second growth at forest edge, also gardens and parks; often near pasture. Also in palm trees in Brazil (Mato Grosso). Lowlands down to sea-level, locally to 1300 m in E Andean foothills.
Food and Feeding. Mostly insectivorous, but also takes fruit. Forages usually in small groups, presumably family parties, mostly in upper parts of trees.
Breeding. Little known. Season at least Jun–Oct in E Bolivia. Nest in Bolivia described as a ragged grassy ball, often containing other material such as snakeskin, scraps of plastic etc., 21 cm high, 13–16 cm wide, with entrance hole 4 cm in diameter located 4 cm down from top, usually located in totai palm (*Acrocomia aculeata*) or in top of evergreen tree, especially horori (*Swartzia horori*), also frequently in artificial site such as roof; nest in E Brazil described as domed, oval in shape, with outside antechamber and inner breeding chamber, situated in tree; in the Mato Grosso (race *unicolor*) may use old nest of thornbird (*Phacellodomus*), stuffing the cavity with feathers; in Peru, has been seen to enter natural cavity in dead tree which probably contained a nest. Eggs 3–4, off-white with darker spots and blotches, especially at blunt end; no information on incubation and fledging periods. Nests sometimes parasitized by Shiny Cowbird (*Molothrus bonariensis*) in Bolivia.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common in some parts of range. Seems to adapt well to forest edge, roadsides and similar habitats. Presently expanding range into N Argentina.
Bibliography. Best *et al.* (1997), Canevari *et al.* (1991), Chapman (1917), Contreras & Andres (1986), Contreras *et al.* (1992), Davis (1993), Guerrero & Arambiza (2001), Hayes (1995), Hellmayr (1934), Hennessey *et al.* (2003), Hilty & Brown (1986), Maillard & Lindo (1998), Meyer de Schauensee (1982), Parker & Goerck (1997), Peres & Whittaker (1991), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Robinson & Terborgh (1997), Selander (1964), Short & Morony (1969), Sick (1993, 1997), Zimmer *et al.* (1997).

PLATE 36

inches 4



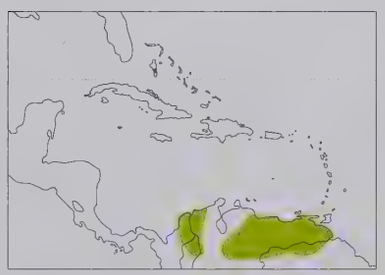
cm 10

9. **White-headed Wren**

Campylorhynchus albobrunneus

French: Troglodyte à tête blanche **Spanish**: Cucarachero Cabeciblanco
German: Weißkopf-Zaunkönig
Other common names: White-headed Cactus-wren

Taxonomy. *Heleodytes albo-brunneus* Lawrence, 1862, Panama Railroad, near summit of Atlantic slope, Panama.
Has been thought to form a superspecies with *C. nuchalis*, *C. fasciatus* and *C. zonatus*. Sometimes treated as conspecific with last, with which may hybridize in S Colombia; proposed race *aenigmaticus* (from Nariño, in SW Colombia) may be a hybrid between the two. Has also been treated as conspecific with *C. turdinus*, but differs distinctly in vocalizations. Two subspecies recognized.
Subspecies and Distribution.
C. a. albobrunneus (Lawrence, 1862) – Panama, from Canal Zone E to W Darién.
C. a. harterti (Berlepsch, 1907) – E Panama (E Darién) and Pacific slope of Colombia (S to Valle).



Descriptive notes. 18·5 cm; 27·5–39 g. Uniquely plumaged wren. Has entire head, nape, throat, chest and most of belly immaculate white (though head frequently stained brown), shoulders, back, rump and uppertail-coverts uniform dull blackish-brown, sometimes a few white feathers on shoulders; primaries and secondaries dull brownish-black; tail dark brown, very inconspicuous fine dark bars on upper surface; thighs and vent diffuse grey-brown; eye dark red; bill dark brown or greyish-brown above, pale horn below; legs lead-grey. Sexes similar. Juvenile has streaky grey-brown crown, diffuse pale speckles on shoulders, buffy face and underparts, buff-cinnamon belly, grey eyes. Race *harterti* has darker upperparts than nominate. VOICE. Song a series of harsh scratchy notes; both sexes sing. Call a harsh "kahk".
Habitat. Humid forest with epiphytes, including somewhat disturbed forest; sea-level to 1500 m.
Food and Feeding. Few detailed data. Stomach contents from Panama include beetles (Coleoptera), orthopterans, ants (Hymenoptera). Forages often in small groups, probably extended family parties, mostly at middle or upper levels of trees; frequently searches among epiphytes.
Breeding. Very poorly known. Few nests described, a globular structure with side entrance, in epiphytes in low tree. No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Generally rather uncommon over most of its range; perhaps more abundant in Darién region of Panama. Occurs in Darién National Park.
Bibliography. Angehr (2003), Anon. (1998b), Chapman (1917), Cracraft (1985), Farley (1955), Haffer (1967, 1975), Hellmayr (1934), Hilty (1997), Hilty & Brown (1986), Meyer de Schauensee (1982), Minzenmayer *et al.* (1995), Ridgely & Gwynne (1989), Ridgway (1904), Robbins *et al.* (1985), Wetmore *et al.* (1984), Willis & Eisenmann (1979).

10. **Stripe-backed Wren**

Campylorhynchus nuchalis

French: Troglodyte rayé **German**: Pantherzaunkönig **Spanish**: Cucarachero Chocorocoy
Other common names: Stripe-backed Cactus-wren, Banded Wren

Taxonomy. *Campylorhynchus nuchalis* Cabanis, 1847, Cumaná, Sucre, Venezuela.
Has been thought to form a superspecies with *C. albobrunneus*, *C. fasciatus* and *C. zonatus*. Three subspecies recognized.
Subspecies and Distribution.
C. n. pardus P. L. Sclater, 1858 – Caribbean coast of Colombia (Magdalena and Bolívar S to c. 8° N).
C. n. brevipennis Lawrence, 1866 – N Venezuela (Yaracuy E to Miranda, S to Guárico).
C. n. nuchalis Cabanis, 1847 – C & E Venezuela (Barinas E to W Sucre and Delta Amacuro, S to Apure and N Bolívar).

Descriptive notes. 17·5 cm; 21·1–25·5 g. Nominate race has buff-grey crown mottled with blackish, hindneck with brownsih or buffy tinge, nape and upperparts conspicuously streaked black and white, primaries and secondaries heavily barred dull black and white, tail strongly barred dull black and white; whitish below, diffuse greyish spots on lower throat, becoming larger and darker on chest and belly; lower flanks diffusely barred blackish; eye white or straw-yellow; bill blackish above, greyish or whitish-flesh below; legs slate-grey. Sexes similar. Juvenile has solid blackish crown, more brownish-black colour on upperparts, wings and tail, reduced markings on underparts, grey iris. Race *pardus* differs from nominate in having less spotting on underparts, heavier bill; *brevipennis* has darker crown than nominate, heavier spotting below. VOICE. Song an unmusical series of 6 or more scratchy notes, given by both sexes and by members of group; partners, sitting close to each other, utter alternating or intercalating phrases with precise timing; up to five group-members may chorus together. Calls harsh and raspy; male learns repertoire of stereotyped calls from older male relatives, vocalizations thus specific to a patrilineal family group, and may also be shared by related males which have moved to other groups; individuals able to recognize this relationship not only within own group, but also for related males in other groups.
Habitat. Dry and semi-humid habitats; open forest, bushland and gallery forest; frequently near small waterbodies. Sea-level to 800 m. Normally not found alongside *C. griseus*.
Food and Feeding. Predominantly invertebrates. Forages at all levels, including on tree trunks.
Breeding. Season Apr–Sept, egg-laying triggered by first heavy rains of wet season; two or three broods, but multiple broods successful only for larger groups. Communal nesting system and social organization the most highly developed within family; group consists of dominant (nesting) pair and up to 12 helpers, mostly offspring produced by dominant pair; all young females and majority of young males ultimately disperse to other territories, such males as remain rise in rank with time and may attain breeding status; loose colony formed by many groups in single area, much competition for vacancies in adjacent groups (especially large ones). Nest a large, untidy domed structure made of grass, fibres and similar material, lined with feathers, placed 2–10 m above ground usually in leguminous tree or palm, frequently near end of slim branches for protection against monkeys; alternatively, abandoned pendent nest of other species, e.g. Rufous-fronted Thornbird (*Phacellodomus rufifrons*), relined with feathers and then used. Eggs usually 4, plain white; incubation by dominant female alone, period 18–21 days; all group-members participate in feeding of young and defence of nest and territory; fledging period probably c. 19 days. Nests not uncommonly parasitized by Shiny Cowbird (*Molothrus bonariensis*). Strong correlation between breeding success and numbers of helpers.
Movements. Apparently sedentary. Dispersal by young birds over short range.
Status and Conservation. Not globally threatened. Uncommon to locally common; abundant in some areas. In prime habitat, group territories (each containing 5–14 individuals) from 1 ha to 4 ha in size and may be contiguous. Occurs in Isla de Salamanca National Park, in Colombia.
Bibliography. Barnés (1939), Brenowitz & Kroodsma (1996), Chapman (1917), Cherrie (1916), Cracraft (1985), Darlington (1931), Friedmann (1948), Friedmann & Smith (1950), Hellmayr (1934), Hilty & Brown (1986), Meyer de Schauensee (1982), Piper (1994), Piper & Slater (1993), Price (1999, 2003), Rabenold, K.N. (1984, 1985, 1990), Rabenold, K.N. & Carla (1979), Rabenold, K.N. & Yaber (1998), Rabenold, P.P., Kerry *et al.* (1991), Rabenold, P.P., Rabenold & Michella (1988), Ridgely & Tudor (1989), Selander (1964), Stevens (1989), Stevens & Wiley (1995), Thomas (1979), Wetmore (1939), Wiley & Wiley (1977), Yaber & Rabenold (1998, 2002), Zack (1991), Zack & Rabenold (1989).

11. **Fasciated Wren**

Campylorhynchus fasciatus

French: Troglodyte fascié **German**: Bindenzaunkönig **Spanish**: Cucarachero Ondeado
Other common names: Fasciated Cactus-wren

Taxonomy. *Furnarius fasciatus* Swainson, 1838, Peru.
Has been thought to form a superspecies with *C. albobrunneus*, *C. nuchalis* and *C. zonatus*. Two subspecies recognized.
Subspecies and Distribution.
C. f. pallescens Lafresnaye, 1846 – SW & S Ecuador (S from Guayas, including Puna I) S to N Peru (Tumbes, N Piura).
C. f. fasciatus (Swainson, 1838) – arid coastal regions of Peru from Piura S to NW Lima, probably also E of R Marañón (Amazonas S to Huánuco).

Descriptive notes. 19 cm; one female 24·9 g. Nominate race has greyish-white supercilium, black-speckled grey crown; blackish-grey shoulders, back and rump, shoulders speckled whitish, rump barred whitish; primaries, secondaries and upperwing-coverts heavily barred blackish and off-white; tail blackish-brown with prominent off-white bars; chin off-white with darker streaks, chest and belly whitish with heavy blackish-grey spots, flanks barred blackish-grey; eye red-brown to pale whitish-tan; bill dark grey or dark brown above, greyish-horn below; legs dark tan or dull yellowish. Sexes similar. Juvenile has markings on underparts less well defined, slate-grey eyes. Race *pallescens* is paler, less well marked below and shorter-billed than nominate. VOICE. Song a series of harsh churring notes interspersed with gurgling notes; duetting or group singer. Call a harsh "churr".
Habitat. Arid and semi-arid areas; thorny scrubland, including areas much modified by human activity; also citrus orchards. In Ecuador in more humid habitat, including deciduous woodland. Sea-level to 1500 m, rarely to 2500 m.
Food and Feeding. Predominantly invertebrates; some vegetable matter. Forages in groups, in bushes and shrubs, also on roofs of farm buildings; occasionally descends to ground.
Breeding. Season May–Aug. Usually co-operative nester, more rarely as solitary pair; groups of up to ten individuals, with one dominant nesting pair, offspring tend to remain in territory in following year and to assist at nest, after which females disperse, but many males remain with group and gradually attain senior and, ultimately, breeding status. Nest domed, with side entrance, built of grass and lined with feathers, in variety of sites, including citrus and mesquite (*Prosopis*) trees and columnar cactus, and once on porch in a house; old mud-oven nest of Pale-legged Hornero (*Furnarius leucopus*) frequently used. Eggs probably 3–4, undescribed; incubation c. 17 days; no information on fledging period; birds roost communally in nest.
Movements. Sedentary; local dispersal by young females.
Status and Conservation. Not globally threatened. Common in parts of range. Seems to adapt well to highly modified habitat, provided that sufficient bushes are left. Status in Peru E of R Marañón requires clarification; possibly extends S into Junín.
Bibliography. Becker & López (1997), Best *et al.* (1997), Bloch *et al.* (1991), Butler (1979), Hellmayr (1934), López & Gastezzi (2000), Meyer de Schauensee (1982), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Taczanowski (1884), Wiedenfeld *et al.* (1985), Williams & Tobias (1994).

12. **Band-backed Wren**

Campylorhynchus zonatus

French: Troglodyte zoné **German**: Tigerzaunkönig **Spanish**: Cucarachero Barrado
Other common names: Band-backed/Banded Cactus-wren, Barred Wren/Cactus-wren

Taxonomy. *Picolaptes zonatus* Lesson, 1832, "California"; error = Orizaba, Veracruz, Mexico.

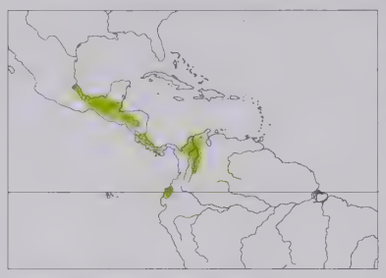
On following pages: 13. Grey-barred Wren (*Campylorhynchus megalopterus*); 14. Tooth-billed Wren (*Odontorchilus cinereus*); 15. Grey-mantled Wren (*Odontorchilus branickii*); 16. American Rock Wren (*Salpinctes obsoletus*); 17. Canyon Wren (*Catherpes mexicanus*).

Has been thought to form a superspecies with *C. albobrunneus*, *C. nuchalis* and *C. fasciatus*. Sometimes considered conspecific with first of those, and may hybridize with it in S Colombia; proposed race *aenigmaticus* (from Nariño, in SW Colombia) is possibly a hybrid between them. Believed by some to be possibly closely related also to *C. megalopterus*; ranges overlap but no evidence of interbreeding. Proposed race *panamensis* (described from WC Panama) very similar to, and intergrading with, *costaricensis*, considered better merged with latter. Seven subspecies recognized.

Subspecies and Distribution.

C. z. zonatus (Lesson, 1832) – E Mexico (Puebla, Veracruz).

C. z. restrictus (Nelson, 1901) – S Mexico (S Veracruz, N Oaxaca) S to Guatemala and Belize.



C. z. vulcanius (Brodkorb, 1940) – S Mexico (Chiapas) S to Nicaragua.

C. z. costaricensis Berlepsch, 1888 – Caribbean slope of Costa Rica S to WC Panama.

C. z. curvirostris Ridgway, 1888 – Santa Marta region of N Colombia.

C. z. brevirostris Lafresnaye, 1845 – N Colombia (except Santa Marta) to NW Ecuador.

C. z. imparilis Borrero & Hernández, 1958 – NE Colombian lowlands.

Descriptive notes. 18–19 cm; 28·3–39·5 g. Distinctive wren with heavily spotted chest, bright cinnamon belly and prominently barred back. Nominate race has crown speckled blackish-grey, nape streaked black and white, back heavily barred black and off-white sometimes with chestnut areas, primaries and secondaries barred black and whitish, tail dull black with off-white bars, especially at side; throat and chest buff-white with circular black spots, belly orange-buff; eye reddish-brown; bill blackish above, paler below; legs yellowish-flesh or yellowish-olive. Sexes similar. Juvenile has blackish crown (capped appearance), back spotted, not barred, greyish chest without spots, pale cinnamon-buff belly. Race *restrictus* is larger and more heavily spotted than nominate; *vulcanius* is less strongly buff, no spots or bars on belly; *costaricensis* is smaller than nominate, with abdomen more tawny, heavier and blacker spotting on chest and throat; *brevirostris* has belly much paler than nominate, juvenile generally paler; *curvirostris* is very similar to previous but smaller, with posterior upperparts deeper buff; *imparilis* differs from last in shorter tail, much less deeply coloured lower underparts. Voice. Song a jumbled series of harsh scratchy notes, usually in phrases of c. 2–3 seconds with frequent repetition; sexes sing in unison. Calls loud and harsh, e.g. "zhek-zhek, karrr".

Habitat. Very varied. Lowland humid forest, forest edge and disturbed areas; at higher altitudes, both in dry oak (*Quercus*) and pine (*Pinus*) forest and in wet epiphytic forest, also edge of cypress (*Cupressus*) forest. Sea-level to 3000 m.

Food and Feeding. Food appears to be mostly invertebrates. Forages at all levels; prises apart loose tree bark and lichens, sometimes while hanging head downwards in manner of tit (Paridae); also forages on ground, by turning over leaves. Sometimes joins mixed-species flocks.

Breeding. Egg-laying Mar–Aug; double-brooded in lowlands, one brood at higher altitudes. Co-operative breeder. Nest, built by male or by both members of pair, an untidy globular structure c. 25–30 cm in diameter, of plant fibres, straw and moss, lined with wool and hair, lateral entrance c. 10 cm across and protected above by short "porch"; placed 2–30 m up, usually 8 m or more, in tree or under cover of epiphytes; nests also built for roosting purposes, often by several (presumably related) individuals. Eggs 3–5, white, with or without a few dark speckles; incubation period probably c. 20 days; chicks fed by both sexes, also by up to five helpers (presumably immature relatives), fledging period 18–19 days; after fledging, family roosts communally, usually in different nest.

Movements. Sedentary; no evidence of even altitudinal movement.

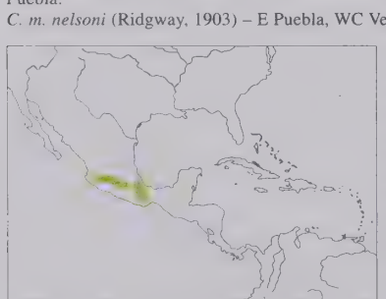
Status and Conservation. Not globally threatened. Common or abundant in much of its range. Occurs in rather broad range of habitats; seems able to tolerate substantial modification of habitat.

Bibliography. Anon. (1998b), Best *et al.* (1997), Binford (1989), Blake (1953), Bloch *et al.* (1991), Brodkorb (1943), Chapman (1917), Cracraft (1985), González-García (1993), Haffer (1975), Hellmayr (1934), Hilty & Brown (1986), Howell & Webb (1995), Land (1970), Lee Jones (2004), Lowery & Dalquest (1951), Meyer de Schauensee (1982), Miller (1995), Monroe (1968), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Ridgway (1904), Selander (1964), Skutch (1940, 1960, 1985b), Slud (1960, 1964), Stiles & Skutch (1989), Thurber *et al.* (1987), Wetmore (1941, 1943).

13. **Grey-barred Wren**

Campylorhynchus megalopterus

French: Troglodyte zébré **German**: Graubinden-Zaunkönig **Spanish**: Cucarachero Serrano
Other common names: Grey-barred Cactus-wren, Grey Wren(!)/Cactus-wren



Taxonomy. *Campylorhynchus megalopterus* Lafresnaye, 1845, Mexico.

Suggested as being closely related to *C. zonatus*, but ranges overlap and no evidence of interbreeding. Race *nelsoni* has been suggested as possibly a separate species. Two subspecies recognized.

Subspecies and Distribution.

C. m. megalopterus Lafresnaye, 1845 – highlands of C Mexico from Jalisco and Michoacán E to W Puebla.

C. m. nelsoni (Ridgway, 1903) – E Puebla, WC Veracruz and N Oaxaca (S Mexico).

Descriptive notes. 17–19·5 cm; 32·8–33·5 g. Large greyish wren with prominent spotting and barring. Nominate race has crown greyish with black feather centres, shoulders and back black, nape with whitish streaks, back prominently barred white; remiges and rectrices barred blackish and off-white; throat and chest whitish with conspicuous black spots, flanks buffy with diffuse blackish bars; eye reddish-brown; bill blackish above, largely grey-black below; legs brownish-flesh. Sexes similar. Juvenile is quite distinct, plumage overall much more buff and brownish, with solid brownish cap, no prominent barring on back, no spots on chest. Race *nelsoni* is smaller than nominate, underpart markings greyish-brown, rather than black. Voice. Song a rapid harsh chatter; both sexes sing in duet. Call a harsh "karrr".

Habitat. Montane forest of various types, including humid pine–oak (*Pinus–Quercus*) forest and epiphytic forest; also pure stands of tall fir (*Abies*) in Michoacán. Occurs in both virgin habitat and areas that have been substantially cut over. At 2100–3150 m.

Food and Feeding. No published information on diet; probably mostly invertebrates. Has finer bill than other members of genus, perhaps indicating that smaller prey taken. Spends most of its time in probing among epiphytes, mosses and lichens, and in pine cones; appears not to forage on the ground.

Breeding. Poorly known. Season probably May–Jun. Few nests described, a domed structure of mosses, entrance hole at side, situated 15–20 m up in oak, conifer or madrono (*Arbutus*) tree. Eggs undescribed; no information on incubation and fledging periods; breeding birds assisted by helpers at nest.

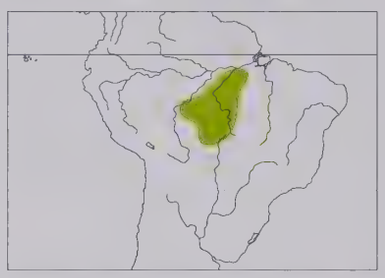
Movements. Apparently entirely sedentary.

Status and Conservation. Not globally threatened. Restricted-range species: present in Sierra Madre Occidental and Trans-Mexican Range EBA and Southern Sierra Madre Oriental EBA. Quite common in many areas of suitable habitat. Appears to be able to tolerate some modification of habitat.

Bibliography. Anon. (1998b), Arizmendi & Márquez (2000), Binford (1989), Blake (1953), Brodkorb (1947), Edwards & Martin (1955), Elliott & Davis (1965), Hellmayr (1934), Howell & Webb (1995), Hutto (1980), Lea & Edwards (1950), Ridgway (1904), Rowley (1984), Selander (1964), Wheatley & Brewer (2001).

Genus *ODONTORCHILUS* Richmond, 1915

14. **Tooth-billed Wren**



Odontorchilus cinereus

French: Troglodyte denté **German**: Zahnschnabel-Zaunkönig **Spanish**: Cucarachero Dentado

Taxonomy. *Odontorhynchus cinereus* Pelzeln, 1868, Salto do Girão, upper River Madeira, Brazil.

Sometimes regarded as conspecific with *O. branickii*, but the two differ significantly in song and habitat. Monotypic.

Distribution. C Brazil (from just S of Amazon, in E Amazonas and Pará, S to E Rondônia and C Mato Grosso) and E Bolivia (NE Santa Cruz).

Descriptive notes. 12 cm; male 11 g. Crown is cinnamon grey-brown, back and shoulders medium grey, primaries and secondaries rather darker; rectrices grey-brown with about six broad greyish-black bars, outermost rectrices with pale tips; ear-coverts grey-brown, throat and chest buffy-grey, flanks greyish-white, undertail-coverts greyish-white with blackish-grey bars; eye dark brown to brick-red; bill black, grey base of lower mandible; legs dark grey. Sexes similar. Juvenile has base of lower mandible brownish. Voice. Song a loud series of notes on same pitch, slower and less trilled than that of *O. branickii*. Call a high-pitched "swee".

Habitat. Tropical lowland forest, from near sea-level to 500 m.

Food and Feeding. No dietary information recorded; probably mostly invertebrates. Feeds in upper canopy of forest, frequently in mixed flocks with tyrant-flycatchers (Tyrannidae), tanagers (Thraupidae) and furnariids.

Breeding. One female in Bolivia in breeding condition on 1st Sept. No other information.

Movements. No information; probably sedentary.

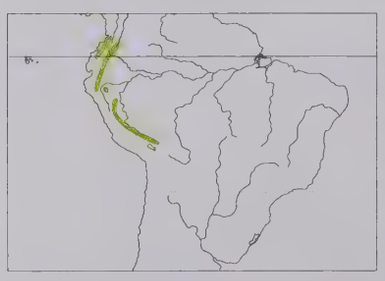
Status and Conservation. Not globally threatened. Relatively sparse over most of its range; fairly common in parts of E Bolivia. Occurs in Rio Cristalino Forest Reserve, in Brazil. Susceptible to deforestation in substantial parts of its range.

Bibliography. Acheson & Davis (2001), Bates *et al.* (1992), Cracraft (1985), Dubs (1992), Forrester (1993), Hellmayr (1934), Hennessey *et al.* (2003), Meyer de Schauensee (1982), Ridgely & Tudor (1989), Sick (1993, 1997), Stotz *et al.* (1997).

15. **Grey-mantled Wren**

Odontorchilus branickii

French: Troglodyte de Branicki **Spanish**: Cucarachero Dorsigrís
German: Graumantel-Zaunkönig



Taxonomy. *Odontorhynchus branickii* Taczanowski and Berlepsch, 1885, Machay, Tungurahua, east Ecuador.

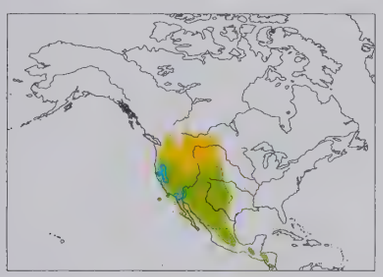
Sometimes regarded as conspecific with *O. cinereus*, but the two differ significantly in song and habitat. Two subspecies recognized.

Subspecies and Distribution.

O. b. minor (Hartert, 1900) – W Andes of S Colombia and extreme N Ecuador.

O. b. branickii (Taczanowski & Berlepsch, 1885) – E Andes of S Colombia (S from W Caqueta) and E Ecuador S on both slopes to W Bolivia.

Descriptive notes. 12 cm; 9–10·2 g. Nominate race has obscure greyish to whitish supercilium, grey-brown ear-coverts streaked greyish-white; brown crown, mid-grey shoulders and back merging into brownish on rump; primaries and secondaries somewhat darker grey than back; tail medium grey with prominent dark bars, outer rectrices with subterminal white bar (visible from below); below, whitish with slight buffy tinge, undertail-coverts strongly barred black; eye brown; bill black above, silver-grey below; legs grey. Sexes similar. Juvenile is more buffy below, brown on forehead duller. Race *minor* is smaller than nominate, with barring on central rectrices vestigial. Voice. Song a high metallic trill on even pitch, faster and more distinctly trilled than that of *O. cinereus*; resembles songs of some North



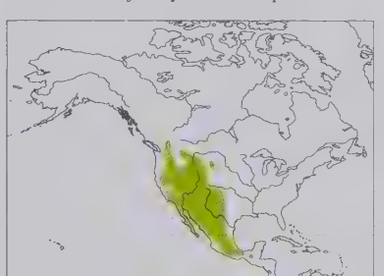
American parulid warblers more than those of any other wren. Callis a high "si-si-si", also atypical for a wren.
Habitat. Humid subtropical and upper tropical forest. Mostly 1400–2200 m, occasionally higher; 800–1100 m on Pacific slope.
Food and Feeding. Few data; stomach contents of specimens contained only invertebrates. Forages high in canopy of forest, solitarily or, frequently, in mixed flocks that include e.g. tanagers (Thraupidae) and becards (*Pachyramphus*).
Breeding. No information.
Movements. Probably sedentary.
Status and Conservation. Not globally threatened. Generally uncommon. Has presumably declined, as parts of its former range are now significantly deforested. Occurs in Podocarpus National Park, in Ecuador.
Bibliography. Best *et al.* (1997), Bloch *et al.* (1991), Chapman (1917), Davies *et al.* (1994), Hellmayr (1934), Hennessey (2004), Hennessey *et al.* (2003), Hilty (1997), Hilty & Brown (1986), Hornbuckle (1999a), Meyer de Schauensee (1982), Perry *et al.* (1997), Ridgely & Gaulin (1980), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Walker (2001).

Genus *SALPINCTES* Cabanis, 1847

16. American Rock Wren
Salpinctes obsoletus

French: Troglodyte des rochers **German**: Felsenzaunkönig **Spanish**: Cucarachero Roquero
Other common names: Rock Wren(!)

Taxonomy. *Troglodytes obsoleta* Say, 1823, South Platte River, Colorado, USA.
Probably closest to *Catherpes* and *Hylorchilus*. Two proposed island races, *pulverius* (from San Nicolas I and San Clemente I, off SW California) and *proximus* (from San Martín I, off NW Baja California), both considered indistinguishable from nominate; described races *costaricensis* (NW Costa Rica) and *fasciatus* (NW Nicaragua) merged with *guttatus*, but one or both possibly merit recognition. Race *exsul*, from San Benedicto I (off WC Mexico), extinct. Five extant subspecies recognized.
Subspecies and Distribution.
S. o. obsoletus (Say, 1823) – breeds W North America from S British Columbia, S Alberta and S Saskatchewan S to coastal California (including islands of San Nicolas and San Clemente), Oklahoma and W Texas, and W, N & C Mexico from Baja California (including San Martín I) S at higher elevations to Oaxaca; N populations migrate to S parts of range.
S. o. guadeloupensis Ridgway, 1876 – Guadalupe I, off W Baja California.
S. o. tenuirostris van Rossem, 1943 – San Benito, off W Baja California.
S. o. neglectus Nelson, 1897 – highlands from S Mexico (Chiapas) S to C Honduras.
S. o. guttatus Salvin & Godman, 1891 – El Salvador S to NW Costa Rica.



Descriptive notes. 14–16 cm; 16·5 g. Nominate race has grey-buff supercilium, greyish-brown crown, nape and back with numerous dark streaks tipped white; mid-back, shoulders and greater upperwing-coverts with obscure darker bars; rump rufous-brown; primaries and secondaries brown with darker bars; rectrices buffy brown with prominent blackish-brown bars and buff tips, widest on outermost rectrices; dull whitish below, belly rufous-buff, chest with fine dark streaks; eyes brown; upper mandible dark horn with pale base, lower mandible pale greyish-pink; legs blackish-brown. Sexes similar. Juvenile is duller, with obscure barring on back, paler underparts. Race *guadeloupensis* is darker and has heavier bill than nominate; *tenuirostris* differs only in having longer, slimmer bill; *neglectus* is darker, greyer and more heavily marked than nominate; *guttatus* is very distinct, much more blotched and barred above and below. Voice. Male repertoire of c. 100 different songs, each a series of identical, repeated syllables, successive songs usually different, as e.g. "kerée kerée kerée", "chair chair chair chair", "deedle deedle deedle deedle", "tur tur tur tur", "kerée kerée kerée trrrrrrr"; female does not sing. Calls short and buzzy, e.g. "chick-urr".
Habitat. Barren rocky hillsides, screes and boulderfalls, also quarries and recently clear-cut areas in rocky terrain. Vagrants frequently on artificial structures, such as breakwaters, which resemble its natural habitat. Sea-level to 3000 m; 1000–3500 m in S of range.
Food and Feeding. Mostly invertebrates; small lizards also taken. Forages among boulders and rocks; very active. Insular race *guadeloupensis* frequents slaughterhouses, where gleans insects from offal.
Breeding. Season from late May in N and at higher elevations; earlier in S, e.g. from mid-Jan in NW Mexico (Baja California) and from early Feb in S USA (California); three broods in S populations, usually two farther N. Nest a cup of grasses and fibres, lined with feathers and fur, usually with foundation of pebbles or small flat stones; foundation, function of which obscure, sometimes quite massive (one weighed 2·2 kg in total, c. 120 times weight of adult bird, with some individual stones up to one third of bird's own weight); usually in crevice in rock-pile or in abandoned hole of gopher (Geomyidae), occasionally in artificial site in abandoned building. Clutch in N of range usually 5–6 eggs, occasionally 4–8, rarely as many as 10, on Guadalupe (race *guadeloupensis*) usually 4, sometimes 5, eggs glossy white with sparse reddish-brown speckles; incubation by female alone, period 12–14 days; fledging period 14–16 days.
Movements. S populations and those on islands apparently sedentary. Migratory in N; withdraws in winter from all of breeding range N of N California, C Nevada, C Arizona, C New Mexico and N Texas. Recorded as vagrant over most of E North America, as far E as Newfoundland, New Jersey and Florida, mostly during Oct–Dec; records also from farther N in Canada, including NW Territories (Mackenzie) and on S shore of Hudson Bay.
Status and Conservation. Not globally threatened. Common in suitable areas over much of its range. Has bred in NC Canada, at Churchill (N Manitoba). Race *exsul*, formerly resident on San Benedicto, in Revillagigedo Group, off W Mexico, became extinct in 1952 following a volcanic eruption. No recent information on status of other two island races (*guadeloupensis* and *tenuirostris*). There is little human pressure on much of its preferred barren habitat, often in rather remote areas.
Bibliography. Anon. (1998b), Baicich & Harrison (1997), Barker (1999), Bond (1940), Brattstrom (1990), Brattstrom & Howell (1956), Bryant (1887), Campbell *et al.* (1997), Ceballos & Valdelamar (2000), Contreras (1997), Contreras & Trevino (1987), DeGraaf & Rappole (1995), Dickey & van Rossem (1938), Gómez de Silva (1995), Grinnell (1928a), Hellmayr (1934), Howell & Webb (1995), Johnsgard (1979), Jones, S.L. Genus *CATHERPES* S. F. Baird, 1858

17. Canyon Wren
Catherpes mexicanus

French: Troglodyte des canyons **Spanish**: Cucarachero Barranquero
German: Schluchtenzaunkönig

Taxonomy. *Thryothorus mexicanus* Swainson, 1829, Real del Monte, Hidalgo, Mexico.
Probably closest to *Hylorchilus*. Other described races, all from USA, are *griseus* (Yakima County, in S Washington), *punctulatus* (Placer County, in EC California) and *polioptilus* (Chisos Mts, in Texas), but plumage variations of these are not constant, and no clear-cut geographical boundaries are apparent. Seven subspecies recognized.
Subspecies and Distribution.
C. m. pallidior A. R. Phillips, 1986 – SW Canada (S British Columbia) and W USA (S to NE Utah and NW Colorado).
C. m. conspersus Ridgway, 1873 – SW USA (from N Nevada and C Colorado) S to NW Mexico (S to C Baja California).
C. m. albifrons (Giraud, 1841) – S USA (SW Texas) and N Mexico (Coahuila, Nuevo León).
C. m. meliphonus Oberholser,1930 – NW Mexico (W Sonora and WC Chihuahua S to Sinaloa and Durango).
C. m. croizati A. R. Phillips, 1986 – S Baja California.
C. m. cantator A. R. Phillips, 1966 – C Mexico (Nayarit S to Michoacán).
C. m. mexicanus (Swainson,1829) – Mexican plateau from Durango and Jalisco S to Colima and Oaxaca, also disjunctly in SW Chiapas.

Descriptive notes. 13–15 cm; 9–18 g. Nominate race has crown and nape grey-brown with whitish speckles, shoulders and back rufous-brown with brown and whitish spots, rump chestnut; remiges chestnut-brown with darker bars, rectrices chestnut-brown with blackish transverse bars; ear-coverts grey-brown, finely spotted with white; chin to chest greyish-white, contrasting chestnut-brown belly richer towards crissum and variably marked black and white; eyes dark brown; bill notably long and decurved, greyish-brown, lower mandible with pale base; legs dull grey-black. Sexes similar. Juvenile is less brightly coloured, speckles on back obscure. Race *pallidior* is paler than nominate, especially on crown; *conspersus* is smaller and paler, with shorter bill; *albifrons* is darker and larger than other races; *meliphonus* is smaller and generally lighter in colour than nominate; *croizati* is also smaller and paler, but with warmer reddish-brown underparts; *cantator* is dark, resembles nominate but smaller. Voice. Song a beautiful descending trill, slowing towards end, terminating with superb series of clear whistles; both sexes sing, female's song usually shorter and with buzzy overtone. Call a loud metallic buzz.
Habitat. Confined to areas with rock faces, such as canyons, more rarely sea cliffs, also ruins; nearby vegetation can be coniferous or deciduous, or mixed. Occurs in arid areas in SW USA and humid areas in S Mexico. Sea-level to 3000 m in Mexico, usually to 1850 m in W USA.
Food and Feeding. Food entirely invertebrates, especially spiders (Araneae), beetles (Coleoptera), bugs (Hemiptera), ants (Hymenoptera) and termites (Isoptera). Forages in narrow crevices in rocks, for which morphologically adapted (long decurved bill, flattened cranium, short tarsi). Has been observed to pilfer paralysed spiders from nests of mud-dauber wasp (*Scelifron cementarium*).
Breeding. From Mar in S, but from as late as Jun in N and at high altitudes; sometimes two broods, rarely three. Nest, built by both sexes, an open cup of moss, wool, hair, etc. on base of coarser twigs, frequently with artificial debris incorporated, sometimes to bizarre extent (one nest had more than 1 kg of such items as pen-nibs, paper clips and the like, stolen from a nearby office), placed in cavity or crevice in rock face, among boulders, in cave or often in ruin or other artificial site; nest sometimes reused in same or subsequent years. In study in NC Colorado (USA): territory size in summer 0·4–2·8 ha (winter 0·2–1·9 ha); mean territory density in summer 4·5/100 ha (winter 3·4/100 ha). Eggs 3–7, usually 6, often fewer in S, mean in NC Colorado 4·5, glossy white with fine reddish-brown speckles; incubation by female alone, fed on nest by male, period 12–19 days, average c. 16–17 days; fledging period 12–19 days, average 15–17 days; young accompanied by parents for up to 2 weeks. Of 28 nests in Colorado study, 22 successfully fledged young and four probably did so.
Movements. Largely sedentary; some altitudinal movement by N populations. Some mobility suggested, however, by occurrences of vagrants in such locations as Saskatchewan (SC Canada) and Nebraska and Kansas (C USA).
Status and Conservation. Not globally threatened. Common to fairly common in suitable habitat. The nature of this species' habitat is such that, in the greater part of its range, human encroachment is relatively rare.

Genus *HYLORCHILUS* Nelson, 1897

18. **Sumichrast's Wren**

Hylorchilus sumichrasti

French: Troglodyte à bec fin **Spanish**: Cucarachero Picofino
German: Schmalschnabel-Zaunkönig
Other common names: Slender-billed Wren

Taxonomy. *Catherpes sumichrasti* Lawrence, 1871, Mato Bejuco, Veracruz, Mexico.
Has been included in genus *Catherpes*. Formerly treated as conspecific with *H. navai*, but the two are quite distinct in plumage and, especially, in vocalizations. Monotypic.
Distribution. SW Veracruz, extreme E Puebla and extreme N Oaxaca, in SC Mexico.

Descriptive notes. 16 cm; female 28·4 g. Upperparts, including flight-feathers, are uniform dark chocolate-brown, slightly more rufous on back; obscure and inconspicuous barring on closed wing; throat whitish-brown, chest orange-brown, belly rich chocolate-brown with small distinct white spots; eyes brown; bill blackish, orange-yellow base of lower mandible; legs dark grey. Sexes similar. Juvenile has dull buff throat with diffuse scaling, whitish flecks on belly. VOICE. Male song of two types, one a sequence of loud, clear ringing whistles starting with a series of short notes and running into longer series of slow descending whistles, the other a shorter verse of 3–5 notes alternating randomly in pitch; female song quite different, a single syllable repeated in series of 4–22 notes; sexes may sing synchronously; songs very different from those of *H. navai*, and neither species responds to tape recordings of the other. Calls also distinct, an emphatic "chewk", a squealing "wheeo" and various scolding notes.
Habitat. Restricted to forested outcrops of karst limestone, including shade coffee plantations on limestone; c. 75–1000 m.
Food and Feeding. Diet mostly invertebrates, including worms, spiders (Araneae), mites (Acarini), bugs (Hemiptera) and beetles (Coleoptera); also, unusually for a troglodytid, small snails frequently taken. Some vegetable matter (small fruit) taken. Feeds mostly on rock surfaces, or by probing into rock crevices with the long bill; also tosses aside fallen leaves in search of prey, and makes short jumping sallies into the air for flying insects, including on one occasion a moth (Lepidoptera).
Breeding. Poorly known. Nest-building observed in Mar, nests with eggs found in May, and adults feeding fledglings in Jul and Aug. Of three known nests, two were in crevice in rocks, the other in roof of limestone cave. Eggs 3, white; no information on incubation and fledging periods; two fledglings from one nest foraged sometimes separately, each with one adult, and sometimes together, with both parents.
Movement. Sedentary.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Total range encompasses c. 6000 km², but the species' required habitat (forested karst outcrops) occupies much smaller area within this; between these pockets of habitat are larger unsuitable areas, now mostly given over to agriculture. Recent investigation located twelve populations, most in outcrops and isolated from others. In areas of occurrence can be very abundant; e.g. one transect in Oaxaca, 738 m long and 200 m wide, yielded a count of 13 males and nine females. Appears able to withstand substantial habitat modification, e.g. the planting of shade coffee, provided that overall forest crown largely intact; can also persist in very small fragments of habitat, down to 0·5 ha. It is unclear whether the species has always been restricted to such outcrops or whether, before destruction of intervening forest, it was more widely distributed. Most serious threat to remaining habitat is from quarrying activities; in addition, some areas have been flooded by construction of new reservoirs.
Bibliography. Anon. (1998b), Arizmendi & Márquez (2000), Blake (1953), Ceballos & Valdelamar (2000), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Crossin & Ely (1973), Gómez de Silva (1997a, 1997b), Gómez de Silva *et al.* (2004), Hardy & Delaney (1987), Hellmayr (1934), Howell & Webb (1995), Pérez-Villafaña *et al.* (1999, 2003), Ridgway (1904), Stattersfield & Capper (2000), Wauer (1986), Wege & Long (1995), Wheatley & Brewer (2001), Whittingham & Atkinson (1996).

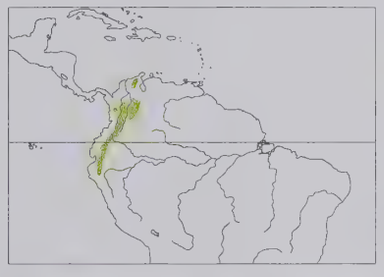
19. **Nava's Wren**

Hylorchilus navai

French: Troglodyte de Nava **German**: Navazaunkönig **Spanish**: Cucarachero de Nava
Other common names: Crossin's Wren

Taxonomy. *Hylorchilus sumichrasti navai* Crossin and Ely, 1973, 26 km north of Ocozocoautla, Chiapas, Mexico.
Originally described as a race of *H. sumichrasti*, but more recent studies of vocalizations indicate that the two are distinct species. Monotypic.
Distribution. S Mexico: confined to very limited area in SE Veracruz and NW Chiapas and, very marginally, NE Oaxaca.
Descriptive notes. 16 cm; female 29·3 g. Has tawny-brown face, greyish lores; crown and upperparts dark, rich brown, remiges faintly barred blackish; throat and upper chest whitish, becoming pale grey on lower chest, with faint scalloping; flanks dark sooty brown, vent dusky grey-brown; eye brown; bill blackish, pale orange-yellow base of lower mandible; legs dark grey. Sexes similar. Juvenile undescribed. VOICE. Song described as a varied, often stuttering warble of mellow whistles, sometimes introduced by few slightly accelerating soft notes and terminating in strongly upslurred note; quite different from song of *H. sumichrasti*, and neither responds to tape recordings of the other's song. Female's song only recently described, an introductory note followed by rapid series of 8 or more loud whistles, appears to be used agonistically; not highly co-ordinated with that of male (in contrast to many tropical troglodytids), usually overlaps with male's song, but may

start near beginning, middle or end of it, somewhat at random. Call a metallic "tink", quite distinct from calls of its congener.
Habitat. Forest on outcrops of karst limestone; c. 75–800 m. In contrast to *H. sumichrasti*, seems to require undisturbed forest; no evidence of colonization of secondary habitat.
Food and Feeding. No data on food; probably largely or wholly invertebrates. Forages on rocky ground and in crevices on rock faces.
Breeding. No information.
Movements. Sedentary.
Status and Conservation. VULNERABLE. Restricted-range species: present in Los Tuxtlas and Uxpanapa EBA. Total range only c. 4800–4900 km², within which suitable habitat covers much smaller area; intervening areas between isolated forested outcrops of karst limestone now largely deforested for agriculture, leaving remaining habitat highly fragmented. Currently known from six sites in E Veracruz, one in W Chiapas and two in NE Oaxaca. Some of its range is protected by the Selva El Ocote Biosphere Reserve, although this contains very little suitable habitat and the species is not present at many sites there; a more important reserve would be the proposed Chimalapas–Uxpanapa Biosphere Reserve. Although the outcrops themselves are unsuitable for agriculture, firewood-gathering at unprotected sites is a significant threat. It has been suggested that the species should more properly be categorized as Endangered.
Bibliography. Anon. (1998b), Arizmendi & Márquez (2000), Atkinson *et al.* (1993), Ceballos & Valdelamar (2000), Collar & Andrew (1988), Collar *et al.* (1992), Crossin & Ely (1973), Gómez de Silva (1995, 1997a), Gómez de Silva & Sada (1997), Gómez de Silva *et al.* (2004), Howell & Webb (1995), Stattersfield & Capper (2000), Wege & Long (1995), Wheatley & Brewer (2001), Whittingham & Atkinson (1996).



Genus *CINNYCERTHIA* Lesson, 1844

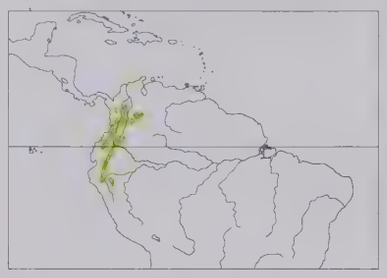
20. **Rufous Wren**

Cinnycerthia unirufa

French: Troglodyte roux **German**: Einfarb-Zaunkönig **Spanish**: Cucarachero Rufo
Other common names: Brown Wren

Taxonomy. *Limnornis unirufus* Lafresnaye, 840, Santa-Fe-de-Bogotá, Colombia.
Three subspecies recognized.
Subspecies and Distribution.
C. u. chakei Aveledo & Ginés, 1952 – Sierra de Perijá, on Colombia–Venezuela border.
C. u. unibrunnea (Lafresnaye, 1853) – Colombia (N part of W Andes, and C Andes) S to N Peru (Piura, Cajamarca).
C. u. unirufa (Lafresnaye,1840) – E Andes in extreme SW Venezuela (Táchira) and Colombia (S to Cundinamarca).

Descriptive notes. 16·5 cm; 21–29 g. Plumage is entirely brown of different shades; crown orange-brown, nape and shoulders deeper chestnut, becoming more reddish-brown on lower back; primaries and secondaries chestnut, narrowly barred blackish; rectrices reddish-brown with inconspicuous darker bars; chin paler, chest orange-brown, becoming reddish-brown on vent; lores blackish; bill and legs black. Sexes similar. Juvenile resembles adult, but barring on flight-feathers largely absent. Nominate race has brown eyes. Race *unibrunnea* is darker and duller than nominate; *chakei* differs in having whitish or grey eyes. VOICE. Song loud and arresting, a rapidly repeated 2-note or 3-note motif, e.g. "chew-tu", with loud metallic trill superimposed, the whole lasting for at least 10 seconds; by both sexes in duet, sometimes with participation of other group-members. Call a soft "churr" or "whit-whit"; loud, harsh "geea" when mobbing intruders.
Habitat. Wet montane forest, forest edge and shrub-forest, often with *Chusquea* bamboo; 2200–3800 m.
Food and Feeding. Few data; food apparently entirely invertebrates. Forages low down; turns over litter on ground. Gregarious; often joins mixed-species flocks.
Breeding. Birds in breeding condition from Jun to Aug in Sierra de Perijá (*chakei*); juvenile of race *unibrunnea* observed in Mar in Colombia. No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common to locally common where suitable habitat remains. Occurs in several protected areas, e.g. Munchique National Park, in Colombia, and Podocarpus National Park, in Ecuador.
Bibliography. Baez *et al.* (1997), Best *et al.* (1997), Chapman (1917), Cracraft (1985), Davies *et al.* (1994), Fjeldså & Krabbe (1990), Hellmayr (1934), Hilty (2003), Hilty & Brown (1986), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Varty *et al.* (1986), Williams & Tobias (1994).



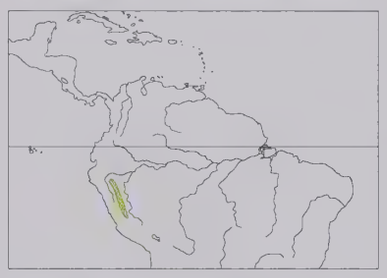
21. **Sharpe's Wren**

Cinnycerthia olivascens

French: Troglodyte de Sharpe **Spanish**: Cucarachero Sepia
German: Nördlicher Sepiazaunkönig
Other common names: Sepia-brown Wren (when merged with *C. peruana* and *C. fulva*)

On following pages: 22. Peruvian Wren (*Cinnycerthia peruana*); 23. Fulvous Wren (*Cinnycerthia fulva*); 24. Sedge Wren (*Cistothorus platensis*); 25. Merida Wren (*Cistothorus meridae*); 26. Apolinar's Wren (*Cistothorus apolinari*); 27. Marsh Wren (*Cistothorus palustris*).

Taxonomy. *Cinnicerthia* [*sic*] *olivascens* Sharpe, 1882, Santa Elena, Antioquia, Colombia.
Formerly treated as conspecific with *C. peruana* and *C. fulva*; recent studies indicate, however, that the three are distinct species, differing in e.g. plumage and/or voice. Two subspecies recognized.
Subspecies and Distribution.
C. o. olivascens Sharpe, 1882 – W & C Andes of Colombia (S from Antioquia) S to extreme N Peru.
C. o. bogotensis (Matschie, 1885) – W slope of E Andes of Colombia (Santander S to Cundinamarca).



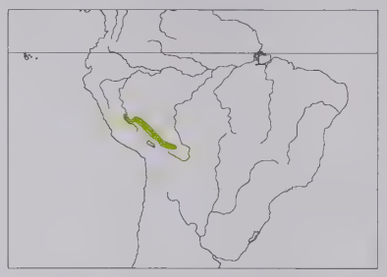
Descriptive notes. 16 cm; male average 25·9 g, female average 23 g. Nominate race has entire plumage different shades of brown, many individuals with variable amount of white on face; crown dark greyish-brown, back and rump reddish-brown, primaries and secondaries bright red-brown with dull blackish bars, extending to greater upperwing-coverts; rectrices chestnut-brown with numerous fine blackish bars; chin and throat pale greyish-brown, belly and vent deep reddish-brown; eye light brown or grey; bill dark grey-brown; legs grey. Sexes similar. Immature is very similar to adult, postocular area greyish. Race *bogotensis* is much darker than nominate, never any white on face. Voice. Song complex and variable, a series of musical phrases with changing stress. Call a soft, low "wurt".
Habitat. Wet mossy forest, including forest edge and cloudforest, often with *Chusquea* bamboo; mainly 1500–3100 m, but down to 900 m on Pacific slope of Colombia (Cauca).
Food and Feeding. No information on diet. Forages on or near the ground, usually in dense vegetation. Gregarious, in flocks of up to ten individuals.
Breeding. Birds in breeding condition in Jun–Aug in Colombia. No other information.
Movements. Presumably sedentary.
Status and Conservation. Not globally threatened. Fairly common in suitable habitat in most of range. Occurs in several protected areas, e.g. Archidona Natural Reserve, in Ecuador.
Bibliography. Best *et al.* (1997), Brumfield & Remsen (1996), Chapman (1917), Clements & Shany (2001), Fjeldså & Krabbe (1990), Hellmayr (1934), Hilty & Brown (1986), Hornbuckle (1999a), Kirwan & Marlow (1996), López *et al.* (2000), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Salaman (1994), Salaman *et al.* (1999).

22. **Peruvian Wren**

Cinnycerthia peruana

French: Troglodyte brun **German**: Sepiazaunkönig **Spanish**: Cucarachero Peruano
Other common names: Peruvian Brown Wren; Sepia-brown Wren (when merged with *C. olivascens* and *C. fulva*)

Taxonomy. *Presbys peruanus* Cabanis, 1873, Maraynioc, Junín, Peru.
Formerly treated as conspecific with *C. olivascens* and *C. fulva*; recent studies indicate, however, that the three are distinct species, differing in e.g. plumage and/or voice. Monotypic.
Distribution. Andes of Peru (from Amazonas S to Ayacucho).



Descriptive notes. 15·5–16 cm; 19·6 g. Has upperparts rich chestnut-brown, nape and back less rufescent than crown and rump; many adults have variable amount of white on the face, usually around eye and on forehead, sometimes considerably more extensive (possibly indicative of social status within group); primaries, secondaries and upperwing-coverts rich chestnut, conspicuously marked with narrow black bars; rectrices rich chestnut-brown, finely barred blackish; chin and throat orange-brown, chest, belly and flanks duller and darker; eyes chestnut; bill dark brown, gape yellow; feet black. Sexes similar. Juvenile apparently resembles adult, but never any white on face. Voice. Song, frequently as duet by the sexes, a magnificent series of rich trills and clear whistles, with some phrases reminiscent of European nightingale (*Luscinia*). Call described as a gravelly, chattering "ch-d-d-d", often given by group-members together.
Habitat. Wet montane forest, second growth and forest edge; 1500–3300 m.
Food and Feeding. No information on food. Usually feeds on or near ground, rummaging around in vegetation and litter. Frequently in groups, seemingly extended families, consisting of a pair of adults with immatures and young juveniles.
Breeding. Poorly documented. Nest with one newly hatched chick and one egg in Sept in Huánuco; also, fledglings observed in Aug and juveniles in Feb, Jun and Nov, indicating possibly protracted breeding season. Huánuco nest pouch-shaped, 20 cm wide, 30 cm long and 15 cm high, pouch 10 cm × 10 cm × 15 cm, with downturned tunnel leading to circular entrance hole, made from rootlets interwoven with green moss, dry bamboo leaves in upper part of pouch, entrance encircled by green moss; suspended from curving bamboo stem; egg pale cream-white with sparse red speckles. No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common in suitable habitat in parts of its range.
Bibliography. Brumfield & Remsen (1996), Clements & Shany (2001), Davies *et al.* (1994), Fjeldså & Krabbe (1990), Gochfeld (1979), Graves (1980, 1985b), Hellmayr (1934), Hilty & Brown (1986), Meyer de Schauensee (1982), Ridgely & Tudor (1989), Taczanowski (1884).

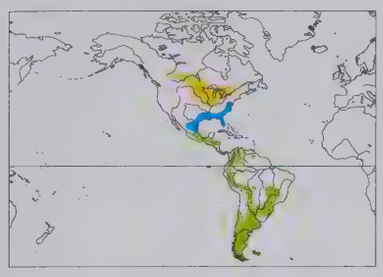
23. **Fulvous Wren**

Cinnycerthia fulva

French: Troglodyte fauve **German**: Südlicher Sepiazaunkönig **Spanish**: Cucarachero Fulvo
Other common names: Superciliated Wren(!); Sepia-brown Wren (when merged with *C. olivascens* and *C. peruana*)

Taxonomy. *Thryophilus fulvus* P. L. Sclater, 1874, Huasampilla, 10,000 feet [c. 3000 m], Cuzco, Peru.
Formerly treated as conspecific with *C. olivascens* and *C. peruana*; recent studies indicate, however, that the three are distinct species, differing in e.g. plumage and/or voice. Three subspecies recognized.
Subspecies and Distribution.
C. f. fitzpatricki Remsen & Brumfield, 1998 – Cordillera de Vilcabamba, in C Peru.
C. f. fulva (P. L. Sclater, 1874) – E Andes of Peru (Cuzco).
C. f. gravesi Remsen & Brumfield, 1998 – S Peru (Puno) S to C Bolivia (Cochabamba).

Descriptive notes. 14·5 cm; male average 18·4 g, female average 14·8 g. Nominate race has supercilium and area above bill pale buff, contrasting with dull brown lores and reddish-brown crown; ear-coverts cinnamon-buff; some adults show white feathering on face (usually less extensive than in *C. peruana*); back reddish-brown, becoming more rufescent on rump; primaries and secondaries reddish-brown on outer webs, numerous narrow blackish bars on closed wing; rectrices reddish-brown with numerous narrow blackish transverse bars; throat buffy white, chest cinnamon-buff, flanks and thighs darker reddish-brown; eyes nut-brown; upper mandible blackish, lower mandible lead-grey; legs dark brown. Sexes similar. Immature resembles adult, but eye duller brown, cap greyish. Race *fitzpatricki* has darker crown than nominate, whitish supercilium and buffy white chin and throat; *gravesi* is paler below, has whitish supercilium contrasting with darker auriculars. Voice. Undescribed; stated to be rather quiet in comparison with *C. peruana*.
Habitat. Wet montane forest ; 1500–3300 m.
Food and Feeding. No information on food items. Forages low in dense vegetation or on ground, often in small flocks.
Breeding. Birds in breeding condition in Jan in Bolivia (La Paz, Cochabamba). No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Fairly common in some locations; e.g. common at Cock-of-the-rock Lodge, in Peru. Generally poorly known.
Bibliography. Brumfield & Remsen (1996), Clements & Shany (2001), Fjeldså & Krabbe (1990), Green (1999), Hellmayr (1934), Hennessey *et al.* (2003), Remsen & Brumfield (1998), Ridgely & Tudor (1989), Walker (2001).



Genus *CISTOTHORUS* Cabanis, 1850

24. **Sedge Wren**

Cistothorus platensis

French: Troglodyte à bec court **German**: Seggenzaunkönig **Spanish**: Cucarachero Sabanero
Other common names: Short-billed Marsh Wren ("*stellaris* group"); Grass Wren (Neotropical races)

Taxonomy. *Sylvia platensis* Latham, 1790, Buenos Aires, Argentina.
Probably closely related to *C. meridae* and *C. apolinari*. Taxonomy complex. Races form three geographical groups: "*stellaris* group" (North America S to Panama), "*aequatorialis* group" (NW South America, from Colombia E to Guyana and S to Bolivia) and "nominate group" (S South America, from N Argentina and SE Brazil S to Tierra del Fuego). Wide disparities in vocalizations suggest that these groups likely to represent three distinct species; also, the two Neotropical groups possibly worthy of further subdivision. Proposed race *boliviae* (from Santa Cruz, in Bolivia) considered indistinguishable from *minimus*. Twenty subspecies recognized.
Subspecies and Distribution.
C. p. stellaris (J. F. Naumann, 1823) – breeds from S Canada (E Saskatchewan, C Manitoba, S Ontario and S Quebec) S in USA to N Kentucky, E Pennsylvania and New York; non-breeding winters from E USA (Virginia) S through coastal states to Texas and NE Mexico.
C. p. potosinus Dickerman, 1975 – NC Mexico (San Luis Potosí).
C. p. tinnulus R. T. Moore, 1941 – C Mexico (Nayarit S to Michoacán, México and Distrito Federal.
C. p. jalapensis Dickerman, 1975 – E Mexico (C Veracruz).
C. p. warneri Dickerman, 1975 – E Mexican lowlands in Veracruz, Tabasco and Chiapas.
C. p. russelli Dickerman, 1975 – Belize (Toledo and Cayo districts).
C. p. elegans P. L. Sclater & Salvin, 1859 – highlands of SE Mexico (from Veracruz) and Guatemala.
C. p. graberi Dickerman, 1975 – interior & E Honduras and NE Nicaragua.
C. p. lucidus Ridgway, 1903 – C Costa Rica S (at least formerly) to W Panama.
C. p. alticola Salvin & Godman, 1883 – mountains of N Colombia, W, N & E Venezuela and W Guyana.
C. p. tolimae Meyer de Schauensee 1946 – N part of C Andes of Colombia (Caldas, Tolima).
C. p. aequatorialis Lawrence, 1871 – S end of C Andes of Colombia S to C Peru (S to C Junín).
C. p. tamae Cory, 1916 – SW Venezuela (S Táchira) and E Colombia.
C. p. graminicola Taczanowski, 1874 – SC Peru (Junín, Cuzco).
C. p. minimus Carriker, 1935 – S Peru S to S Bolivia.
C. p. tucumanus Hartert, 1909 – NW Argentina (Jujuy S to Catamarca and Tucumán).
C. p. polyglottus (Vieillot, 1819) – Paraguay and SE Brazil.
C. p. platensis (Latham, 1790) – E Argentina (E from Córdoba and Mendoza).
C. p. hornensis (Lesson, 1834) – C Chile and S Argentina (S from c. 41° S) S to Cape Horn.
C. p. falklandicus Chapman, 1934 – Falkland Is.
Descriptive notes. 9–11·5 cm; male 7·8–8·9 g and female 7·1–8·9 g (North American *stellaris*), average 9 g (one Central American population), 8·2–9·8 g (Argentina). Nominate race has bright buff supercilium, blackish-brown crown, shoulders and back with conspicuous pale buff streaks; rump and uppertail-coverts buff-brown, few streaks; upperwing-coverts buff-brown, some buff streaks; primaries and secondaries with dark inner webs, buff-brown outer webs with conspicuous dark markings (obvious bars on closed wing); rectrices buff-brown with blackish-brown bars; whitish-buff below, somewhat darker on chest, orange-buff on flanks and lower belly; eyes brown; bill dull blackish above, yellowish below; legs pinkish-brown, feet darker brown. Sexes similar. Juvenile resembles adult, but reduced white streaking above, paler underparts. Race *hornensis* is similar to nominate but more heavily streaked above; *falklandicus* resembles previous, but has heavier bill, longer wings and proportionately shorter tail; *tucumanus* is longer-billed than nominate, lower back and rump unspotted; *polyglottus* is smallest of "nominate group", with slender bill, narrow buffy-white supercilium, unspotted rump, blackish inner webs of rectrices; *aequatorialis*

has bright buff lores, heavy bars on rectrices, broad buffy supercilium; *alticola* is similar to last, but wing and tarsus shorter, supercilium less obvious; *tamae* is also similar, but generally more rufescent; *graminicola* is paler, crown well streaked buff; *minimus* is smaller than previous, inner webs of rectrices black; *tolimae* is larger than *aequatorialis*, less rufescent on upperparts, duller on side of neck and body; *stellaris* has ground colour of crown less dark than nominate, crown streaks buff-white, shoulders orange-buff, outer webs of flight-feathers barred with orange-buff and dark brown, orange-buff pectoral band and flanks, lower flanks with darker bars; *tinnulus* is paler and more buffy than previous, with little crown streaking; *potosinus* resembles last, but paler and more sandy; *jalapensis* is darker brown than preceding two, with more extensive black on crown; *warneri* is paler than last; *russelli* has darker and richer coloration, with reddish-brown nape; *elegans* is strongly striped on back, crown heavily streaked; *graberi* is more grey than last, little streaking on crown; *lucidus* has more heavily streaked crown, with dorsal stripes whitish. Voice. Male has large repertoire of songs (300–400 in some populations), quality of songs varies considerably, from dry staccato chatter (North America) to more liquid phrases (Central and South America); North American males improvise songs, but tropical and S races imitate songs; successive songs usually different, but under low motivation male may give several songs of one kind before switching; song in Falklands (race *falklandicus*) repetition of warbled phrases e.g. "siu-siu-siu", "chiwi-chiwi-chiwi" and "cli-cli-cli", each separated by low trill. Female does not sing. Calls a sharp "chad" or "tak", also less intense "chep" singly or in series; also "ti-ti-ti" in Falklands; scolds with low nasal buzz.

Habitat. In North America, breeds mainly in damp, sedgy meadows, often with small scattered bushes; sometimes margins of *Sphagnum* bogs with cotton-grass (*Eriophorum*); sometimes found in weedy rice fields, but (in contrast to *C. palustris*) not usually in areas of standing water; in winter, both fresh and brackish sedge meadows, as well as palmetto prairie, old fields with matted vegetation, grassy marsh edge and similar. South American populations occupy wider variety of habitats, from open grass savanna in Venezuela and partially flooded alder (*Alnus*) forest and bamboo bogs in Colombia to wet high-altitude *páramo* grassland in Ecuador, dry *cerrado* grassland in Brazil, borders of tidal marshes in Argentina, and tussac (*Parodiochloa flabellata*) grassland in Falkland Is; sea-level to 4000 m.

Food and Feeding. Stomach contents of wintering individuals (race *stellaris*) in SE USA (Florida) included ants (Hymenoptera), bugs (Hemiptera), weevils (Curculionidae), ladybirds (Coccinellidae), moths and caterpillars (Lepidoptera), and locusts, grasshoppers and crickets (Orthoptera); a specimen of *hornensis* taken in mid-winter in Tierra del Fuego (when ground snow-covered) had been feeding on insects and grass seeds. Forages mostly low down in vegetation; skulks.

Breeding. N race *stellaris* has extended season May–Sept, early nesting concentrated mostly in NC part of range (e.g. Saskatchewan, North Dakota, Minnesota, Wisconsin), frequently much later, Jul–Sept, in E & S parts (probable that same individuals involved, as arrival in latter areas often coincides with disappearance from N areas); in S of species' range, recently fledged young seen in Jan and May in Ecuador and in Apr in Peru ("*aequatorialis* group"); nesting Oct–Dec in Falklands (race *falklandicus*), one brood. Following details refer to race *stellaris* except where otherwise stated. Male frequently polygamous; often in loose colonies. Male builds multiple nests (up to nine per season), the one used for breeding being lined by female, nest globular, c. 10 cm tall, 8 cm wide and 8 cm deep, side entrance c. 2·5 cm in diameter, leading to cavity c. 6 cm deep, 4 cm long and 6 cm wide, built with fine grasses and sedges interwoven with plant down, lined with feathers, down and fine grasses, located in sedges and tall grasses, usually 25–50 cm above ground; nest of race *falklandicus* a ball of grass well lined with white feathers or wool, 0·3–1·1 m above ground, and one of *hornensis* was in bore of disused cannon (this race stated to surround nest entrance with thorns). Clutch 4–8 eggs (average 7) for first broods, fewer than 6 for second broods, unmarked white, but *hornensis* eggs variously described as white with light reddish tones, spotted with reddish or brown flecks (in contrast to those of *stellaris*) or plain white; incubation by female alone, period c. 14 days; chicks fed almost entirely by female, male involvement at most very limited and often none, fledging period 12–14 days.

Movements. North American populations (*stellaris*) highly migratory, with no overlap in breeding and non-breeding grounds; in addition, appears to be nomadic during breeding season. Nocturnal migrant. Spring migration begins early Apr in S part of range, peak over N part late Apr and first two weeks of May; post-breeding migration to S starts Aug or early Sept. Males may, on average, winter farther N than females. Extralimital occurrences in California and New Mexico. Remaining populations, including Mexican and Central American races of "*stellaris* group", appear to be sedentary, as do South American ones; S race *hornensis* spends austral winter in a very severe climate with snow cover, but the fact that type specimen was "taken at sea twenty leagues south-east of Cape Horn" suggests at least some partial migration.

Status and Conservation. Not globally threatened. Locally fairly common to uncommon. Because of its nomadic habits in North America, very difficult to census accurately; some evidence suggests regular increase in Canada over years 1991–2000; may have increased during period of European colonization as forest clearance produced suitable habitat. Highest population density perhaps up to 68 males/10 ha, but densities on average usually much lower. Was considered a "Species of Special Concern" during 1982–1986 owing to depressed populations in Midwest prairie region; currently considered "Endangered", "Threatened" or of "Special Concern" in nine states in Midwest and NE USA. Little detailed information about Central and South American populations; fairly common to uncommon in Mexico; race *lucidus* apparently extirpated in Panama but still quite common in parts of Costa Rica; uncommon to rare in SE Brazil. Falklands population (*falklandicus*) estimated at 1300–2300 pairs during 1983–1993.

Bibliography. Anon. 25. Merida Wren

Cistothorus meridae

French: Troglodyte du Mérida **German**: Meridazaunkönig **Spanish**: Cucarachero de Mérida
Other common names: Paramo Wren

Taxonomy. *Cistothorus platensis meridae* Hellmayr, 1907, El Loro, 3000 m, Mérida, Venezuela.
Probably closely related to *C. platensis* and *C. apolinari*. Monotypic.

Distribution. Venezuelan Andes from S Trujillo (Teta de Niquitao) S to N Táchira.

Descriptive notes. 10 cm. Has off-white supercilium, broader behind eye, brown-mottled ear-coverts and lores; crown and nape medium brown, streaked darker brown, shoulders and upper back blackish-brown, streaked off-white, rump and uppertail-coverts barred dull blackish and rich brown; upperwing-coverts bright buffy brown, conspicuously barred dark brown; outer webs of primaries and secondaries barred blackish-brown and buff-brown; rectrices medium brown, sharply barred blackish; chin and throat off-white, chest buffy, flanks deeper buff with a few diffuse darker bars, thighs buff with dull blackish-brown bars; eyes brown; bill brown above, pale pinkish below; legs pinkish-grey. Sexes similar. Juvenile undescribed. Voice. Male repertoire of 20–25 different songs, repertoire varying individually and geographically, song mostly of two or three phrases, some of these rather pure whistles, others more raspy or buzzy, one song repeated several times before switching to another; female occasionally utters dry trill of simple notes accompanying male song. Scolds with low buzz.

Habitat. Wet areas of *páramo*, typically with the hirsute ground plant *Espeletia* ("*frailejón*") and bushes; 3000–4100 m.

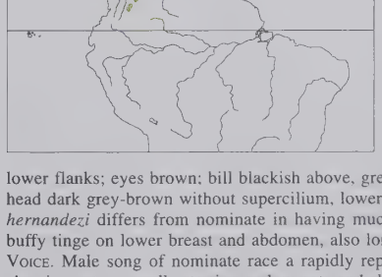
Food and Feeding. Arthropods; no published details on items. Forages low down in vegetation.

Breeding. Season not recorded. Duetting song type more typical of a monogamous wren than of a routinely polygamous one. No breeding nests described; dormitory nest (several found in May and Jun) domed, with side entrance, outer shell of woven grass stems, inner lining made of fine hairs taken from *Espeletia* leaves, one placed 50 cm up in an *Espeletia* plant, the others in clumps of sedge. No other information.

Movements. Some evidence of local movement, probably altitudinal; seems to vacate some areas in rainy season.

Status and Conservation. Not globally threatened. Restricted-range species: present in Cordillera de Mérida EBA. Reasonably common in many places; all known sites fall within an area of no more than c. 200 km × 40 km. Despite its small global range, the harsh nature of its habitat does not invite much human interference. Some areas of its range are protected.

Bibliography. Cracraft (1985), Farabaugh (1996), Fjeldså (1985), Fjeldså & Krabbe (1990), Hellmayr (1934), Hilty (1999), Kroodsma (1998), Kroodsma *et al.* (2001), Meyer de Schauensee & Phelps (1978), Ridgely & Tudor (1989), Wheatley (1994).



26. Apolinar's Wren

Cistothorus apolinari

French: Troglodyte d'Apolinar **German**: Apolinarzaunkönig **Spanish**: Cucarachero de Apolinar
Other common names: Apolinar's Marsh Wren

Taxonomy. *Cistothorus apolinari* Chapman, 1914, Suba marshes, 8600 feet [c. 2620 m], 4 miles [c. 6·4 km] east of Bogotá, Colombia.
Probably closely related to *C. platensis* and *C. meridae*. Recently described race *hernandezi* differs markedly from nominate in habitat requirements, social organization and vocalizations, and possibly represents a separate species; further study required. Two subspecies recognized.

Subspecies and Distribution.
C. a. apolinari Chapman, 1914 – Cundinamarca and Boyacá, in Colombian Andes.
C. a. hernandezi Stiles & Caycedo, 2002 – Sumapaz massif (S of Bogotá), in Cundinamarca (Colombia).

Descriptive notes. 12 cm; one male 17·7 g (*hernandezi*). Nominate race has crown dull chestnut-brown, side of face grey-brown, very obscurely patterned; postocular supercilium very obscure, slightly paler than crown and ear-coverts; back and shoulders blackish-brown, lateral streaks of whitish-buff extending to mid-back; lower back and rump bright rufescent brown; upperwing-coverts medium brown, barred dark brown; outer webs of primaries and secondaries barred dark brown and pale buff-brown; rectrices rufescent, barred blackish-brown; pale buff-brown below, lighter on throat, darker on chest, more rufescent on lower flanks; eyes brown; bill blackish above, grey below; legs grey. Sexes similar. Juvenile has head dark grey-brown without supercilium, lower nape buff, back less streaked than adult. Race *hernandezi* differs from nominate in having much more whitish on underparts, without strong buffy tinge on lower breast and abdomen, also longer wing, shorter tail, longer and heavier bill. Voice. Male song of nominate race a rapidly repeated sequence of half a dozen harsh, sawing churring notes, usually starting on low note and alternating up and down, or a series of rising and falling churrs mixed with harsh gravelly notes; repertoire of 6–7 song types. By contrast, *hernandezi* has larger repertoire of at least 11 song types, and both sexes sing, female often initiating a bout of song; communal singing frequent with this race, males singing antiphonally with different songs or in duet with similar song types.

Habitat. Nominate race inhabits marshland and lake-edge vegetation, especially cat-tails (*Typha*) and bulrushes (*Scirpus*); occurs at 2500–3000 m, one site at 3015 m. Race *hernandezi* in boggy páramo dominated by the shrub *Diplostephium revolutum*, also more open *páramo* with *Espeletia grandiflora*, but the dwarf bamboo *Chusquea tessellata* (used for nesting) appears to be an essential requirement; 3800–3900 m.

Food and Feeding. Details of food items of nominate race come entirely from faecal samples collected from trapped individuals; predominantly *Chironomus* midges (74%), followed by spiders

(Araneae), assorted dipteran flies, mosquitoes (Culicidae), lepidopteran larvae, and similar; largest prey item recorded was damselflies (Zygoptera). For race *hernandezi*, "well-digested insect remains" found in stomach. When foraging, climbs up vegetation stems and then drops down to near water level.

Breeding. Little information on nominate race: males in breeding condition in Mar and Aug, eggs recorded in Jul, recently fledged young as late as Oct, possibly double-brooded; may breed in loose colonies; one nest (possibly a surplus non-breeding nest) described, an unlined ball c. 15 cm in diameter, made of *Typha* leaf strips, placed 1·5 m above water level in thick *Typha*. Race *hernandezi* a co-operative breeder, with groups of 5–10 individuals participating in care and defence of nest, although only one pair breeds; nest roughly spherical, side entrance, coarsely woven from grass stems and leaves, lined with woolly leaves of *Espeletia*; 2 eggs, white, incubated by female alone. Nests (of nominate race) parasitized by Shiny Cowbird (*Molothrus bonariensis*).

Movements. Sedentary. Individuals of nominate race observed away from regular sites, perhaps indicating some tendency for local movement.

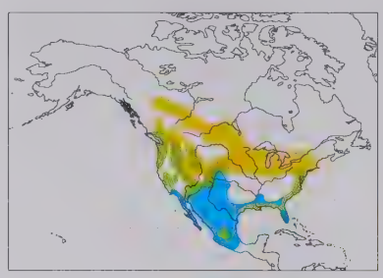
Status and Conservation. ENDANGERED. Restricted-range species: present in Colombian East Andes EBA. Rare. Global range covers c. 1570 km², but found only in very limited areas within this. Has always been highly restricted in range and in habitat. If the races are upgraded taxonomically, to represent two full species, nominate would be classified as Critical. One recent estimate of total population of nominate is in region of 250 adults; up to 95% of its habitat in the Cundinamarca–Boyacá Altiplano has been destroyed in the last 50–70 years, and much of remainder is in danger of degradation through landfilling, sedimentation, pollution and recreational use; a further recent threat comes from nest parasitism by Shiny Cowbird, first documented in 1999, since when several cases have occurred, and cowbird populations in the area appear to be increasing. Presently, the largest known populations of nominate are at Laguna de Tota (Boyacá) and Laguna de Fúquene (Cundinamarca), each estimated at c. 50 pairs; several locations near Bogotá may hold up to 20 pairs. Race *hernandezi* has been recorded from only two locations, both in the Sumapaz National Park (Cundinamarca), where its population density seems to be quite high; because of security considerations, other possibly suitable locations not yet investigated. Protected habitat includes also El Cocuy National Park (Boyacá), but, given the current state of civil disorder in Colombia, designation as a protected area does not necessarily guarantee actual protection. It is suggested that *hernandezi* merits the conservation category of Vulnerable.

Bibliography. Borrero (1953), Cadena (2003), Caycedo & Renjifo (2002), Chapman (1917), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Farabaugh (1996), Fjeldså (1985), Fjeldså & Krabbe (1990), Hellmayr (1934), Hilty (1985), Hilty & Brown (1986), King (1978/79), Kroodsma (1998), Meyer de Schauensee (1982), Negret (2001), Renjifo *et al.* (1997), Ridgely & Tudor (1989), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stiles & Caycedo (2002), Varty *et al.* (1986), Velásquez *et al.* (2000), Wege & Long (1995).

27. Marsh Wren

Cistothorus palustris

French: Troglodyte des marais **German**: Sumpfzaunkönig **Spanish**: Cucarachero Pantanero
Other common names: Long-billed Marsh Wren; Eastern Marsh Wren ("nominate group"); Western Marsh Wren ("*paludicola* group")



Taxonomy. *Certhia palustris* A. Wilson 1810, borders of the Schuylkill and Delaware Rivers, Pennsylvania, USA.

Sometimes placed in a monotypic genus *Telmatodytes*, but probably closely related to *C. meridae* and *C. apolinari*. Recent studies of song types suggest that W races ("*paludicola* group", also including *browningi*, *pulverius*, *plesius*, *aestuarinus*, *clarkae* and *deserticola*) constitute a separate species from N & E ones ("nominate group"); this possibility supported by DNA studies of populations in limited area of sympatry, where there appears to be an effective reproductive isolation even in habitats where individuals of each song type co-exist. Affinities of isolated C Mexican race *tolucensis* uncertain; studies required. Sixteen subspecies recognized.

Subspecies and Distribution.

C. p. browningi Rea, 1986 – extreme SW Canada (SW British Columbia) S in W USA to C Washington; non-breeding also to SW Washington.
C. p. paludicola S. F. Baird, 1864 – SW Washington and NW Oregon.
C. p. pulverius (Aldrich, 1946) – breeds from C British Columbia and C Idaho S to NE California and NW Nevada; non-breeding NW Oregon and C California S to C Mexico and S Texas.
C. p. plesius Oberholser, 1897 – breeds from SE Idaho S to C Colorado and New Mexico; non-breeding C California, Nevada and Kansas S to C Mexico.
C. p. aestuarinus (Swarth, 1917) – C California (Sacramento and San Joaquin Valleys to San Joaquin delta); non-breeding also W to California coast.
C. p. clarkae Unitt *et al.* 1996 – coastal S California (Los Angeles S to San Diego).
C. p. deserticola Rea, 1986 – interior of S California.
C. p. laingi (Harper, 1926) – breeds SC Canada (N Alberta and C Saskatchewan E to SE Manitoba) and extreme N USA (NE Montana); non-breeding S USA (S Texas) and Mexico (S to E Jalisco, Oaxaca and C Veracruz).
C. p. iliacus Ridgway, 1903 – breeds from Manitoba and SW Ontario S in USA to E Kansas and Missouri; non-breeding S USA (E from SE Texas) and interior Mexico (S as far as Tlaxcala).
C. p. dissaeptus Bangs, 1902 – breeds from S Ontario S to N Ohio, West Virginia and S New England; non-breeding S to S Florida and E Mexico (S to Veracruz).
C. p. palustris (A. Wilson, 1810) – breeds E USA (from Rhode Island S to coastal Virginia and Potomac Valley); non-breeding from New Jersey S to South Carolina, sparsely to Florida.
C. p. waynei (Dingle & Sprunt, 1932) – coasts of S Virginia and North Carolina.
C. p. griseus Brewster, 1893 – coastal marshes from NE South Carolina S to NE coast of Florida.
C. p. thryophilus (Oberholser, 1903) – Gulf coast of Texas and Louisiana.
C. p. marianae W. E. D. Scott, 1888 – Gulf coast from Mississippi E to Florida.
C. p. tolucensis (Nelson, 1904) – C Mexico (Hidalgo and México S to Puebla).

Descriptive notes. 11·5–12·5 cm; male 10·5–13·5 g, female 9–13·5 g. Nominate race has black-brown crown, darkest at side, contrasting prominent pale grey supercilium, medium-brown ear-coverts, olive-brown side of neck; centre of back dull blackish, contrastingly streaked whitish, side of back, shoulders and rump medium brown; outer webs of primaries and secondaries rather obscurely barred brown and blackish-grey; rectrices medium brown, strongly barred darker brown, especially at sides; throat and underparts pale greyish, becoming buffy at sides, lower belly buff, becoming richer and warmer on flanks and vent; eyes brown; bill dark brown above, yellowish-brown below, especially at base; legs pale brown. Sexes similar. Juvenile is generally duller than

adult, white streaks on back reduced or absent, barring on flight-feathers more diffuse, often a dull buff chestband. Race *waynei* is darker above and duller than nominate, undertail-coverts barred dusky; *marianae* resembles previous, but generally sootier and less rufous, with duller flanks; *thryophilus* is smaller and paler than last, smaller and darker than nominate; *griseus* is much greyer than nominate, lacking rich brown tones, with pale, dull flanks; *dissaeptus* has dull brownish flanks and uppertail-coverts, without bars or spots; *iliacus* is similar to previous, but more reddish-brown on flanks, more extensive pale wing markings; *laingi* is less rufescent than previous, paler brown above and with black areas reduced; *paludicola* is warm brown above, with extensive black on crown; *plesius* has pale, dull flanks and upperparts, black on crown usually restricted to side; *pulverius* is similar to last but still paler and duller, with little or no trace of brown chestband; *browningi* is darker than previous two, little black on crown; *clarkae* is brighter and richer brown, with deep rufous rump and flanks; *aestuarinus* has brown colours dark and dingy, but black of crown more intense and extensive; *deserticola* is closest to previous, but with white streaks on back more prominent and brown wash on chest and flanks brighter; *tolucensis* is darker on chest and sides than other races, with back to upper rump almost entirely black and white. VOICE. Male song a bubbling chatter. Two types of singer, suggesting two species: in W (from Pacific E to Great Plains) male repertoire well over 100 songs, whereas in E (Great Plains E to Atlantic Ocean) c. 30–60 different songs; quality of songs also differs, those of W males consisting of great variety of buzzes, rattles, whistles and trills, those of E males less varied and less complex; non-learned call notes also differ between E and W. Females do not sing.

Habitat. Breeds usually in areas with standing water of various depths: most N populations in stands of cat-tail (*Typha latifolia* and *T. angustifolia*), common reed (*Phragmites australis*) or bulrushes (*Scirpus*), S coastal populations usually in brackish marshes where dominant plants are various species of cordgrass (*Spartina*). In winter occurs in both freshwater and brackish habitats. From sea-level to at least 1000 m; disjunct Mexican population (race *tolucensis*) from 1000 m to 2500 m.

Food and Feeding. Mostly arthropods; documented prey items include hymenopterans (ants, bees, wasps), beetles (Coleoptera), bugs (Hemiptera), dipteran flies, dragonfly larvae (Odonata), harvestmen (Opiliones) and spiders (Araneae). In addition, frequently attacks eggs both of conspecifics and of other species, e.g. Red-winged Blackbird (*Agelaius phoeniceus*) or Yellow-headed Blackbird (*Xanthocephalus xanthocephalus*), also occasionally those of such species as Least Bittern (*Ixobrychus exilis*); eggs may be simply attacked or actually eaten. Usually forages low in marsh vegetation, right down to water level.

Breeding. Breeds from May onwards in N, earlier farther S, multiple-brooded (especially in S); no data on isolated Mexican race (*tolucensis*). Polygamy common, but extent appears to vary geographically; in study in SE USA (Georgia) only 5% of males had more than one partner, whereas in S Canada (Manitoba) one population had ten unmated males, 53 monogamists, 48 bigamists and nine trigamists (arguing for skewed sex ratio of only 0·65 males per female). No observations of young helping in rearing of subsequent broods, although this recorded in captivity. Male builds large number of nests (sometimes more than 20 in a season), female then inspects these and adds lining to the one selected; construction of a skeleton non-breeding nest may be completed in 2 days, but complete breeding structure may take 5–8 days; nest domed, c. 18 cm high and 12 cm wide, side entrance hole with small sill (which prevents eggs from rolling out in wind), built of thin strips of leaves and grass, lined with fine leaves, cat-tail down and feathers; usually located c. 1 m (occasionally 3 cm, or up to 5 m) above water or tide level; non-breeding nest distinguished by absence of sill on entrance hole. Clutch size 3–10 eggs, usually 4–6, tending to be larger in N populations (e.g. average 6 in Manitoba and Washington, only 3–4 in Florida), clutch size diminishes as season progresses; egg colour varies somewhat according to race, generally various shades of brown with darker dots and spots, rarely white (sometimes a single white egg in otherwise normal clutch); incubation by female alone, 13–16 days, female may show hostility to male while incubating; chicks tended mainly by female, male's involvement highly variable, in some cases he provides substantial help in brood-feeding, in others (especially when polygamous) little or none; young fledge in c. 13–15 days, may be fed by one or both parents for further 2 days or so.

Movements. Resident and migratory. N populations highly migratory; breeding areas from Canada (interior British Columbia, Alberta) E to New England essentially vacated in winter, although occasional individuals remain as far N as S Ontario. E coastal populations (from S Massachusetts S to S Texas) sedentary or nearly so, with some partial migration in N. Much less migratory in W, where S populations sedentary and those in extreme N partially migratory. Mexican population (race *tolucensis*) appears to be totally sedentary. Judging from casualties at buildings, a nocturnal migrant. One significant long-distance ringing recovery, of individual ringed in S Canada (Saskatchewan) recovered in S USA (Louisiana). Vagrant in Bermuda and Cuba; apparently also in Greenland.

Status and Conservation. Not globally threatened. Common or abundant in many areas with suitable habitat. Densities in optimum habitat can be remarkably high, e.g. up to 167 pairs/ha in coastal *Spartina* marshes in Georgia, although in most habitats density is much lower. Historically, this species has suffered substantial habitat loss through wetland drainage; more recently, with creation of artificial water impoundments, local increases have been recorded. Isolated instances of breeding in NE Ontario and Nova Scotia; stated also to have nested in Greenland. This species' habit of attacking eggs may, in some circumstances, be a limiting factor on populations of the blackbirds *Agelaius phoeniceus* and *Xanthocephalus xanthocephalus*; these two species exhibit hostility towards the wren, to the point even of destroying its nests.

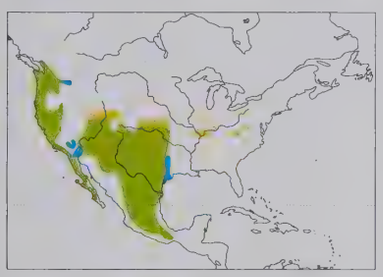
Genus *THRYOMANES* P. L. Sclater, 1862

28. Bewick's Wren

Thryomanes bewickii



French: Troglodyte de Bewick **German**: Buschzaunkönig **Spanish**: Cucarachero Colinegro

Taxonomy. *Troglodytes bewickii* Audubon, 1827, five miles [8 km] from St Francesville, Louisiana, USA.

Taxonomy complex and highly disputed. Sometimes placed in genus *Troglodytes*, on basis of voice, behaviour and plumage, but this is without reference to DNA considerations; in past, considered by some to form a superspecies with *Troglodytes sissonii* in *Thryomanes*, with suggestion that they might even be conspecific; current information suggests present species may be closely related to *Thryothorus ludovicianus*. Other proposed races: from S California (USA), *correctus* (San Benito County S to San Diego), *nesophilus* (islands of Santa Rosa, Santa Cruz and Anacapa) and *catalinae* (Santa Catalina I), all synonymized with *charienturus*; also, birds from C Mexico (Jalisco, S Zacatecas), described as race *percnus*, appear indistinguishable from *murinus*. Races *leucophrys* (San Clemente I, off S California) and *brevicauda* (Guadalupe I, off Baja California) both extinct. Sixteen extant subspecies recognized.

Subspecies and Distribution.

T. b. calophonus Oberholser, 1898 – extreme SW Canada (SW British Columbia) and W USA (W Washington, W Oregon); non-breeding N California.
T. b. atrestus Oberholser, 1932 – SC Oregon, NE California and WC Nevada.
T. b. marinensis Grinnell, 1910 – NW California (Del Norte S to Marin County).
T. b. spilurus (Vigors, 1839) – C coastal California S to Monterey Bay.
T. b. drymoecus Oberholser, 1898 – C California (including Sacramento Valley).
T. b. charienturus Oberholser, 1898 – S California (S from San Benito County) and NW Mexico (Baja California S to c. 30° N), including some offshore islands.
T. b. cerroensis (Anthony, 1897) – I de Cedros and adjacent mainland of Baja California.
T. b. magdalenensis Huey, 1942 – SW Baja California (26° N S to 24° N).
T. b. eremophilus Oberholser, 1898 – interior SW USA (E California, Nevada and S Utah E to W Texas) and WC Mexico (NE Sonora, Chihuahua and Coahuila S to N Zacatecas).
T. b. bewickii (Audubon, 1827) – C USA (Nebraska and N & E Kansas E to Mississippi).
T. b. cryptus Oberholser, 1898 – W & S Kansas, W Oklahoma and much of Texas (except W) S to NE Mexico (N Nuevo León, N Tamaulipas).
T. b. pulichi (A. R. Phillips, 1986) – E Kansas, Oklahoma.
T. b. sadai (A. R. Phillips, 1986) – coast from S Texas to C Tamaulipas.
T. b. murinus (Hartlaub, 1852) – C plateau of Mexico (from S Zacatecas and S Nuevo León S to Jalisco, Michoacán, Morelos and Tlaxcala).
T. b. mexicanus (Deppe, 1830) – S Mexico (S Puebla, W Veracruz, Oaxaca).
T. b. altus Aldrich, 1944 – very locally E USA (mainly Kentucky, Tennessee, West Virginia, Virginia).

Descriptive notes. 12–13·5 cm; 7·8–11·8 g. Nominate race has greyish lores, conspicuous white postocular supercilium, ear-coverts mottled grey and grey-brown; crown and upperparts rich dark brown, becoming more rufous on rump, feathers of lower back with concealed white spots; primaries and secondaries medium brown, barred blackish-brown on outer webs; central rectrices grey-brown with narrow, sharply defined black bars, outer rectrices blackish with extensive grey-white tips; chin and throat off-white, chest greyish-white, belly buff-white, lower flanks dull brown; eyes brown; bill blackish-brown, pale base of lower mandible; legs dark brown. Sexes similar. Juvenile resembles adult but generally paler, feathers of underparts often with dusky edgings. Race *calophonus* is richer brown above than nominate, flanks more brown, bill longer; *marinensis* is similar to previous but with thinner bill, shorter wing and tail; *spilurus* is browner, less reddish, with stronger brown tinge on flanks; *drymoecus* is larger, duller and paler than nominate; *atrestus* resembles last, but darker and greyer above, and larger; *charienturus* is most like *drymoecus*, but shorter bill, longer tail, less brown upperparts; *cerroensis* is paler and more grey than previous, with still shorter bill; *magdalenensis* resembles last, but smaller and paler grey; *eremophilus* is greyer above and white below, with rather large bill; *murinus* differs from previous in smaller size, darker brown upperparts; *cryptus* is larger than nominate, upperparts more grey, underparts whiter; *pulichi* is less reddish-brown above than nominate; *sadai* is generally small and dull, with little rufescent tinge on flanks; *mexicanus* has dark crown, is dingy white below, heavy barring on crissum; *altus* is darker and more sooty than nominate. Voice. Male has repertoire of 10–20 songs (number varying geographically) that consist of 2–4 phrases or buzzes or repeated notes, sings one song many times before switching to another; young males disperse from natal area, learn the songs at location where they breed. Female does not sing. Calls "plit" as alarm, also scolding buzz.

Habitat. Very varied. Bushy areas, brushland, well-vegetated suburban areas, regenerating farmland; in W North America *chaparral*, but also in pinyon–juniper (*Pinus–Juniperus*) woodland, mesquite (*Prosopis*), riparian cottonwoods (*Populus*); in Mexico found in wide variety of habitats, including arid cactus scrub and city parks with large trees.

Food and Feeding. Food mostly invertebrates. In examination of stomach contents in SW USA (California), 31% of items were bugs (Hemiptera), 21% beetles (Coleoptera), 17% bees and wasps (Hymenoptera), 12% caterpillars, butterflies and moths (Lepidoptera), and remainder various other arthropods. Some vegetable matter taken, especially in winter. Forages on ground and in low vegetation.

Breeding. Egg dates in USA early Mar in Texas to late Apr in E; multiple-brooded in S parts of range, more often single-brooded in NW; no data on Mexican populations. Small proportion of males (15% in one study) polygamous; more rarely, female polyandrous. Nest usually an open cup, more rarely domed, made of grass, rootlets and similar, lined with finer material, often including snakeskins, usually located in cavity such as nestbox or woodpecker (Picidae) hole, or in natural or artificial cranny of wide variety of types, e.g. crevice in rocks, shelf in outbuilding, hole in abandoned motor vehicle, etc. Eggs 3–8, average 5·8, white with variable amounts of brown, lilac or purplish spotting; incubation by female alone, 14–16 days; young fed usually by both sexes, although polygamous male may give less or no help, fledging period 14–16 days.

Movements. Largely sedentary over most of range, with some post-breeding withdrawal from N fringes. E populations migratory, wintering in S states.

Status and Conservation. Not globally threatened. Generally common in much of range. Two races extinct: *brevicauda* (from Guadalupe I, off Baja California) disappeared c. 1903, probably as a result of habitat destruction caused by introduced goats and predation by feral cats; *leucophrys* (from San Clemente I, California) became extinct some time prior to 1986. Over most of range in W North America and also, apparently, in Mexico, this species is frequently common in suitable habitat; decreases reported in British Columbia and increases in Texas and New Mexico. Populations in E North America (race *altus*) expanded greatly in 19th century as a result of clearing of forest for agriculture, with colonization of West Virginia by 1834, Pennsylvania in 1843, New Jersey in 1890 and S Canada (S Ontario) in 1898; subsequently, however, there were major population losses, and at present time only very small numbers survive in Iowa and E of R Mississippi (principally in Kentucky, West Virginia, Virginia and Tennessee). It has been proposed that *altus* be listed as Endangered.

Genus *FERMINIA* Barbour, 1926

29. Zapata Wren

Ferminia cerverai

French: Troglodyte de Zapata **German**: Kubazaunkönig **Spanish**: Cucarachero de Zapata
Other common names: Cervera's Wren, Cuban Marsh Wren, Fermina Wren

Taxonomy. *Ferminia cerverai* Barbour, 1926, Santo Tomás, Zapata Peninsula, Cuba.

A highly aberrant species, with uncertain affinities. May be most closely related to *Cistothorus* or *Troglodytes*, but in need of much further study, especially of its DNA, to elucidate its true taxonomic relationships. Monotypic.

Distribution. Zapata Swamp, in W Cuba.

Descriptive notes. 15·5–16 cm. Has blackish-brown crown feathers finely edged paler brown; side of face mottled brownish-buff, inconspicuous eyestripe; upperparts dark brown with blackish bars, lateral bars extending across wing-coverts and flight-feathers; rectrices long, with diffuse fluffy ends, blackish-brown with fine greyish-brown lateral bars; chin pale whitish-buff, chest more brown, flanks darker brown, lower flanks with prominent transverse blackish bars; thighs and vent brownish, diffusely barred darker brown; eyes clear brown; bill dark brown above, paler yellow-brown below; legs brownish. Sexes similar. Juvenile is like adult, but with fine black speckles on throat, diffuse blackish-brown speckles and flank barring less distinct. Voice. Male song a series of 4–7 clear gurgling whistles interspersed with harsher churring notes, often continuing for a minute or more; female song, often in duet with that of male, is simpler, resembling extended series of call notes, "achut-chut-chut-chut-churr". Calls include low harsh "chut chut", "churr-churr" etc.

Habitat. Restricted to savanna-type swamp, where dominant vegetation sawgrass (*Cladium jamaicense*) and *Typha dominguensis*, with scattered bushes (used as songposts). Water level is variable, with standing water in rainy season but not during dry season.

Food and Feeding. Diet quite varied. Mainly invertebrates, including e.g. beetles (Coleoptera), bugs (Hemiptera), crickets (Orthoptera), caterpillars (Lepidoptera), spiders (Araneae); also slugs, snails and snail eggs. Frogs eaten, also small *Anolis* lizards, including one specimen c. 10 cm long. Some vegetable matter, including lichen and the seeds of *Chrysbalanus hicacus*. Feeds low down in vegetation, and quite frequently on the ground, scratching in search of prey.

Breeding. Poorly known; first nest discovered in 1986, and total of only five described. Season apparently protracted, specimens with enlarged testes in Jan, eggs at end of Feb, and nests with well-feathered young on 2nd May and 12th Jun; possibly double-brooded. Nest, built by both sexes, a ball of sawgrass leaves c. 20 cm tall, external diameter c. 14 cm, side entrance c. 4·1–4·3 cm wide, interior lined with feathers, situated c. 20–70 cm above ground in sawgrass. Clutch 2 eggs, unmarked white; incubation by female alone, no information on duration of incubation and fledging periods; both sexes attend fledglings.

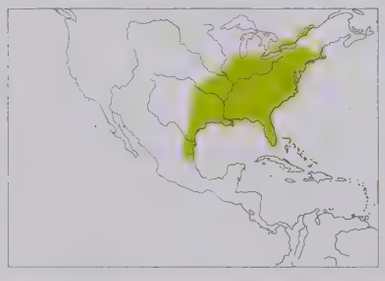
Movements. Sedentary.

Status and Conservation. ENDANGERED. Restricted-range species: present in Cuba EBA. Has always been confined to a small area of the Zapata Swamp. Following its discovery, in 1926, was

On following pages: 30. Carolina Wren (*Thryothorus ludovicianus*); 31. White-browed Wren (*Thryothorus albinucha*); 32. Black-throated Wren (*Thryothorus atrogularis*); 33. Sooty-headed Wren (*Thryothorus spadix*); 34. Black-bellied Wren (*Thryothorus fasciatoventris*); 35. Plain-tailed Wren (*Thryothorus euophrys*); 36. Inca Wren (*Thryothorus eisenmanni*); 37. Moustached Wren (*Thryothorus genibarbis*); 38. Whiskered Wren (*Thryothorus mystacalis*).

believed to be quite common in its tiny range, a situation that prevailed until at least 1962. It then appeared to decline, and several expeditions failed to locate it, leading to fears that it was extinct; these searches, however, were conducted around the type locality, which had been extensively burnt, while other areas were not explored. More recently, this species has been rediscovered, and small additional populations, totalling c. 24 individuals, have been found in a new location several kilometres N of the traditional sites. Recent estimates suggest total population of c. 120–140 pairs, quite extensively distributed in the swamp; population density apparently low, and not all seemingly suitable habitat occupied. Main threats to its survival are the burning of grass, sometimes accidental, sometimes deliberate, to facilitate the hunting of edible terrapins (Emydidae); also possible predation by introduced mongooses (Herpestidae). A management plan for the area, which would also benefit the Zapata Rail (*Cyanolimnas cerverai*) and the local, nominate race of Zapata Sparrow (*Torreornis inexpectata*), is in preparation.

Bibliography. Abreu *et al.* (1999), Anon. (1998b), Barbour (1926, 1928), Bond (1985), Bruner (1934), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Fitzpatrick (2002), Forneris & Martínez (2003), Garrido (1980, 1985), Garrido & García (1975), Garrido & Kirkconnell (2000a), González (1982), Gundlach (1873), Hellmayr (1934), King (1978/79), Kirkconnell *et al.* (1999), Llanes & Mancina (2002), Martínez & Martínez (1991), Morton (1979), Raffaele *et al.* (1998, 2003), Soto *et al.* (1993), Stattersfield & Capper (2000).



Genus *THRYOTHORUS* Vieillot, 1816

30. **Carolina Wren**

Thryothorus ludovicianus

French: Troglodyte de Caroline **Spanish**: Cucarachero de Carolina
German: Carolinazaunkönig
Other common names: Mocking Wren

Taxonomy. *Sylvia ludoviciana* Latham, 1790, Louisiana.
Traditionally placed in present genus as its only North American representative; recent DNA work, however, suggests that it may be more closely allied with *Thryomanes*. Often considered to include *T. albinucha* as a geographically disjunct race, a view supported by recent observations of similarities in song. Proposed race *oberholseri* (occurring in CS Texas and possibly adjacent parts of Mexico) rather puzzling, said to be more rufescent than *lomitensis* but plumage is variable; perhaps a variant of latter and probably not worthy of recognition. Seven subspecies recognized.
Subspecies and Distribution.
T. l. ludovicianus (Latham,1790) – SE Canada (S Ontario, irregularly E to S Quebec) and E USA (S Wisconsin and New England S to Texas and N Florida).
T. l. miamensis Ridgway, 1875 – Florida S from c. 30° S.
T. l. nesophilus Stevenson, 1973 – Dog I, off NW Florida.
T. l. burleighi Lowery, 1940 – islands of Cat, Ship and Horn, off Mississippi coast.
T. l. lomitensis Sennett, 1890 – Texas and extreme NE Mexico (N Tamaulipas).
T. l. berlandieri S. F. Baird, 1858 – NE Mexico (E Coahuila, Nuevo León, SW Tamaulipas).
T. l. tropicalis Lowery & Newman, 1949 – NE Mexico (E San Luis Potosí, S Tamaulipas).

Descriptive notes. 12·5–14 cm; 15–22 g. Nominate race has conspicuous white supercilium narrowly bordered above and below with black; brown stripe behind eye; ear-coverts dull white to pale buff, with dusky edging; crown and back rich brown, becoming chestnut-brown on rump; shoulders and greater upperwing-coverts warm rich brown, small white spots on lesser primary coverts; primaries and secondaries warm brown with dark brown barring; rectrices colder brown than rump, narrowly barred dark brown; chin and throat dull whitish, chest buff, flanks and lower belly rich warm buff; eye red-brown; bill grey-brown with yellowish base; legs flesh-coloured. Distinguished from all other North American wrens by large size, prominent white supercilium, rich brown upperparts. Sexes similar. Juvenile is generally paler than adult, buff tips on wing-coverts. Race *miamiensis* is larger than nominate, darker above and below; *nesophilus* has whiter supercilium and paler underparts; *burleighi* has duller and more sooty upperparts, less distinct tail barring; *berlandieri* is smaller than nominate, but with larger bill, duller above, and with flanks sometimes barred dusky; *lomitensis* is similar to previous but duller above and paler below, flanks frequently barred; *tropicalis* is darker above than last two, tail heavily barred. Voice. Male repertoire of c. 30 different songs, each a loud, ringing, emphatic "tea-kettle tea-kettle tea-kettle" or "liberty-liberty-liberty", or similar phonetic rendition; delivers a series of one song before switching to another. Female not known to "sing" in complex fashion of male (or of tropical female congeners), instead utters a dry, non-learned rattle as male sings.
Habitat. Very varied. Natural habitats include woodlands of hardwoods, such as oak (*Quercus*), and mixed coniferous–hardwood forests. Common also in forest edge, well-vegetated suburban areas, abandoned farmland; frequently in wet bottomland. Island races *nesophilus* and *burleighi* found in palmetto and slash pine (*Pinus elliottii*). Sea-level to middle elevations; to 2000 m in Mexico.
Food and Feeding. Bulk of food invertebrates, including beetles (Coleoptera), bugs (Hemiptera) and grasshoppers (Orthoptera); small vertebrates such as tree-frogs, lizards and, rarely, small snakes also taken. Some vegetable matter, e.g. seeds, fruit pulp, eaten. N populations frequently patronize feeding stations, where suet a popular food. Forages usually in pairs or family parties, mostly in lower levels of dense vegetation. Will forage in leaf litter, turning over debris in search of prey; occasionally "tree-creeps" while probing into crevices of bark. Has been seen to wedge hard-coated seeds in crannies and to hammer them open in manner of a nuthatch (*Sitta*).
Breeding. Egg-laying starts in May in Canada (Ontario), earlier farther S (from late Mar in Tennessee); may be triple-brooded, nesting continuously until Aug, in S USA; no data on Mexican populations. Usually monogamous, partners remaining faithful for several years, but one observation of possible polygamy; territory maintained throughout year, usually by a pair, sometimes by a single male. Bulk of nest-building by male, sometimes bringing material to female, which adds it to the structure; nest a substantial domed structure with side entrance, built of dried grass, bark strips, horsehair etc., as well as with debris such as string and cast snakeskins, lined with finer material; usually located 1–3 m up, rarely to 10 m, in partial or complete cavity, including artificial sites such as nestbox, cavity in shed, tin can and even bizarre situations such as in pocket of a hung-up jacket, also occasionally in hole in bank or similar site; nests in totally enclosed sites may lack roof. Clutch 3–6 eggs, 5 most common in Tennessee, 4 in Alabama, eggs white or cream with brown or reddish-brown spots, especially around blunt end; incubation by female alone, fed on nest by male, period 12–16 days, average 14·8 days; young fed by both sexes, fledging period 12–14 days. Nests frequently parasitized (up to 25% of nests) by Brown-headed Cowbird (*Molothrus ater*).
Movements. Largely sedentary; ringing studies show that, in most cases, territory is occupied throughout year by the same pair. Some apparent wandering, possibly by juveniles; although great majority of ringing returns show little or no movement, some distant recoveries recorded, greatest of which involved a juvenile ringed in coastal Massachusetts (USA) and recovered six weeks later in New Hampshire, 250 km away. Furthermore, a substantial number of extralimital records in such diverse locations as E New Mexico and Colorado, S Manitoba, Nova Scotia and La Madeleine Is (Gulf of St Lawrence).
Status and Conservation. Not globally threatened. Generally common over much of range. N populations fluctuate widely, both in numbers and in extent of distribution, in response to severe winters; total Ontario population in period 1981–1985 was only a few dozen pairs, but much more numerous and widely spread in 2001. Has been very successful in adapting to habitats much modified by human activity.

(1998b), Baicich & Harrison (1997), Beal *et al.* (1916), Bent (1948), Blake (1953), Borror (1956), Brenowitz & Kroodsma (1996), Bystrak (1979), Contreras (1997), Cook (1990), Cyr & Larivée (1995), Eberhardt (1994, 1996), Gaunt *et al.* (1996), Godfrey (1986), Grzybowski (1995), Haggerty & Morton (1995), Haggerty *et al.* (2001), Helgeson (1980), Hellmayr (1934), Howell & Webb (1995), Hyland *et al.* (2000), Hyman (2002), Jawor & Gray (2003), Johnsgard (1979), Kollars *et al.* (2000), Lowery (1940), Marra & Remsen (1997), McAtee (1950), Messerly (1998), Minzenmayer *et al.* (1995), Morton (1982, 1987), Morton & Shalter (1977), Naguib (1996), Nealen & Perkel (2000), Nice & Thomas (1948), Peck & James (1997), Pogue & Grzybowski (1997), Price *et al.* (1995), Ramsey (1987), Richard (1987), Richards (1981), Ridgway (1904), Robinson & Robinson (1999), Root (1988), Rosene (1954), Shuler (1965), Shy & Morton (1986), Simpson (1982, 1984, 1985), Stevenson (1973), Strain & Ronald (1988), Taylor *et al.* (1983), Townsend (1909), Udvardy (1963), Urban (1959), Wiedenfeld *et al.* (1992).

31. **White-browed Wren**

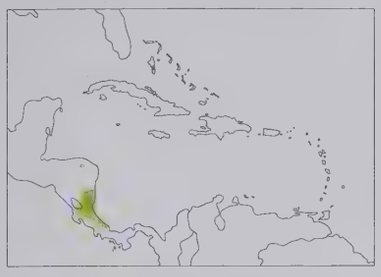
Thryothorus albinucha

French: Troglodyte de Cabot **Spanish**: Cucarachero Cejiblanco
German: Weißbrauen-Zaunkönig
Other common names: Cabot's Wren

Taxonomy. *Troglodytes albinucha* Cabot, 1847, Yalahao, Quintana Roo, Mexico.
Regarded by many authorities as a geographically disjunct race of *T. ludovicianus*, a view supported by recent observations of similarities in song. Recent specimens from Nicaragua not racially assigned, presumed to belong with *subfulvus*. Two subspecies recognized.
Subspecies and Distribution.
T. a. albinucha (Cabot, 1847) – Yucatán Peninsula: E Mexico (Yucatán, Campeche except SW, Quintana Roo), N Guatemala (Petén) and N Belize.
T. a. subfulvus W. deW. Miller & Griscom, 1925 – C Guatemala and W Nicaragua.

Descriptive notes. 11·5–13·5 cm. Nominate race has brown lores and eyestripe, white supercilium, ear-coverts mottled grey and blackish; crown and back dark olive-brown, becoming more rufous on lower back and rump; concealed whitish spots on feathers of lower back; upperwing-coverts medium brown, primaries and secondaries rufescent brown with diffuse darker barring; rectrices blackish-brown, outer feathers with grey bars on tips and outer webs; chin and chest off-white, flanks buffy brown, occasionally with obscure barring, crissum barred blackish and white; eye brownish-red; bill dark yellowish-brown, base paler; legs flesh-coloured. Distinguished from generally similar *T. ludovicianus* by more olive, less rufous, upperparts, much paler underparts, usually no flank barring. Sexes similar. Juvenile undescribed. Race *subfulvus* is more cinnamon on underparts than nominate, and with indistinct bars on flanks. Voice. Song a series of loud whistles and gurgles, apparently very similar to that of *T. ludovicianus*; reported as responding to playback of song of latter. Calls include querulous descending buzzy trill, which also occurs in song; buzzing churrs as alarm.
Habitat. Dry scrub and forest; in S Yucatán more humid forest. In Nicaragua dry thorn-scrub, as well as semi-deciduous broadleaf forest.
Food and Feeding. No published data available on food items. Forages mostly in lower levels of scrub.
Breeding. No information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common in parts of range in Mexico, where large areas of suitable habitat remain. No information on populations farther S. In W Nicaragua, race *subfulvus* known from a single confirmed specimen, but recent specimens from this region presumed to involve same taxon; apparently occurs also in arid C Guatemala, but litle information available.

Bibliography. Blake (1953), England (2000), Hellmayr (1934), Howell & Webb (1995), Klaas (1968), Land (1970), Lee Jones (2004), Lowery & Berrett (1963), Martínez-Sánchez (1989), Miller & Griscom (1925), Ridgway (1904), Smithe (1966), Tramer (1974), Van Tyne (1935).



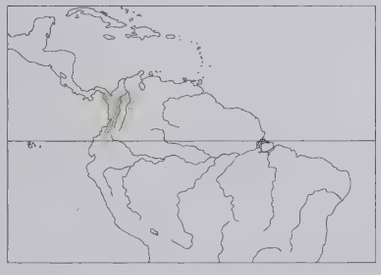
32. **Black-throated Wren**

Thryothorus atrogularis

French: Troglodyte à gorge noire **Spanish**: Cucarachero Gorginegro
German: Schwarzkehl-Zaunkönig
Other common names: Northern Black-throated Wren

Taxonomy. *Thryothorus atrogularis* Salvin, 1865, Tucurriquí, Costa Rica.
Formerly regarded as conspecific with *T. spadix*, but the two are quite distinct in plumage and song and are widely separated geographically. Monotypic.

Distribution. Caribbean lowlands and foothills in SE Nicaragua (S from about San Juan del Norte), Costa Rica (extending W to Pacific slope on some volcanoes), and W Panama (W Bocas del Toro); recently found also in E Honduras.



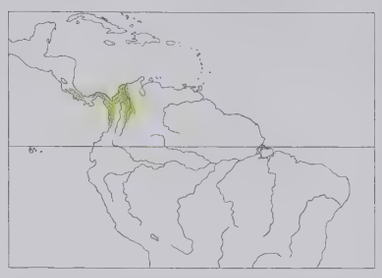
Descriptive notes. 15 cm; male 24·3–27·3 g, female 22·5 g. A very dark, black-throated wren, in plumage rather reminiscent of some antbirds (Formicariidae). Lores and ear-coverts are black with some white markings; crown and upperparts deep reddish-brown, more rufescent on rump; primaries and secondaries uniform dark reddish-brown; rectrices blackish-brown, inconspicuous buffy markings on outer webs of lateral feathers; chin, throat and upper chest black, interspersed with reddish-brown on central chest; lower chest and belly reddish-chestnut, undertail-coverts black with fine white transverse bars; eye reddish-brown; bill grey to black; legs blackish or dark brown. Sexes similar. Juvenile is more uniform and much duller than adult, upperparts dull dark brown, white streaks on ear-coverts absent, throat dull blackish-brown, not contrasting sharply with lower chest, no white bars on undertail-coverts. Voice. Song a distinctive series of rich whistles ending in a trill which may be pitched higher or lower than preceding phrases; female often adds a series of notes at end of a phrase. Call a fast, nasal to wooden rattling "praaaaht", and guttural rolling "beewr" or "bweeurr".
Habitat. Lowland and foothill forest, especially regenerated clearings and other second growth; frequently associated with water, although less so than *T. nigricapillus*.
Food and Feeding. Few data on food; appears to be mainly insects and spiders. Forages usually low down in tangled vegetation, often in pairs.
Breeding. Season in Costa Rica apparently Apr/May–Aug. No other information.
Movements. Appears to be sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in the Central American Caribbean Slope EBA. Locally common in Costa Rica and W Panama; only recently discovered in E Honduras, where status uncertain. Some parts of range protected in national parks and other reserves.
Bibliography. Angehr (2003), Anon. (1998b), Blake & Loiselle (1991), Hellmayr (1934), Ridgely & Gwynne (1989), Slud (1960, 1964), Stiles & Skutch (1989), Wetmore *et al.* (1984).

33. **Sooty-headed Wren**

Thryothorus spadix

French: Troglodyte moine **German**: Rußkopf-Zaunkönig **Spanish**: Cucarachero Cabecigrís
Other common names: Southern Black-throated Wren, Smoky-headed Wren

Taxonomy. *Pheugopedius spadix* Bangs, 1910, Naranjito, River Dagua, Valle, Colombia.
Formerly regarded as conspecific with *T. atrogularis*, but the two are quite distinct in plumage and song and are widely separated geographically. Two subspecies recognized.
Subspecies and Distribution.
T. s. xerampelinus Griscom, 1929 – Pacific slope of extreme E Panama (Darién).
T. s. spadix (Bangs, 1910) – Pacific lowlands of Colombia from Chocó S to Nariño, in N also extending E to middle Magdalena Valley (in Santander).



Descriptive notes. 14·5 cm. Nominate race has black lores with some white markings, black ear-coverts conspicuously streaked white; crown dull blackish, back, shoulders, upperwing-coverts and rump bright chestnut; primaries and secondaries bright chestnut on exposed webs; rectrices chestnut-brown with conspicuous lateral black bars; chin and throat black with some white feathers below angle of bill, contrasting strongly with bright chestnut lower throat and chest; lower chest and belly duller, centre of belly greyish-brown with darker mottling; eye brown; upper mandible blackish-grey, lower mandible blue-grey; legs dull grey. Sexes similar. Juvenile is generally duller than adult, with less contrast between crown and throat, and between back and chest. Race *xerampelinus* is paler than nominate, with less reddish-brown on flanks. Voice. Song, production antiphonally by both sexes, a series of c. 6 loud gurgling whistles, with one phrase frequently repeated; lacks the terminal trill of *T. atrogularis*.
Habitat. Humid forest, forest edge and cloudforest, especially areas with heavy moss growth; also dense secondary forest. Mostly 800–1800 m, but down to 400 m in Colombia.
Food and Feeding. Food mostly or entirely invertebrates; stomach contents of Panamanian specimens included beetles (Coleoptera), true bugs (Hemiptera), ants (Hymenoptera), crickets (Gryllidae), caterpillars and spiders (Araneae). Forages low down in vegetation, usually in pairs; does not routinely join mixed flocks. Has been seen to follow the army ant *Laridus predator* in Colombia.
Breeding. Little published information. Season apparently protracted, with nest-building observed in Mar and Dec, eggs in Sept, and breeding-condition adults in C Andes of Colombia from Apr to Sept. Nest a ball of coarse material and leaves, entrance at side; one was placed c. 1 m up in a *Heliconia*. Eggs 2, white, finely spotted with reddish around large end; no information on incubation and fledging periods.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Fairly common in suitable habitat in Colombia. Uncommon in Panama, where occurs in Darién National Park.
Bibliography. Angehr (2003), Anon. (1998b), Chapman (1917), Cracraft (1985), Donegan & Dávalos (1999), Hellmayr (1934), Hilty (1977, 1997), Hilty & Brown (1986), Meyer de Schauensee (1982), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Robbins *et al.* (1985), Stiles *et al.* (1999), Wetmore *et al.* (1984).

34. **Black-bellied Wren**

Thryothorus fasciatoventris

French: Troglodyte à ventre noir **Spanish**: Cucarachero Ventrinegro
German: Bindenbauch-Zaunkönig
Other common names: Band-bellied Wren

Taxonomy. *Thriothorus* [*sic*] *fasciato-ventris* Lafresnaye, 1845, "Bogotá", Colombia.
Three subspecies recognized.
Subspecies and Distribution.
T. f. melanogaster Sharpe, 1882 – SE Costa Rica (S from mouth of Golfo de Nicoya) and W Panama (E to Canal Zone).
T. f. albigularis (P. L. Sclater, 1855) – E Panama (E from Canal Zone) and NW Colombia (Chocó).
T. f. fasciatoventris Lafresnaye, 1845 – NW & C Colombia (E to foothills of Santa Marta Mts, S to lower Cauca Valley and middle Magdalena Valley.

Descriptive notes. 15 cm; mean both sexes 24 g. Nominate race has conspicuous white supercilium, edged with black above, contrasting strongly with crown and with blackish-brown eyestripe; crown rich brown, back and rump richer chestnut-brown; primaries and secondaries less richly coloured, with inconspicuous darker barring; rectrices medium brown with darker transverse bars; chin, throat and chest gleaming white, sharply contrasting black band across lower chest; belly black with conspicuous white bars, becoming buffy on flanks and lower belly; vent barred dull black and grey, thighs dark brown with diffuse darker barring; eye reddish-brown or light brown; bill blackish to greyish, bluish on lower mandible; legs fuscous black. Sexes similar. Juvenile is very different from adult, has dull chestnut upperparts becoming brighter on rump, dull greyish-white throat, dull grey-brown side of chest, brown belly sometimes with very obscure barring, no sharp contrast between chest and belly. Race *albigularis* has darker brown upperparts and less conspicuous white bars on belly than nominate; *melanogaster* is largest, with upperparts richer chestnut and underpart barring much reduced, barring on undertail-coverts light chestnut-brown. Voice. Song a spectacular series of rich, liquid gurgling notes, each phrase of 3–8 notes repeated frequently before changing to different motif; both sexes sing, but not truly antiphonally (songs overlapping to a degree), female song distinctive, being of a higher frequency. Alarm call a low rasping chatter.
Habitat. Humid, dense low-lying vegetation, especially on streambanks and other wet areas; particularly *Calathea* and *Heliconia* thickets in Costa Rica. Sea-level to 500 m in Costa Rica, to 1000 m in Colombia.
Food and Feeding. Little recorded information; food items from stomach contents include insects and spiders (Araneae). Rather solitary, appears not to maintain extended family groups for feeding and does not routinely associate with mixed flocks. Forages especially in low vine tangles close to ground, occasionally up in canopy.
Breeding. Few nests found. Season probably May–Jul in Costa Rica; nest-building in early Feb and birds in breeding condition Mar–Jul in Colombia. Nest (in Costa Rica) a globular structure, with side entrance protected by "visor", made of dry strips of *Heliconia* leaves, situated 1–2 m up in *Heliconia* thicket. No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Poorly known; probably uncommon. Density is stated as being low compared with that of others species in genus. Occurs in Darién National Park, in Panama.
Bibliography. Anon. (1998b), Boggs (1961), Chapman (1917, 1936), Cracraft (1985), Haffer (1975), Hellmayr (1934), Hilty (1977), Hilty & Brown (1986), Meyer de Schauensee (1982), Morton (1980), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Ridgway (1904), Robbins *et al.* (1985), Slud (1964), Stiles & Skutch (1989), Wetmore *et al.* (1984), Willis & Eisenmann (1979).

35. **Plain-tailed Wren**

Thryothorus euophrys

French: Troglodyte maculé **German**: Fraserzaunkönig **Spanish**: Cucarachero Coliliso
Other common names: Black-crowned Wren (*atriceps*); Spot-chested Wren (*euophrys*)

Taxonomy. *Thryothorus euophrys* P. L. Sclater, 1860, Lloa, not far south of Quito, Pichincha, Ecuador.
Closely related to, and has been considered to form a superspecies with, *T. eisenmanni*, but differs markedly in song and (especially the races geographically closest to latter) in plumage; neither species responds to playback of the other's song. Four subspecies recognized.
Subspecies and Distribution.
T. e. euophrys P. L. Sclater, 1860 – W Andes of extreme S Colombia (Nariño) and Ecuador.
T. e. longipes J. A. Allen, 1889 – E Andes of Ecuador.
T. e. atriceps (Chapman, 1924) – NW Peru (NE Piura, Cajamarca).
T. e. schulenbergi Parker & O'Neill, 1985 – N Peru S of R Marañón (Amazonas, San Martín).

Descriptive notes. 16 cm; male average 36 g, female average 31·5 g. Nominate race has grey-white supercilium, dull blackish eyestripe; crown dark brownish-grey, nape bright brown, becoming richer chestnut on central back and rump; shoulders and upperwing-coverts chestnut-brown; concealed inner webs of primaries and secondaries blackish-brown, outer webs bright reddish-brown; rectrices plain red-brown; throat dull whitish, black malar stripe, upper chest speckled grey and dull black, lower chest unmarked grey-brown; flanks, lower belly and thighs rich brown; eye light brown; upper mandible dark grey, lower mandible bluish-grey; legs bluish-grey. Sexes similar. Juvenile has crown tinged olive-grey, throat rufous without blackish spots or grey tinge, underparts dull white. Race *longipes* has reduced dark markings on chest, more grey underparts, less white on throat; *atriceps* has blackish crown, even less spotting below; *schulenbergi* is larger and duller than nominate, most similar to previous but crown and nape greyish, supercilium pale greyish, posterior underparts less brown. Voice. Song loud and carrying, a series of varied phrases of loud, gurgling chortling whistles, repeated many times; frequently produced by both sexes antiphonally. Contact call a loud "choo-chip, choo-chip-chip", unlike typical troglodytid calls; also a wheezy "zwee".
Habitat. Dense montane undergrowth, especially thickets of *Chusquea* bamboo. 1850–3500 m, mostly above 2000 m.

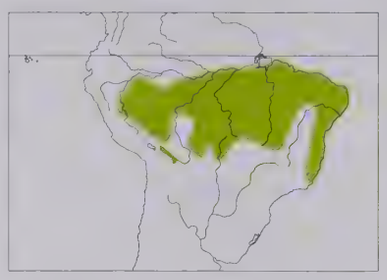
Food and Feeding. Little information; diet mostly invertebrates. Forages in pairs, generally low down; plucks insects from undersides of leaves.
Breeding. Season apparently protracted; in Ecuador, juveniles in Jul in NW and in Nov and Jan in NE. Nest and eggs undescribed.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common in many locations. Present in a number of protected areas, e.g. Podocarpus National Park (Ecuador). As *Chusquea* bamboo, a preferred habitat, frequently colonizes disturbed areas (e.g. rockslides), some human activity may increase available habitat for this species.
Bibliography. Baez *et al.* (1997), Best *et al.* (1997), Bloch *et al.* (1991), Clements & Shany (2001), Davies *et al.* (1994), Fjeldså & Krabbe (1990), Hellmayr (1934), Hilty & Brown (1986), Meyer de Schauensee (1982), Parker & O'Neill (1985), Parker *et al.* (1985), Ridgely & Greenfield (2001), Ridgely & Tudor (1989).

36. Inca Wren

Thryothorus eisenmanni

French: Troglodyte inca **German**: Inkazaunkönig **Spanish**: Cucarachero Inca

Taxonomy. *Thryothorus eisenmanni* Parker and O'Neill, 1985, San Luis, Cuzco, Peru.
Closely related to, and has been considered to form a superspecies with, *T. euophrys*, but differs markedly in song and (especially when compared with geographically closest races of latter) in plumage; neither species responds to playback of the other's song. Monotypic.
Distribution. Cuzco (from Cordillera de Vilcabamba S to valleys of R Santa Marta and R Urubamba), in S Peru.



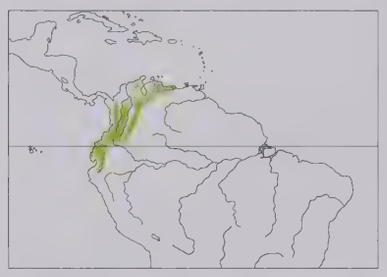
Descriptive notes. 16 cm; male 22–27 g, female 19–23 g. Male has crown, nape, upper half of ear-coverts and lores dull black, broad white supercilium, lower half of ear-coverts white with fine black streaks; remainder of upperparts bright russet, tail duller russet with obscure darker bars, remiges and greater primary coverts blackish-brown with russet-brown edges; most of throat white, dull black submoustachial stripe; breast and upper belly white with bold blackish streaks, flanks and undertail-coverts dull yellow-brown; eye chestnut or reddish-brown; upper mandible dark brown, lower mandible blue-grey or silver-blue with blackish tip; legs greyish-horn or grey-black. Female (on basis of small amount of material available) differs constantly from male, has crown charcoal-grey, rectrices usually unbarred, belly usually unstreaked. Juvenile undescribed. Voice. Song consists of sequences of rapidly repeated chortling whistles, in groups of c. 10 rising and falling notes continuing for a minute or more; sexes sing antiphonally, female song higher-pitched than that of male. Call a sharp "chip-chip-chip".
Habitat. Largely confined to thickets of *Chusquea* bamboo; avoids dense well-shaded forest. 1830–3350 m.
Food and Feeding. Little information. Stomach contents of specimens included small beetles (Coleoptera), caterpillars and cockroaches (Blattodea). Typically forages in pairs or in groups of up to six individuals (possibly family parties), at 0·5–1·5 m above ground. Does not routinely participate in mixed flocks.
Breeding. No information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in the Bolivian and Peruvian Upper Yungas EBA. Discovered as recently as 1985. Notwithstanding its small range, seems to be fairly common in suitable habitat. As its habitat of *Chusquea* bamboo thrives on artificially disturbed sites, such as roadsides, as well as on naturally disturbed ones, such as rockslides and revegetating landslides, this species may have increased in numbers since its initial discovery.
Bibliography. Clements & Shany (2001), Fjeldså & Krabbe (1990), Parker & O'Neill (1985), Ridgely & Tudor (1989), Vuilleumier *et al.* (1992), Walker (2001).

37. Moustached Wren

Thryothorus genibarbis

French: Troglodyte à moustaches **Spanish**: Cucarachero Bigotudo Brasileño
German: Wangenstreif-Zaunkönig

Taxonomy. *Thryothorus genibarbis* Swainson, 1838, Bahia, Brazil.
Closely related to *T. mystacalis*; treated as conspecific by some authorities, but has quite distinct song and differs also in habitat requirements. Four subspecies recognized.
Subspecies and Distribution.
T. g. juruanus H. von Ihering, 1905 – upper Amazonia in E Peru (Ucayali) and W Brazil (E to R Madeira and upper R Purus), probably also into N & W Bolivia.
T. g. genibarbis Swainson, 1838 – E Brazil from R Madeira E to Atlantic coast (Maranhão S to Espírito Santo).
T. g. intercedens Hellmayr, 1908 – C Brazil (Mato Grosso, Goiás).
T. g. bolivianus (Todd, 1913) – Amazonian Bolivia (N Santa Cruz).
Descriptive notes. 15·5 cm; 16·2–22·8 g. Nominate race has grey-brown lores and black postocular stripe, contrasting white eyering and supercilium; ear-coverts grey-black, conspicuously streaked white; crown and nape olivaceous grey-brown, back, rump and wing-coverts bright chestnut; primaries and secondaries dull blackish-brown on concealed inner webs, chestnut on exposed outer webs; rectrices dull brown with c. 8–10 narrow blackish bars; black malar stripe contrasting with white moustachial stripe; throat and upper chest off-white, lower chest buffy, flanks and belly deeper brown, becoming reddish-brown on undertail-coverts; eye reddish-brown; bill often black but somewhat variable; legs grey. Sexes similar. Juvenile has browner crown than adult, with duller, less chestnut back, less clearly defined facial markings (especially malar stripe), more diffuse bars on tail. Race *juruanus* is generally larger, larger-billed and paler below than nominate; *intercedens* has more slender bill, crown less sooty, no grey tinge on foreneck, somewhat duller underparts; *bolivianus* is closest to previous, but has deeper ochraceous underparts, darker grey on neck side, ashy tinge on foreneck. Voice. Song, often produced antiphonally by pair-members, a series of fast rollicking phrases, frequently repeated, phrases often followed by rapid "cho cho cho"; lacks the slower gurgling quality of *T. mystacalis* song, more closely resembles song of *T. coraya*. Call note a whining "jeeyr", which also occurs in the song.



Habitat. Forest edge, including riverine forest, especially dense thickets of *Bambusa* bamboo. Sea-level to middle elevations; to 1500 m in Bolivia.
Food and Feeding. No published information on food items; probably largely or entirely invertebrates. Forages generally low down in vegetation, often in pairs.
Breeding. No information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Fairly common over much of its reasonably extensive range. Suitable habitat is widely distributed and not under excessive threat. Occurs in several protected areas, e.g. Amazonia Lodge, in Peru, and Rio Cristalino Forest Reserve, in Brazil.
Bibliography. Davis (1993), Dubs (1992), Fjeldså & Maijer (1996), Hellmayr (1934), Hennessey *et al.* (2003), Mallet-Rodrigues & Marinho (2003), Meyer de Schauensee (1982), Oren & Parker (1997), Parker & Goerck (1997), Peres & Whittaker (1991), Perry *et al.* (1997), Pinto & Camargo (1961), Ridgely & Tudor (1989), Robinson & Terborgh (1997), Rosenberg (1997), Sick (1993, 1997), Stotz *et al.* (1997), Zimmer *et al.* (1997).

38. Whiskered Wren

Thryothorus mystacalis

French: Troglodyte à favoris **Spanish**: Cucarachero Bigotudo Montano
German: Bartstreif-Zaunkönig
Other common names: Dusky-tailed Wren (*macrurus*)

Taxonomy. *Thryothorus mystacalis* P. L. Sclater, 1860, Pallatanga, Chimborazo, Ecuador.
Closely related to *T. genibarbis*; treated as conspecific by some authorities, but has quite distinct song and differs also in habitat requirements. Eight subspecies recognized.
Subspecies and Distribution.
T. m. consobrinus Madarász, 1904 – Sierra de Perijá and Andes of W Venezuela (S Lara S to Mérida).
T. m. ruficaudatus Berlepsch, 1883 – N Venezuela (C Falcón and Yaracuy E to Miranda).
T. m. tachirensis Phelps, Sr & Gilliard, 1941 – S Táchira (Páramo de Tamá), in SW Venezuela.
T. m. saltuensis (Bangs, 1910) – W & C Andes of Colombia.
T. m. yananchae Meyer de Schauensee, 1951 – E Nariño (Yananchá), in SW Colombia.
T. m. mystacalis P. L. Sclater, 1860 – S Colombia and W Ecuador.
T. m. macrurus J. A. Allen, 1889 – E slope of C Andes and W slope of E Andes, in Colombia.
T. m. amaurogaster (Chapman, 1914) – E slope of E Andes, in Colombia.

Descriptive notes. 16 cm; 29 g (Venezuela). Nominate race has greyish-white supercilium from bill to above central ear-coverts, dull blackish ear-coverts speckled white, dull black lores, off-white crescent under eye; crown greyish-black, nape olivaceous grey, back, shoulders and rump bright chestnut; primaries and secondaries blackish-grey on concealed inner webs, rufescent on outer webs, giving rufescent-brown appearance on closed wing; tertials blackish-grey; rectrices rufescent-brown, barred dull black; chin and throat off-white, prominent black malar stripe edged whitish above; chest grey, becoming olivaceous grey on belly, flanks more rufescent; eye brown; bill black above, silvery grey or grey-brown below; legs grey. Sexes similar. Juvenile is generally duller than adult, less well marked on face, malar stripe largely absent, throat suffused with buff, eye yellowish. Race *saltuensis* is similar to nominate but with more grey chest, clearer grey crown, less distinct tail barring; *yananchae* differs from nominate in having slaty-grey crown; *macrurus* has dingy brown tail with longitudinal barring on rectrices; *amaurogaster* is much darker than nominate, with sooty-brown crown, ochraceous-tawny underparts; *consobrinus* has more slender bill than nominate, buff-tinged supercilium, buffy foreneck and chest; *tachirensis* is darker overall than previous, crown dusky olive, throat white; *ruficaudatus* generally lacks transverse bars on rectrices, has more buff on face than nominate, deep rufous edgings on primaries and secondaries. Voice. Sexes sing in duet, producing a splendid series of loud gurgling whistles, frequently rising or falling in pitch. Call note a deep throaty "bong bong".
Habitat. Dense undergrowth at edge of humid forest and in regenerating clearings; not usually in unbroken forest interior. Mostly 1200–2400 m, sometimes to 2800 m; locally down almost to sea-level in Ecuador.
Food and Feeding. No information on food. Forages in pairs, from ground level up to 10–12 m, often in *Heliconia* thickets.
Breeding. Season appears to be quite protracted, from late Dec, with nest-building still observed in May. Nest a large ball c. 20 cm in diameter, side entrance, made of roots and grass, located at height of 0·3–6·5 m in fork of small tree or in ferns. No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common over much of its range. Occurs in several protected areas, including e.g. Macarao National Park, in Venezuela, and Río Palenque Science Centre, in Ecuador.
Bibliography. Allen (1998), Beebe (1949), Best *et al.* (1997), Chapman (1917), Fjeldså & Krabbe (1990), Hellmayr (1934), Hilty (2003), Hilty & Brown (1986), Kirwan & Marlow (1996), López *et al.* (2000), Miller (1963), Pople *et al.* (1997), Ridgely & Gaulin (1980), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Wetmore (1939).

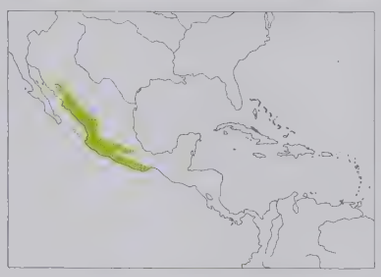
39. Coraya Wren

Thryothorus coraya

French: Troglodyte coraya **German**: Corayazaunkönig **Spanish**: Cucarachero Coraya

Taxonomy. *Turdus coraya* J. F. Gmelin, 1789, Cayenne, French Guiana.
Substantial vocal and plumage differences between lowland and highland populations in Venezuela suggest the possibility that more than one species are involved. Ten subspecies recognized.
Subspecies and Distribution.
T. c. ridgwayi Berlepsch, 1889 – E Venezuela (S Delta Amacuro, E Bolívar) and W Guyana (W of R Essequibo).
T. c. coraya (J. F. Gmelin, 1789) – Guyana (E of R Essequibo), Suriname, French Guiana and adjacent N Brazil (E of Manaus).
T. c. caurensis Berlepsch & Hartert, 1902 – E & SE Colombia, S Venezuela (S Bolívar, S Amazonas) and N Brazil (E to Manaus).
T. c. obscurus J. T. Zimmer & Phelps, Sr, 1947 – Auyán-tepui, in E Bolívar (E Venezuela).
T. c. barrowcloughianus Aveledo & Pérez, 1994 – tepuis of SE Bolívar (Roraima, Cuquenán), in SE Venezuela.
T. c. griseipectus Sharpe, 1882 – E Ecuador, NE Peru (N of R Marañón) and adjacent extreme W Brazil.
T. c. albiventris Taczanowski, 1882 – N Peru (E slopes of Andes in San Martín).
T. c. amazonicus Sharpe, 1882 – E Peru S of R Marañón (S Loreto S to Huánuco).
T. c. cantator Taczanowski, 1874 – C Peru (E Junín).
T. c. herberti Ridgway, 1888 – N Brazil S of Amazon (from R Tapajós E to R Tocantins and W Maranhão).



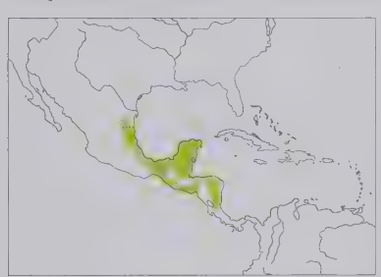
Descriptive notes. 14·5 cm; mean 23·8 g. Nominate race has face, including lores and ear-coverts, black with variable amounts of white markings, white supercilium; crown blackish-brown, upperparts deep reddish-brown, somewhat paler and more rufous on rump; primaries and secondaries greyer than back, rectrices brownish-black with pale grey-brown bars; chin and throat white, chest buff, becoming buffish-brown on belly; undertail-coverts reddish-brown with black bars; eye brown or orange-brown; bill blackish, grey base; legs bluish-grey. Distinguished from other members of genus by combination of heavy markings on face, plain white throat and unpatterned underparts. Sexes similar. Juvenile is very different from adult, has black on side of face replaced by dull blackish-grey, with white markings indistinct, back and rump much less rufescent, throat and chest dull grey, warm colours on belly much reduced, iris greyish-brown. Race *ridgwayi* has underparts deep ochraceous to bright brown; *griseipectus* has bright rufous upperparts, pale grey chest, dark rufescent-brown flanks; *caurensis* is similar to previous, but paler on flanks; *obscurus* resembles last, but with more rufous underparts; *barrowcloughianus* has bright chestnut upperparts; *herberti* has more extensive black on side of face, unbarred uppertail-coverts; *albiventris* is nearly white on middle of breast and abdomen, with reduced brown on flanks; *amazonicus* is similar to nominate, but lighter and less chestnut above, less rufescent flanks; *cantator* resembles last, but supercilium reduced and white streaks on side of head lacking, has almost solid black ear-coverts, and tailbars bright cinnamon-brown (not dull brownish-grey). Voice. Song, by both sexes in duet, a loud, prolonged and varied medley of bubbles and whistles; call a characteristic "chidip chidip choopee".
Habitat. Humid forest and second growth, especially along riverbanks, including both *várzea* and *terra firme*. Generally lowlands, from sea-level to 500 m; locally to 1850 m, and occasionally to 2400 m, on Venezuelan tepuis.
Food and Feeding. Stomach contents include spiders (Araneae), beetles (Coleoptera) and orthopterans (Locustidae); also some seeds. Forages in vegetation from ground level to several metres up; frequently associates with antwrens and antbirds (Thamnophilidae).
Breeding. Little known; only two nests described. Breeding occurs over much of year in the Guianas, eggs noted on 25th Feb, newly fledged juveniles from mid-Jan to late Apr, nest construction in mid-Jul and an occupied nest in late Sept. Nest, built by both sexes, an ovoid ball of twigs and dead leaves, one in a bush and other on top of a mossy tree stump, 3–4 m above ground. Eggs 2, rosy white with fine dark speckles, especially at thick end; no information on incubation and fledging periods.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Widespread, and in many areas quite common. Appears able to colonize second growth and moderately disturbed areas. Occurs in several protected areas, e.g. Canaíma National Park, in Venezuela.
Bibliography. Bangs & Penard (1918), Best *et al.* (1997), Bloch *et al.* (1991), Chapman (1931), Cohn-Haft *et al.* (1997), Cracraft (1985), Friedmann (1948), Gilliard (1941), Haverschmidt (1968), Haverschmidt & Mees (1994), Hellmayr (1934), Hilty (2003), Hilty & Brown (1986), Mayr & Phelps (1967), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Novaes (1974), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Sick (1993, 1997), Snyder (1966), Tostain *et al.* (1992), Willard *et al.* (1991).

40. Happy Wren

Thryothorus felix

French: Troglodyte joyeux **German**: Buntwangen-Zaunkönig **Spanish**: Cucarachero Feliz

Taxonomy. *Thryothorus felix* P. L. Sclater, 1860, Juquila, Oaxaca, Mexico.
In past, suggested as possibly conspecific with *T. maculipectus*. Six subspecies recognized.
Subspecies and Distribution.
T. f. sonorae (van Rossem, 1930) – S Sonora and N Sinaloa, in NW Mexico.
T. f. pallidus Nelson, 1899 – C Sinaloa and W Durango S to Jalisco and NW Michoacán.
T. f. lawrencii Ridgway, 1878 – María Madre I (Tres Marías Group), off Nayarit (W Mexico).
T. f. magdalenae Nelson, 1898 – María Magdalena I (Tres Marías Group).
T. f. grandis Nelson, 1900 – drainage of R Balsas (S México, Morelos, SW Puebla, N Guerrero), in W Mexico.
T. f. felix P. L. Sclater, 1860 – SW Mexico from SE Jalisco S to W Oaxaca.



Descriptive notes. 12·5–14 cm; 9–16·4 g. Nominate race has white supercilium, contrasting black sides of face and of neck with prominent white markings; crown and upper back deep reddish-brown, becoming paler on lower back; shoulders, primaries and secondaries rufous-brown, rectrices brown to greyish-brown with darker bars; throat whitish, narrow black malar stripe; underparts warm buff; eye dark brown; bill black, grey base; legs dark grey. Distinguished from *T. sinaloa* by well-defined facial pattern, buff underparts. Sexes similar. Juvenile is similar to adult, but facial markings more diffuse, underparts tinged greyish. Race *sonorae* is much paler than nominate, with pure white chin and throat; *pallidus* is smaller and paler than nominate; *lawrencii* is similar to previous but still paler, with less strongly marked cheeks; *magdalenae* also has obscure face markings but is generally darker than last; *grandis* is intermediate in coloration between nominate and *pallidus* but larger than both. Voice. Song an arresting series of rollicking, gurgling whistles, delivered antiphonally by both sexes, each providing constant phrases that differ from those of the other. Frequently mutually territorial with *T. sinaloa*, each species reacting to the other's song (territories do not overlap); on Tres Marías Is, where latter species absent, local races (*lawrencii* and *magdalenae*) have less song variation than do mainland races.
Habitat. Dry tropical forest, including thorn-forest, and oak–hornbeam (*Quercus–Carpinus*) woodland; also in disturbed habitat and second growth. Sea-level to 2000 m.
Food and Feeding. Mostly invertebrates, including beetles (Coleoptera), caterpillars, bugs (Hemiptera), hymenopterans and others; some vegetable matter, including fruit. Forages low down, from ground to about 2 m, occasionally higher, to 10 m.
Breeding. Breeds late May and Jun, island populations (*lawrencii* and *magdalenae*) several weeks later. Nest a retort-shaped bag of grass, fibres and similar material, built over a twig so that entrance hangs over one side and pouch over the other; frequently sited next to wasp nest, or in acacia (*Acacia*) defended by the aggressive symbiotic ant *Pseudomyrmicus*, which provide protection from terrestrial predators; c. 3 m up, occasionally as high as 18 m, rarely on ground (ground-nesting more frequent in island races). Usually 5 eggs, unmarked bluish-white; no information on incubation and fledging periods.
Movements. Mostly sedentary; some evidence of vertical movements by higher-altitude populations at N edge of range.
Status and Conservation. Not globally threatened. Quite common over much of its range. Appears to be able to tolerate substantial habitat disturbance.
Bibliography. Anon. (1998b), Arizmendi & Márquez (2000), Binford (1989), Blake (1953), Brown (1977), Brown & Lennon (1979), Forcey (2002), Grant (1966a, 1966b), Hellmayr (1934), Howell & Webb (1995), Hutto (1980), Peterson, Escalona *et al.* (2003), Ridgway (1904), Rowley (1966), Short (1974), Stager (1957).

41. Spot-breasted Wren

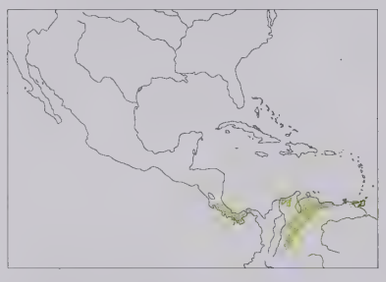
Thryothorus maculipectus

French: Troglodyte à poitrine tachetée **Spanish**: Cucarachero Pinto
German: Fleckenbrust-Zaunkönig

Taxonomy. *Thriothorus* [*sic*] *maculipectus* Lafresnaye, 1845, Veracruz, Mexico.
Sometimes treated as conspecific with *T. rutilus* and *T. sclateri*, despite great differences in plumage and vocalizations; in past, suggested as possibly being conspecific with *T. felix*. Proposed races *varians* (Pacific slope from Chiapas, in S Mexico, S to El Salvador) and *petersi* (N Honduras S to N Costa Rica) are considered indistinguishable from *umbrinus*. Four subspecies currently recognized.
Subspecies and Distribution.
T. m. microstictus (Griscom, 1930) – NE Mexico (SE Nuevo León and C Tamaulipas S to E San Luis Potosí and N Veracruz).
T. m. maculipectus Lafresnaye, 1845 – E Mexico (Veracruz S to Puebla and N Oaxaca).
T. m. canobrunneus Ridgway, 1887 – SE Mexico (Yucatán Peninsula), N Belize and N Guatemala (N Petén).
T. m. umbrinus Ridgway, 1887 – S Mexico (NE Oaxaca, Tabasco, Chiapas), S Belize, Guatemala (except Petén), El Salvador, N & S Honduras, and Caribbean slope of Nicaragua and N Costa Rica.

Descriptive notes. 12·5–14 cm; male 14·3–16·8 g, female 12·4–16·2 g. Nominate race has white supercilium, sides of face and of neck streaked black and white; crown and upperparts reddish-brown, becoming more chestnut on rump; primaries and secondaries very obscurely barred darker; rectrices dull brown with narrow dark bars; whitish-grey below, prominently spotted black on throat, chest and centre of belly, unspotted orange-buff on lower belly and flanks; eye red-brown; bill blackish; legs blue-grey. Differs from *T. rutilus* in heavily spotted chest, from *T. sclateri* in much warmer-coloured back. Sexes similar. Juvenile is much more obscurely and less extensively marked on face and underparts. Race *microstictus* is less rufescent above than nominate, with smaller and less profuse chest spots; *umbrinus* is larger and generally darker; *canobrunneus* is paler than nominate, with light cinnamon-buff crown. Voice. Song a cheerful series of clear whistling gurgles, given by both sexes antiphonally, male's section consisting of 5–7 notes, female's of 2–4.
Habitat. Quite varied, including disturbed and regenerating habitats. Forest and forest edge, as well as cocoa and citrus plantations. Occurs in both dry forest on limestone and more humid coastal forest. Sea-level to 1300 m in Mexico and Honduras; to only 200 m in Costa Rica.

On following pages: 42. Rufous-breasted Wren (*Thryothorus rutilus*); 43. Speckle-breasted Wren (*Thryothorus sclateri*); 44. Bay Wren (*Thryothorus nigricapillus*); 45. Riverside Wren (*Thryothorus semibadius*).



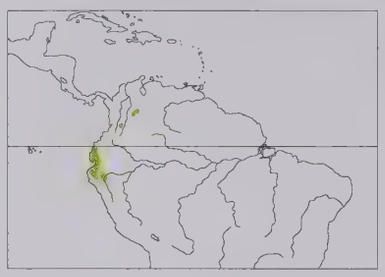
Food and Feeding. Little information on food, probably predominantly invertebrates. Forages usually in pairs or family parties, low down in tangled vegetation.
Breeding. Mar–Jul in Mexico and Apr–Jul in Costa Rica. Nest dome-shaped with side entrance, overall dimensions c. 10 cm × 15 cm, entrance hole c. 4 cm in diameter and without tunnel, typically 1–6 m above ground level in crotch of tree or in ferns, once in hanging flower basket. Eggs 3–4, white with heavy reddish-brown streaks or blotches; no information on incubation and fledging periods; young fed by both sexes.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Frequently quite common. Appears able to make use of moderately disturbed habitat. Occurs in several protected areas, e.g. Blue Hole National Park, in Belize.
Bibliography. Anon. (1998b), Bangs (1903), Binford (1989), Blake (1953), Brodkorb (1943), Contreras (1997), González-García (1993), Hellmayr (1934), Howell, S.N.G. & Webb (1995), Howell, T.R. (1957), Klaas (1968), Komar & Domínguez (2001), Land (1970), Lee Jones (2004), Meyer de Schauensee (1982), Miller (1995), Monroe (1968), Paynter (1955, 1957), Rowley (1984), Russell (1964), Skutch (1940), Smithe (1966), Stiles & Skutch (1989), Tashian (1952), Van Tyne (1935), Waide (1980), Wetmore (1943), Winker *et al.* (1996).

42. **Rufous-breasted Wren**

Thryothorus rutilus

French: Troglodyte des halliers **German**: Rotbrust-Zaunkönig **Spanish**: Cucarachero Pechirrufo
Other common names: Bush Wren, Speckled Wren, (Trinidad) Jungle Wren

Taxonomy. *Thryothorus rutilus* Vieillot, 1819, "l'Amérique septentrionale" = Trinidad.
Sometimes treated as conspecific with *T. maculipectus* and *T. sclateri*, despite great differences in plumage and vocalizations. Seven subspecies recognized.
Subspecies and Distribution.
T. r. hyperythrus Salvin & Godman, 1880 – Pacific slope of Costa Rica and W Panama (E to R Chepó, in Darién).
T. r. laetus Bangs, 1898 – N Colombia (Santa Marta, Magdalena) and extreme NW Venezuela (Perijá Mts).
T. r. rutilus Vieillot, 1819 – N & W Venezuela (coastal mountains from Falcón E to Sucre and Monagas, both slopes of Andes from NW Lara S to Táchira) and Trinidad.
T. r. tobagensis (Hellmayr, 1921) – Tobago.
T. r. intensus (Todd, 1932) – SW Venezuela (NW Táchira).
T. r. interior (Todd, 1932) – W slope of E Andes (Lebrija Valley, in Santander), in Colombia.
T. r. hypospodius Salvin & Godman, 1880 – E slope of E Andes of Colombia (Boyacá, Meta).



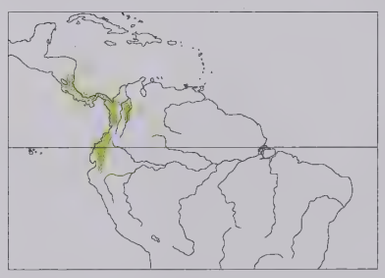
Descriptive notes. 14 cm; 13·5–18·5 g. Distinctive. Nominate race has white supercilium edged black above, face and throat conspicuously marked with black and white speckles; crown and upperparts warm brown, primaries and secondaries duller and very obscurely barred; tail grey-brown, heavily barred blackish-brown; bright chestnut-brown chest sharply demarcated from throat, rest of underparts duller chestnut, centre of belly greyish-white; eye light reddish-brown; bill black, bluish-grey base; legs grey. Sexes similar. Juvenile is generally duller than adult, with facial pattern less sharply defined. Race *hyperythrus* is similar to nominate, but some blackish spots on chest; *laetus* resembles previous but underpart colours richer and warmer; *hypospodius* has tawny colour restricted to chest, flanks duller, upperparts more rufescent, crown deeper rufous; *interior* is paler below, with yellow-ochre breast, pale olive-brown flanks; *intensus* is more richly coloured below than nominate, often with some dark spotting; *tobagensis* has heavier and stronger bill, longer wings and duller chest than nominate. Voice. Sexes sing antiphonally; male may also sing on his own, or the sexes may duet. Considerable geographical variation in song; in Central America, male song 4–7 pure, clear whistles, female 3–4 weaker notes; by contrast, one song type in Venezuela consists of clear whistles mixed with trills. Immatures have different song, rambling and undeveloped, which with time includes some of the clear notes of adult. Call notes churring and raspy, resembling sound made by running one's fingernails over a comb.
Habitat. Rainforest and cloudforest, thickets, second growth and forest edge; not usually in interior of dense forest. Sea-level to 1900 m.
Food and Feeding. Recorded prey items include beetles (Coleoptera), bugs (Hemiptera), flies (Diptera) and hymenopterans; occasionally small seeds. Forages in pairs or in family groups, usually low down in tangles of vegetation, but sometimes quite high in trees.
Breeding. Season Jan–Jul in Costa Rica and Trinidad, and Dec–Jul in Colombia. Nest, built by both sexes, a bulky domed structure with sides c. 13 × 15 cm and 13 cm high, made of grasses, bamboo leaves and dry stalks, lined with finer material and seed down, located 10 cm to as much as 12 m above ground in vegetation tangle. Clutch 2–3 eggs in Central America, 2–4 in Trinidad, eggs white with brown spots, especially at blunt end; incubation by female alone, period c. 18 days; nestlings fed by both parents, fledging in c. 16 days.
Movements. Appears to be totally sedentary.
Status and Conservation. Not globally threatened. Common in suitable habitat over much of its range. Occurs in a number of protected areas, including e.g. Alexander Skutch Private Reserve, in Costa Rica, Isla de Salamanca National Park, in Colombia, and Henri Pittier National Park, in Venezuela.
Bibliography. Anon. (1998b), Blake (1958), Cracraft (1985), ffrench (1986, 1991), Friedmann & Smith (1955), Hellmayr (1934), Herklots (1961), Hilty (2003), Hilty & Brown (1986), Meyer de Schauensee (1982), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Skutch (1960, 1985b), Slud (1964), Snow (1985b), Stiles & Skutch (1989), Wetmore *et al.* (1984), White (2002).

43. **Speckle-breasted Wren**

Thryothorus sclateri

French: Troglodyte de Sclater **Spanish**: Cucarachero Jaspeado
German: Pünktchenbrust-Zaunkönig
Other common names: Maranon Wren

Taxonomy. *Thryothorus sclateri* Taczanowski, 1879, Guajango, River Marañón, Cajamarca, Peru.
Sometimes treated as conspecific with *T. maculipectus* or *T. rutilus*, or with both, but all three differ substantially in plumage and in song. Race *paucimaculatus* suggested by some as meriting rank of full species. Three subspecies recognized.
Subspecies and Distribution.
T. s. columbianus (Chapman, 1924) – Colombia, on W slope of C Andes (in Valle) and, disjunctly, W slope of E range (in Cundinamarca).
T. s. paucimaculatus Sharpe, 1882 – W Ecuador (Manabí S to Loja).
T. s. sclateri Taczanowski, 1879 – R Marañón drainage in extreme S Ecuador and N Peru (Cajamarca).



Descriptive notes. 13·5–14 cm. Nominate race has narrow white supercilium, dark eyestripe, sides of face and of neck mottled black and white; crown reddish-brown, back and rump medium brown; primaries and secondaries olivaceous brown with very obscure, inconspicuous darker barring; rectrices barred grey and dull black; chin to upper belly covered in fine black and white bars, these becoming broader and more diffuse on lower belly and flanks, which are also washed buff; eye reddish-brown; bill dark brown above, grey below; legs dark slate. Sexes similar. Juvenile is like adult, but markings below do not extend so far down on belly, iris brown. Race *columbianus* is smaller and duller than nominate, upperparts and flanks less warm and more olivaceous brown; *paucimaculatus* has much less extensive markings on underparts, with tendency towards spotting rather than barring. Voice. Song a series of fast, repeated phrases; probably an antiphonal singer. Call similar to sound made by scraping one's fingernails along a comb.
Habitat. Thickets and undergrowth in forests, both humid and (in S Ecuador) more arid. At 1300–2000 m in Colombia, to c. 1600 m in Ecuador and Peru.
Food and Feeding. No data on food items other than "insects" (stomach contents, Ecuador). Forages in forest understorey, usually in pairs; frequently joins mixed flocks with antbirds (Thamnophilidae) and others.
Breeding. No information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Locally fairly common to common. Suitable habitat remains in substantial areas of range, and this species can be reasonably numerous in such places. Occurs in several protected areas, e.g. Podocarpus National Park and Río Palenque Science Centre, in Ecuador.
Bibliography. Best *et al.* (1997), Clements & Shany (2001), Davies *et al.* (1994), Hilty & Brown (1986), Parker *et al.* (1995), Ridgely & Tudor (1989, 2001), Walker (2002), Wiedenfeld *et al.* (1985), Williams & Tobias (1994).

44. **Bay Wren**

Thryothorus nigricapillus

French: Troglodyte à calotte noire **Spanish**: Cucarachero Cabecinegro
German: Kastanienzaunkönig
Other common names: Black-capped Wren (S races)

Taxonomy. *Thryothorus nigricapillus* P. L. Sclater, 1860, Nanegal, c. 4000 feet [c. 1220 m], Pichincha, Ecuador.
Sometimes considered conspecific with *T. semibadius*, but differs in plumage and no evidence of intergradation where ranges approach in Costa Rica and W Panama; separation also supported by recent DNA analyses. In addition, N group of unbarred races (*costaricensis*, *castaneus*, *odicus*, *reditus*) sometimes treated as a separate species; in view of intergradation of the two groups in E Panama, however, most authorities merge them into a single species, notwithstanding major plumage differences between the geographical extremes. Seven subspecies recognized.
Subspecies and Distribution.
T. n. costaricensis (Sharpe, 1882) – SE Nicaragua (R Escondido) S through Caribbean drainage to W Panama.
T. n. castaneus Lawrence, 1861 – W Panama from Veraguas E to Canal Zone.
T. n. odicus Wetmore, 1959 – Escudo de Veraguas I, off NW Panama.
T. n. reditus (Griscom, 1932) – Caribbean slope of E Panama.
T. n. schottii (S. F. Baird, 1864) – E Panama (Darién) and NW Colombia (Antioquia, Chocó).
T. n. connectens (Chapman,1912) – SW Colombia (Cauca, Nariño).
T. n. nigricapillus P. L. Sclater, 1860 – W Ecuador (Esmeraldas S to El Oro).

Descriptive notes. 14·5 cm; 17·7–26·3 g. Distinctive. Nominate race has black face except for grey lores, narrow white supercilium, incomplete white eyering, white patch on rear ear-coverts; crown and nape black, back, shoulders and rump rich chestnut-brown; primaries and secondaries warm chestnut with black barring; rectrices rich brown, boldly barred black; throat white; underparts white, becoming warm brown on lower belly and flanks, with conspicuous blackish barring that increases from breast towards rear; eye light mouse-brown to red-brown; bill black above, dull bluish-grey below, orange-yellow at base; legs dark grey to black. Sexes similar. Juvenile is generally less brightly coloured than adult, with less contrast between crown and back. Race *connectens* has more extensive barring below than nominate; *schottii* has underpart barring narrower than in nominate; *castaneus* has white throat, contrasting rich chestnut underparts with no, or very little, barring; *costaricensis* is similar to previous but with deeper, richer chestnut below; *odicus* is generally paler than last, with larger bill; *reditus* is lighter-coloured, with more white on breast and some black barring on sides and abdomen. Voice. Song a varied series of loud ringing whistles, repeated, then varied and again repeated; frequently sings antiphonally, duets being initiated by female. Female responds strongly to playback of female song; male responds to tapes of both male and female songs, but paired males respond most to male song and unpaired males to female song. Call a diagnostic "heetowip" and a guttural "chu-r-r-k".
Habitat. Humid second growth and forest edge, especially near water; usually not in interior forest, which tends to be inhabited by *T. spadix*. Occurs in riverside reedbeds in E Panama (Darién), but may occur in drier habitat in Nicaragua. Sea-level to 1100 m.

Food and Feeding. Food probably entirely invertebrates; stomach contents from Panama included spiders (Araneae), earwigs (Dermaptera), beetles (Coleoptera) and cockroach eggs (Blattodea). Forages often in pairs, mostly low down in thick vegetation.
Breeding. Apparently protracted season in Panama, young hatchlings in Mar and nest-building in Nov; Jan–Aug in Colombia. Nest, built by both sexes, an "elbow-shaped" structure of grass stems, lined with finer grasses, usually located 1–5 m up in crotch of shrub. Eggs 3, white with cinnamon speckles, especially around blunt end; no information on incubation and fledging periods.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common in suitable habitat over much of its range.
Bibliography. Allen (1998), Anon. (1998b), Best *et al.* (1997), Bloch *et al.* (1991), Brenowitz & Kroodsma (1996), Butler (1979), Carriker (1910), Chapman (1917), Cracraft (1985), Duguay (1997), González *et al.* (2003), Griscom (1932a), Haffer (1975), Hellmayr (1934), Hilty (1997), Hilty & Brown (1986), Levin (1988, 1996a, 1996b, 1998), Meyer de Schauensee (1982), Pople *et al.* (1997), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Robbins *et al.* (1985), Salaman (1994), Slud (1960, 1964), Stiles & Skutch (1989), Stone (1918), Wetmore *et al.* (1984), Williams & Tobias (1994).

45. **Riverside Wren**

Thryothorus semibadius

French: Troglodyte des ruisseaux **German**: Uferzaunkönig **Spanish**: Cucarachero Ribereño
Other common names: Salvin's Wren

Taxonomy. *Thryothorus semibadius* Salvin, 1870, Bugaba, actually Chiriquí, Panama.
Sometimes considered conspecific with *T. nigricapillus*, but differs in plumage and no evidence of intergradation where ranges approach in Costa Rica and W Panama; separation also supported by recent DNA analyses. Monotypic.
Distribution. Mainly in Pacific drainage from C Costa Rica (S from S end of Golfo de Nicoya) S to W Panama.
Descriptive notes. 13–14 cm; 17 g. Has upper lores and upper supercilium black, lower part of lores and lower supercilium white; chin grey, ear-coverts and side of throat dull black with white spotting; crown bright orange-brown, nape, back and rump chestnut-brown; shoulders and primary and secondary wing-coverts blackish-grey, barred narrowly greyish-white; primaries and secondaries orange-brown with dull blackish bars; rectrices dull blackish with narrow buff-white bars; throat to

vent whitish-grey with narrow black bars, ground colour becoming more buffy posteriorly; eye light reddish-brown; bill black above, grey below; legs dull grey. Sexes similar. Juvenile is duller than adult, has fine blackish scaling on crown, black bars below less well defined, eye dull brown. Voice. Song, by both sexes, consists of loud ringing phrases of 1–4 notes, repeated frequently, then changing to different, continuously repeated phrase. Juvenile has different song, a long-drawn-out medley of low, sweet notes. Calls include harsh churr and various clear tinkling notes.
Habitat. Dense vegetation, particularly along borders of watercourses, swampy woodland edge and in steep precipices; sea-level to 1200 m.
Food and Feeding. Stomach contents include beetles (Coleoptera), cockroach eggs (Blattodea), spiders (Araneae) and earwigs (Dermaptera). Large insects dismembered piecemeal before being eaten. Forages low down, usually in pairs or in family groups; will briefly join mixed flocks attending ant swarms, but does not routinely follow army ants. Despite its close association with watercourses, does not forage at water's edge.
Breeding. Season very protracted, eggs found in Costa Rica in Feb, Jul, Aug and Dec. Nest, probably built by both sexes, constructed mostly from fine fibrous material, with some moss on roof, a globular structure with deep indentation on lower side where it fits over a single supporting twig, thereby dividing it into an antechamber on one side of twig and nesting chamber on other, downward-pointing entrance hole leading into antechamber; placed low down, typically 1·5–2·2 m above ground, frequently over flowing water; dormitory nests less substantial in construction. Eggs 2, white with fine pale brown or cinnamon speckles concentrated mostly at thick end; incubation by female alone, period 18–19 days; nestlings fed by both sexes, fledging period c. 16 days; family-members remain together for much of year.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in the South Central American Pacific Slope EBA. Common in suitable habitat over much of its range.
Bibliography. Angehr (2003), Anon. (1998b), González *et al.* (2003), Hellmayr (1934), Leck & Hilty (1970), Ridgely & Gwynne (1989), Ridgway (1904), Skutch (1940, 1960, 1985b, 2001), Slud (1964), Stiles & Skutch (1989), Wetmore *et al.* (1984).

PLATE 40

inches 3

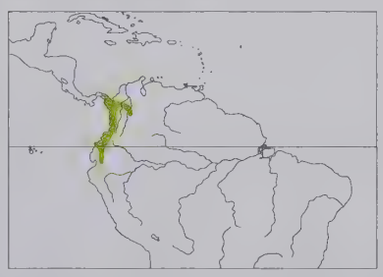
cm 8

46. Stripe-breasted Wren

Thryothorus thoracicus

French: Troglodyte flammé **Spanish**: Cucarachero Pechirrayado
German: Streifenbrust-Zaunkönig

Taxonomy. *Thryothorus thoracicus* Salvin, 1865, Tucurriquí, Costa Rica.
Sometimes treated as conspecific with *T. leucopogon*, but differs significantly in both song and plumage. Monotypic.
Distribution. Caribbean slope from SE Honduras and NE Nicaragua (Bonanza) S to W Panama (Bocas del Toro E to Coclé, rarely to Canal Zone).



Descriptive notes. 11·5–12·5 cm; mean 17·6 g. Highly distinctive, with diagnostic chest pattern. Has lores blackish-grey, sides of face and of neck blackish-grey conspicuously streaked white; crown grey-brown; back, shoulders, primary and secondary wing-coverts and rump dark umber, coverts with narrow black bars; primaries and secondaries dull buff-brown, finely barred blackish; rectrices dull blackish, barred buff-brown; throat and chest with conspicuous broad black, white and grey streaks, producing teardrop appearance, and contrasting abruptly with unmarked dull olive-brown lower belly; eye red-brown; bill greyish-black above, bluish-grey below; legs grey-brown. Sexes similar. Juvenile is more russet above, crown with black scales, throat and chest greyish-brown with irregular white and dusky stripes, eye dull brown. Voice. Two distinct song types, very different from each other: one type, frequently heard at dawn, a uniform series of whistles on one note, very similar to song of some small owls such as Ferruginous Pygmy-owl (*Glaucidium brasilianum*), and seemingly uttered by one bird only, probably male; second type, often given antiphonally by both sexes, a cheerful series of liquid bubbling whistles, of c. 6–10 notes. Juveniles have a sweet, rambling song, quite different from that of adults. Calls include rolling "cherk" or "ch-r-r-k", as well as series of soft guttural chatters.
Habitat. Woodland edge, open areas of forest and tangled vegetation along streams; in Costa Rica, cacao plantations at lower elevations and shade coffee plantations higher up. Occurs from sea-level up to 1100 m.
Food and Feeding. Few data on food; prey items fed to young include spiders (Araneae), moths (Lepidoptera), caterpillars, cockroaches (Blattodea) and other insects. Typically, forages low down in thick vegetation.
Breeding. Season Mar–Jul in Costa Rica. Nest, built by both sexes, a globular two-part structure made of fibres and leaf skeletons with outer covering of green moss, chamber on one side of supporting twig and, dangled on other, a downward-pointing entrance and vestibule; placed typically in shrub or cacao bush, or on top of palm fronds, 1·5–6 m above ground; nests also used as dormitories. Eggs 2–3, unmarked white or bluish-white; incubation by female alone, period not recorded; young fed by both sexes, for c. 16 days.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common in some locations; appears able to adapt to very modified habitats, such as plantations. Occurs in some protected areas, including Braulio Carrillo National Park, in Costa Rica.
Bibliography. Angehr (2003), Anon. (1998b), Blake & Loiselle (1991), Hellmayr (1934), Howell (1957), Meyer de Schauensee (1982), Ridgely & Gwynne (1989), Skutch (1972), Slud (1960, 1964), Stiles & Skutch (1989), Wetmore *et al.* (1984).

47. Stripe-throated Wren

Thryothorus leucopogon

French: Troglodyte balafré **Spanish**: Cucarachero Gorgirrayado
German: Streifenkehl-Zaunkönig
Other common names: Festa's Wren

Taxonomy. *Thryophilus leucopogon* Salvadori and Festa, 1899, River Peripa, Pichincha, Ecuador.
Sometimes treated as conspecific with *T. thoracicus*, but differs significantly in both song and plumage. Recently discovered population in W San Blas (Panama) not yet assigned to either race, tentatively included in *grisescens*. Two subspecies recognized.
Subspecies and Distribution.
T. l. grisescens (Griscom, 1932) – Caribbean slope in E Panama (W San Blas, Darién) and N Colombia.
T. l. leucopogon (Salvadori & Festa, 1899) – E Panama (Pacific slope of Darién) and Pacific drainage of Colombia and Ecuador.

Descriptive notes. 12 cm. Rather nondescript wren with diffuse throat markings. Nominate race has grey-brown lores, greyish-white supercilium, ear-coverts streaked dull black and greyish-white; crown and upperparts dark brown, more rufescent on rump; primaries and secondaries reddish-brown with fine blackish bars; rectrices dull reddish-brown, narrowly barred dull blackish; chin and throat sharply streaked with grey-white and blackish, streaks extending below ear-coverts, well demarcated from deep rufescent-buff upper chest; rest of underparts rufescent buff, becoming darker and richer on lower belly and vent; eye light brown or reddish-brown; bill black or dark grey above, light grey with blackish tip below; legs grey-black or grey-brown. Sexes similar. Juvenile is like adult but with less clearly defined streaking, eye brown (without reddish tinge). Race *grisescens* is noticeably greyer and paler, above and below, than nominate. Voice. Song a tuneless repetition of 2–3 notes, "chi-chi-chi"; no data on antiphonal or duetting song. Calls resemble some elements of song.
Habitat. Edges of secondary forest and *várzea*; sea-level to 900 m.
Food and Feeding. Few data on food; stomach contents "insects". Usually found in pairs, foraging 3–10 m up in thick vegetation; routinely participates in mixed flocks with other species.
Breeding. Nest-building observed at beginning of Mar in Panama; birds in breeding condition in Apr in NW Colombia. Nest an untidy ball with side entrance, usually placed near end of small branch with little effort at concealment. No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Not well known; apparently rather scarce throughout much of its range. Occurs in Darién National Park, in Panama.
Bibliography. Anon. (1998b), Best *et al.* (1997), Chapman (1917), Christian (2001), Haffer (1975), Hilty & Brown (1986), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Stiles *et al.* (1999), Wetmore *et al.* (1984).

48. Banded Wren

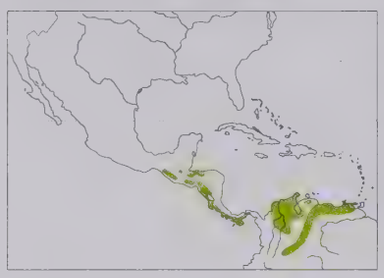
Thryothorus pleurostictus

French: Troglodyte barré **German**: Akazienzaunkönig **Spanish**: Cucarachero Ventribarrado

Taxonomy. *Thryothorus pleurostictus* P. L. Sclater, 1860, Vera Paz, Guatemala.
Seven subspecies recognized.
Subspecies and Distribution.
T. p. nisorius P. L. Sclater, 1870 – SC Mexico (Michoacán E to Puebla).
T. p. oaxacae Brodkorb, 1942 – S Mexico (Guerrero E to Oaxaca).
T. p. acaciarum Brodkorb, 1942 – S Mexico (Chiapas).
T. p. oblitus (van Rossem, 1934) – Pacific lowlands from E Chiapas S to W El Salvador.
T. p. pleurostictus P. L. Sclater, 1860 – E Guatemala (Zacapa).
T. p. lateralis (Dickey & van Rossem, 1927) – C & E El Salvador and SW Honduras.
T. p. ravus (Ridgway, 1903) – Pacific lowlands of Nicaragua and N Costa Rica.

Descriptive notes. 14–15 cm; 14–23·8 g. Rather distinctive wren with heavy barring on flanks. Nominate race has dull blackish-brown lores, off-white supercilium, ear-coverts with fine speckles of black and off-white; crown and nape reddish-brown, shoulders, back and rump more rufescent; primaries and secondaries reddish-brown with narrow blackish bars, some white on webs; rectrices cinnamon-brown, barred dull blackish; chin, throat and chest unmarked greyish-white; prominent black bars on chest side, becoming wider lower down and extending across lower belly; undertail-coverts barred sharply black and white; eye dark brown; bill dark brown above, bluish-tinged flesh colour below; legs light brown to horn-brown. Sexes similar. Juvenile lacks most of facial markings, has chin and throat mottled brownish, unbarred underparts pale dull buff, mottled with darker brown. Race *nisorius* is larger than nominate, with more extensive barring on underparts; *oaxacae* is very like nominate but lacking white on primary webs; *acaciarum* is more buff on belly, with heavier flank barring; *oblitus* is larger and less warmly coloured above; *lateralis* is smaller and more brightly rufescent above than previous; *ravus* is smaller than nominate, with more brightly rufescent upperparts, less prominent barring on primaries and secondaries. Voice. Song a striking and beautiful series of varied whistles and gurgled trills, in some ways reminiscent of Common Nightingale (*Luscinia megarhynchos*); calls include a harsh nasal churring and short trills.
Habitat. Generally found in rather dry habitats; arid scrub-forest and tropical deciduous forest, including second growth. In swamp-forest in El Salvador, sometimes in mangrove swamps in Honduras and Costa Rica. Sea-level to 1600 m in Mexico; to 1100 m in Honduras and 800 m in Costa Rica.
Food and Feeding. Few data on prey items; invertebrates, including spiders (Araneae), recorded. Generally forages in pairs or family groups, usually low down or on ground; also higher up in trees if ground cover sparse.
Breeding. Season May–Jul in Mexico; in S Mexico and El Salvador extending into Aug, possibly to take advantage of second-hand nests. Nest shaped like old-fashioned chemical retort, built of weed stems, rootlets and similar material, lined with finer grasses, typically hung in crotch of tree, entrance tube sloping downwards at c. 45 degrees on one side and nesting chamber on other side; usually located 1–3 m up, frequently in bull's-horn acacia (*Acacia collinsii*) harbouring aggressive symbiotic ants, or near pendent nest of hornets (Vespidae) or in irritating nettle bush (*Urtica*); old pendent nest of Yellow-olive Flycatcher (*Tolmomyias sulphurescens*) 2–10 m up near end of slender branch frequently used in El Salvador. Eggs 2–5, sometimes white, more frequently pale blue to deeper sky-blue; no information on incubation and fledging periods.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Reasonably common to abundant in much of its range.
Bibliography. Anon. (1998b), Binford (1989), Blake (1953), Blake & Hanson (1942), Brodkorb (1942), Dickey & van Rossem (1938), Friedmann *et al.* (1957), Hellmayr (1934), Howell & Webb (1995), Joyce (1990), Komar & Domínguez (2001), Land (1970), Molles & Vehrencamp (1999, 2001a), Monroe (1968), Ridgway (1904), Rowley (1966, 1984), Skutch (1940), Slud (1964, 1980), Stiles & Skutch (1989).

49. Rufous-and-white Wren



Thryothorus rufalbus

French: Troglodyte rufalbin **German**: Rotrückenzaunkönig **Spanish**: Cucarachero Rufiblanco

Taxonomy. *Thryothorus rufalbus* Lafresnaye, 1845, "Mexico"; error = Guatemala.
Sometimes considered to include *T. nicefori* as a race. Six subspecies recognized.

On following pages: 50. Niceforo's Wren (*Thryothorus nicefori*); 51. Sinaloa Wren (*Thryothorus sinaloa*); 52. Plain Wren (*Thryothorus modestus*); 53. Canebrake Wren (*Thryothorus zeledoni*); 54. Buff-breasted Wren (*Thryothorus leucotis*); 55. Superciliated Wren (*Thryothorus superciliaris*); 56. Fawn-breasted Wren (*Thryothorus guarayanus*); 57. Long-billed Wren (*Thryothorus longirostris*); 58. Grey Wren (*Thryothorus griseus*).

Subspecies and Distribution.
T. r. transfinis Friedmann, 1947 – extreme S Mexico (Chiapas).
T. r. rufalbus Lafresnaye, 1845 – highlands of Guatemala and El Salvador.
T. r. sylvus A. R. Phillips, 1986 – NW Honduras.
T. r. skutchi A. R. Phillips, 1986 – W Honduras S on Pacific slope to Panama (E to Canal Zone, also locally on Caribbean drainage).
T. r. cumanensis (Cabanis, 1861) – N Colombia and N Venezuela (Falcón E to Paría Peninsula, S to E Guárico and S Anzoátegui).
T. r. minlosi (Berlepsch, 1884) – NW Venezuela (W Zulia, and Cojedes S to S Táchira and W Apure) and E Colombia (S to Meta).

Descriptive notes. 14·5–16·5 cm; male mean 28 g, female mean 25 g. A strikingly rufous and rather large wren with conspicuous black and white facial markings. Nominate race has narrow grey-white supercilium, behind eye narrowly bordered blackish above and below; lores and post-ocular eyestripe brown, ear-coverts mottled whitish-buff and dull black; crown dark ochraceous brown, back and shoulders more rufescent, rump fox-brown; primaries and secondaries reddish-brown with blackish-brown barring; tail rufous-brown with narrow blackish bars; throat and chest off-white, chest mottled obscurely with greyish, flanks dull ochraceous brown, undertail-coverts barred blackish; eye hazel-coloured or reddish-brown; bill black above, bluish-flesh below; legs pale plumbeous grey. Sexes similar. Juvenile differs from adult in more obscure facial markings, more mottled chest, diffuse barring on undertail-coverts. Race *transfinis* has longer tail than nominate; *sylvus* is darker and redder above, with shorter, more broadly barred tail; *skutchi* is similar to previous, but with more black on side of head, paler dorsal part of tail; *cumanensis* resembles previous but paler above, whiter on chest; *minlosi* is darker above than last, with more heavily streaked ear-coverts, deeper tawny-brown flanks. VOICE. Song an almost strigid-like series of 4–5 slow, hooting whistles, often preceded and followed by a higher note, quite unlike that of any other *Thryothorus* wren; calls include a castanet-like chattering and a harsh alarm. Sexual differences studied in Costa Rica: male song has lower frequency characteristics; male sings more frequently, and male alone shows increased output at dawn; average repertoire size for male 10·8 song types, for female 8·5; most duetting results from female responding to male song.
Habitat. Mostly rather dry deciduous forest and forest edge, including plantations; less commonly in semi-humid forest. Found in gallery forest in Venezuelan *llanos*; in El Salvador, occurs in thickets of the palm *Bactris subglobosa* in non-breeding season. Mostly 300–1500 m, but down to sea-level in El Salvador in winter months.
Food and Feeding. Food mostly invertebrates, also some vegetable matter (berries). Forages low down in leaf litter and vine tangles, usually alone. During times of food scarcity, has been seen to kill nestlings of *Troglodytes musculus*, not to eat them, but apparently simply to eliminate competition for food.
Breeding. May–Jun in Costa Rica, Mar to early May in El Salvador and May–Jul in Venezuela. Nest a globular structure of grass, with downward-sloping entrance tube, frequently placed in bull's-horn acacias (*Acacia collinsii* or *A. cornigera*) hosting aggressive symbiotic ants. Eggs 2–3, rarely 4, unmarked blue-green or sky-blue; no information on incubation and fledging periods; young fed by female alone; family breaks up quite soon after fledging. Frequently parasitized by American Striped Cuckoo (*Tapera naevia*).
Movements. Largely resident; some evidence of altitudinal movement in El Salvador, where it occurs in coastal forest in the winter months but not in summer.
Status and Conservation. Not globally threatened. Generally considered to occur rather sparsely over much of its range. Does, however, show some ability to live in modified or artificial habitat, such as plantations. Present in several protected areas, including e.g. Carara Biological Reserve, in Costa Rica, Isla de Salamanca National Park, in Colombia, and Henri Pittier National Park, in Venezuela.
Bibliography. Ahumada (2001), Anon. (1998b), Blake (1953, 1962), Brenowitz & Kroodsma (1996), Carriker (1910), Chapman (1917), Dickey & van Rossem (1938), Farabaugh (1984), Freed (1987a), Friedmann & Smith (1950), Hellmayr (1934), Hilty (2003), Howell & Webb (1995), Komar & Domínguez (2001), Land (1970), Loetscher (1952), Mennill & Vehrencamp (2005), Meyer de Schauensee (1982), Monroe (1968), Morton & Farabaugh (1979), Ridgely & Tudor (1989), Ridgway (1904), Slud (1964, 1980), Stiles & Skutch (1989), Wetmore *et al.* (1984), Winnett-Murray (1987).

50. Niceforo's Wren

Thryothorus nicefori

French: Troglodyte de Niceforo **Spanish**: Cucarachero de Nicéforo
German: Niceforozaunkönig

Taxonomy. *Thryothorus nicefori* Meyer de Schauensee, 1946, San Gil, south of Bucaramanga, Santander, Colombia.
Taxonomic status uncertain, possibly a well-marked race of *T. rufalbus*; requires further study, especially of vocalizations (including alarm calls). Monotypic.
Distribution. San Gil area of Santander, in Colombia.

Descriptive notes. 14·5 cm. Has conspicuous white supercilium in front of and behind eye, contrasting with grey-brown eyestripe; ear-coverts mottled whitish-grey and dark grey-brown; crown and upperparts greyish-brown, obscurely barred darker brown, rump and lower back warmer brown, concealed white spots on feathers of lower back; primaries and secondaries rufescent brown, barred blackish; rectrices medium brown with darker bars; throat whitish, blackish malar stripe; underparts white, becoming grey on side of chest and buffy grey on flanks; eye reddish-brown; bill horn-colour above, whitish below; legs dull blue-grey. Differs from similar *T. rufalbus* in having much greyer upperparts. Sexes similar. Juvenile undescribed. VOICE. Poorly known. Song stated to be "exactly like that of *T. rufalbus*", but has also been suggested that it differs from latter's in duration.
Habitat. Dense acacia (*Acacia*) scrubland in upper tropical zone, at c. 1100 m. Appears unable to adapt to coffee plantations.
Food and Feeding. No published data.
Breeding. No information.
Movements. Presumably sedentary.
Status and Conservation. CRITICAL. Restricted-range species: present in the Colombian East Andes EBA. Seven specimens were taken in 1945, and a few more in the 1950s and 1960s. The species was not then observed until 1989, when two individuals were seen, and on two occasions in Jul 2000, when a single individual was observed, in xerophytic acacia scrub alongside the R Fonce. Suitable habitat in the vicinity of the most recent observations is estimated at no more than 1 km² in extent, and even this is in imminent danger from potential urban development. This wren seems to have very limited tolerance of habitat modification, and is absent from coffee plantations. Current remaining habitat is vulnerable to burning and to overgrazing by cattle and goats. In the absence of historical data, it is not known how extensive the original range may have been.
Bibliography. Adams *et al.* (2003), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Hilty (1985), Hilty & Brown (1986), López & Cadena (2002), Meyer de Schauensee (1946a, 1982), Negret (2001), Ridgely & Tudor (1989), Stattersfield & Capper (2000).

51. Sinaloa Wren

Thryothorus sinaloa

French: Troglodyte du Sinaloa **German**: Sinaloazaunkönig **Spanish**: Cucarachero Sinaloense
Other common names: Bar-vented Wren

Taxonomy. *Thryophilus sinaloa* S. F. Baird, 1864, Mazatlán, Sinaloa, Mexico.
Relationships with *T. rufalbus* uncertain. Three subspecies recognized.
Subspecies and Distribution.
T. s. cinereus (Brewster, 1889) – NW Mexico (NE Sonora S to N Sinaloa and W Chihuahua).
T. s. sinaloa (S. F. Baird, 1864) – C Sinaloa and adjacent W Durango S to Michoacán.
T. s. russeus (Nelson, 1903) – C Guerrero E to W Oaxaca, in S Mexico.

Descriptive notes. 12·5–14 cm; male 13·1–16·6 g, female 13·5–16·4 g. Nominate race has whitish supercilium, medium-brown lores and eyestripe, side of face and ear-coverts speckled blackish and grey-white; crown dull brown, becoming more rufous on back and, especially, on rump; primaries and secondaries rufous-brown with narrow darker barring; rectrices rufous-brown, transversely barred blackish-brown; throat and chest grey-white, chest side grey, flanks ochraceous brown, crissum whitish, strongly barred black; eye hazel-brown; bill medium horn-colour above, almost whitish below; legs pale reddish-brown. Differs from rather similar *T. felix* in having less prominent facial markings, pale brown (not warm rufous) flanks. Sexes similar. Juvenile has less distinct facial markings than adult, flanks washed with dusky. Race *cinereus* is decidedly paler and greyer than nominate; *russeus* is richer and darker in colour than nominate, with deep russet-brown back, cinnamon-rufous uppertail-coverts. VOICE. Song of male a cheerful series of clear, gurgling whistles interspersed with rapid trills, in some ways reminiscent of that of Common Nightingale (*Luscinia megarhynchos*); female song similar but shorter and more simple; unlike *T. felix*, does not sing in syncopated duets. Calls include churring notes and a loud chatter.
Habitat. Inhabits various types of open woodland, including thorn-forest, oak–hornbeam (*Quercus–Carpinus*) woods and tropical deciduous forest; often found in quite disturbed habitat. From sea-level up to 2000 m.
Food and Feeding. No recorded data on food; presumably mostly invertebrates. Forages at low or medium levels in vegetation.
Breeding. Nests in May and Jun at lower altitudes, but as late as Jul higher up; possibly double-brooded. Nest retort-shaped, usually made of grass stems, placed over branch, breeding chamber on one side and downward-pointing entrance tube on the other, typically at height of 1·3–3·5 m and frequently next to hornet nest or in acacia (*Acacia*) occupied by aggressive symbiotic ants. Eggs usually 5, unmarked bluish-white; no information on incubation and fledging periods.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common over much of its range. Frequently found in disturbed habitat.
Bibliography. Anon. (1998b), Arizmendi & Márquez (2000), Blake (1953), Brown (1977), Brown & Lennon (1979), Corcuera & Butterfield (1999), Friedmann *et al.* (1957), Grant (1966b), Hellmayr (1934), Howell & Webb (1995), Hutto (1980), Jones, R. (1998), Peterson & Navarro-Sigüenza (2000), Ridgway (1904), Ornelas *et al.* (1993), Short (1974), Stager (1954).

52. Plain Wren

Thryothorus modestus

French: Troglodyte modeste **German**: Cabaniszaunkönig **Spanish**: Cucarachero Modesto
Other common names: Cabanis's Wren, Modest Wren

Taxonomy. *Thryothorus modestus* Cabanis, 1861, San José, Costa Rica.
Frequently treated as conspecific with *T. zeledoni*, but the two differ substantially in song and plumage. Two subspecies recognized.
Subspecies and Distribution.
T. m. modestus Cabanis, 1861 – S Mexico (extreme E Oaxaca, Chiapas), C & S Guatemala, W Honduras and El Salvador S in Pacific watershed to Costa Rica.
T. m. elutus (Bangs, 1902) – Pacific drainage of Panama from about Costa Rican border to just E of Canal Zone.
Descriptive notes. 12·5–14 cm; male average 19·7 g, female average 17·9 g. A rather featureless wren, without strong facial markings or prominent barring or streaking. Nominate race has white supercilium, grey-brown lores and eyestripe; cheeks and ear-coverts mottled dark greyish-brown and grey-white; crown dark grey-brown, back rufous-brown, rump orange-rufous; primaries and secondaries warm brown with obscure darker bars; rectrices rufescent brown with narrow darker bars; throat white, chest pale greyish-buff, centre of belly buffy white, flanks, belly side and undertail-coverts warm orange-buff; eye bright reddish-brown; bill dark brown above, pale leaden-blue below; legs

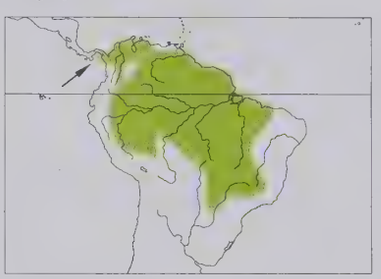
bluish-slate. Differs from *T. zeledoni* in smaller size, much warmer coloration. Sexes similar. Juvenile has dark brown eye and flesh-coloured lower mandible. Race *elutus* is duller and more pale than nominate, and has longer bill, shorter tail and yellow eyes. Voice. Song a loud motif of 3–4 clear whistles, "chin-cheer-gwee" or "chin-cheery-gwee", sometimes given entirely by male, but frequently as a perfectly timed antiphonal performance, male giving first 2 or 3 notes and female the final one; unmated male has softer, less strident song; recently fledged juvenile sings quite differently, a low diffuse rambling song reminiscent of that of Grey Catbird (*Dumetella carolinensis*). Calls include harsh "chur" and tinkling "chi-chi-chi".
Habitat. Forest edge, second growth, well-vegetated gardens, overgrown citrus plantations with epiphytes, and similar habitats, in both dry and humid areas; avoids dense wet forest. Sea-level to c. 2000 m.
Food and Feeding. Food mostly insects and spiders (Araneae); an adult seen to feed a berry to fledgling. Usually found in pairs, foraging low down in dense vegetation, occasionally higher up in trees. Has been seen to attack eggs of other species, but more probably as a means of reducing competition than for actual food.
Breeding. Season in Costa Rica very protracted, with active nests found in Jan–Sept. Nest elliptical, the short axis being horizontal, circular entrance hole facing slightly downwards and sometimes protected by short lintel, made from grasses and vegetable fibres, lined with plant down, located 0·5–3 m up in dense vegetation; dormitory nest much more flimsy, unlined. Eggs 2, rarely 3, unmarked white; incubation by female alone, period 18 days; fledging period c. 14 days or more.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Common or abundant in much of its range. Adapts well to modified and regenerating habitat.
Bibliography. Anon. (1998b), Binford (1989), Blake (1953, 1958), Carriker (1910), Dearborn (1907), Dickey & van Rossem (1938), Fleischer & Tarr (1995), Hellmayr (1934), Howell & Webb (1995), Komar & Domínguez (2001), Land (1970), Monroe (1968), Ridgely & Gwynne (1989), Ridgway (1904), Skutch (1940, 1960, 1985b), Slud (1964, 1980), Sousa *et al.* (1982), Stiles & Skutch (1989), Wetmore *et al.* (1984), Willis (1980), Willis & Eisenmann (1979), Winker *et al.* (1999), Winnett-Murray (1987).

53. Canebrake Wren

Thryothorus zeledoni

French: Troglodyte de Zeledon **German**: Zeledonzaunkönig **Spanish**: Cucarachero de Zeledón
Other common names: Zeledon's Wren

Taxonomy. *Thryophilus zeledoni* Ridgway, 1878, Talamanca, Costa Rica.
Frequently treated as a race of *T. modestus*, but the two differ substantially in plumage and song. Monotypic.
Distribution. Caribbean drainage from E & SE Nicaragua (Greytown, Los Sabalos) S to W Panama (Bocas del Toro).



Descriptive notes. 14 cm. Has white supercilium contrasting sharply with grey crown and with grey-brown eyestripe; ear-coverts mottled grey and off-white; upperparts brownish-grey, becoming olivaceous on rump; primaries and secondaries dull grey-brown with obscure darker barring; rectrices olivaceous brown with conspicuous darker bars; off-white below, becoming grey on chest and grey-buff on lower belly; eye grey-brown; bill black above, grey below; legs dark olive. Differs from somewhat similar *T. modestus* in larger size and considerably more grey coloration. Sexes similar. Juvenile has more obscure facial markings and duller underparts than adult. Voice. Sexes sing in complex duet, with three main components, each distinctive in structure: rapid and highly co-ordinated alternation of two-part phrases by female and very brief, fast, low-frequency phrases by male, the whole preceded by somewhat longer, higher-frequency phrase of 4-6 elements by male; sexes have repertoire of each of their respective components, and phrase types are specifically associated with each other to form repertoire of duet types. Very occasionally, male's introductory phrase, frequently given also as solo song, is omitted.
Habitat. Second growth, regenerating farmland and wild canebrakes; absent from virgin forest. Sea-level to about 600 m; not reaching elevations occupied by *T. modestus*.
Food and Feeding. No data on food items. Forages in lower levels of dense undergrowth.
Breeding. Following details mostly from study of ringed population (21 pairs, 11 nests located) in Costa Rica, Mar–Aug. Nest ovoid, dimensions c. 10 cm × 6·7–10·3 cm, height 16–19 cm, side entrance at top with "visor" forming slight downward-pointing tunnel, made from plant fibres, lined with seed down and feathers; built by female, taking c. 3 days; placed 0·65–1·65 m above ground across thin horizontal branch, usually in dense scrub or vine tangle; much flimsier dormitory nests also built, by both sexes. Eggs 2 or 3, clear pale blue; incubation 14 days; chicks fed by both parents, nestling period 14–15 days; young sometimes leave nest before fully able to fly, fed near nest for 2 further days, before following parents away from it. Success low: of 20 eggs laid, 11 hatched and two chicks survived to independence; predation by e.g. snakes and coatis (*Nasua narica*) thought largely responsible; nests also parasitized by Bronzed Cowbird (*Molothrus aeneus*).
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common in parts of its range. Seems to adapt well to moderately disturbed habitat.
Bibliography. Carriker (1910), Eisenmann (1957), Hellmayr (1934), Mann *et al.* (2003), Marschall-Ball & Slater (2003), Ridgely & Gwynne (1989), Slud (1964), Stiles & Skutch (1989), Wetmore *et al.* (1984).

54. Buff-breasted Wren

Thryothorus leucotis

French: Troglodyte à face pâle **Spanish**: Cucarachero Pechihabano
German: Weißohr-Zaunkönig
Other common names: Buff-bellied Wren

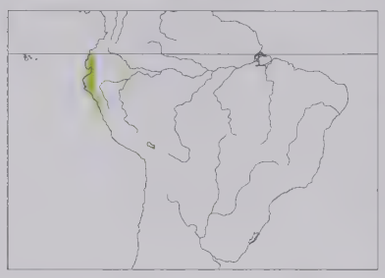
Taxonomy. *Thryothorus leucotis* Lafresnaye, 1845, Honda, River Magdalena, Tolima, Colombia.
Forms a superspecies with *T. superciliaris*, *T. guarayanus* and *T. longirostris*. Taxonomy disputed; has variously been treated as conspecific with any one of these, or all merged as a single species. In addition, race *rufiventris* has sometimes been treated as a full species. Eleven subspecies recognized.
Subspecies and Distribution.
T. l. galbraithii Lawrence, 1861 – E Panama (E from Canal Zone) and NW Colombia (Chocó, N Antioquia).
T. l. conditus (Bangs, 1903) – Coiba I and Pearl Is (Rey, San Miguel, Viveros), off S Panama.
T. l. leucotis Lafresnaye, 1845 – N Colombia from R Sinu E to Santa Marta, and S into Magdalena Valley.
T. l. collinus (Wetmore, 1946) – Serranía de Macuira, in N Guajira (N Colombia).
T. l. venezuelanus Cabanis, 1851 – N Colombia (E Santa Marta, plains of Guajira) and NW Venezuela (N & E Zulia E to Yaracuy, Cojedes and Aragua, S to Barinas).
T. l. zuliensis Hellmayr, 1934 –NW Venezuela (W Zulia S to NW Táchira and W Mérida) and adjacent Colombia (Norte de Santander).
T. l. hypoleucus (Berlepsch & Hartert, 1901) – NC Venezuela (N Apure, Guárico, S Anzoátegui, N Bolívar).
T. l. albipectus Cabanis, 1849 – NE Venezuela (SE Monagas S to N & E Bolívar), the Guianas and NE Brazil (E Amazonas E to N Maranhão, S to N Mato Grosso).
T. l. bogotensis (Hellmayr, 1901) – E Colombia and C Venezuela (S Táchira and extreme SW Barinas E to W Bolívar and Amazonas).
T. l. peruanus (Hellmayr, 1921) – lowlands of E Ecuador, SE Colombia, E Peru (S to Junín) and W Brazil (Amazonas).
T. l. rufiventris P. L. Sclater, 1870 – EC Brazil (Mato Grosso, Goiás, Minas Gerais) S to extreme E Paraguay.

Descriptive notes. 14–14·5 cm; male average 21 g, female average 18 g. Nominate race greyish lores, white supercilium, brown eyestripe, ear-coverts mottled grey-brown and whitish; crown and upperparts uniform greyish-brown, becoming warm orange-brown on rump and uppertail-coverts; upperwing-coverts greyish-brown, narrowly barred blackish; primaries and secondaries conspicuously barred buff-brown and blackish; rectrices dull reddish-brown, barred blackish; chin and throat off-white, chest buffy, belly cinnamon, becoming deep cinnamon-buff on lower flanks and vent; eye dusky brown; bill black above, whitish or bluish-flesh below; legs grey or lead-blue. Differs from *T. modestus* in more distinctly barred wings and tail, with much stronger buff colour below. Sexes similar. Juvenile resembles adult but with more diffuse facial markings. Race *venezuelanus* is less rufescent and with paler underparts than nominate; *bogotensis* resembles previous but is more rufescent on upperparts, darker on underparts; *collinus* is also similar, but darker below; *zuliensis* has more intense colour, especially on upperparts; *hypoleucus* has upperparts olivaceous rather than rufous, and pale underparts; *albipectus* has limited rufescent tone above, paler below than nominate; *peruanus* is closest to previous, but smaller, shorter-tailed, with darker upperparts, duller underparts; *rufiventris* is also similar, but with underparts deep ochraceous, bill longer; *conditus* has much plainer face, and is larger, and deeper in colour, than nominate; *galbraithii* resembles last, but paler and rather smaller. Voice. Song is a complex antiphonal production of both sexes, a series of abrupt sharp notes mixed with short clear whistles, resulting in a motif, frequently repeated, of c. 12 or more notes; juvenile male (using male song-type) sings antiphonally with the mother, female with father. Call a rapid "chit-cho-cho".
Habitat. Second growth, brush and forest edge; frequently associated with water. In Venezuela, largely confined to gallery forest in N, in *várzea* in S (Amazonas); common in mixed habitat of mangrove and flooded palm (*Manicaria*) forest in Delta Amacuro. Sea-level to 950 m in Venezuela; to 300 m in Ecuador.
Food and Feeding. Largely invertebrates; stomach contents in Suriname beetles (Coleoptera), hymenopterans, bugs (Hemiptera), lepidopterans and flies (Diptera), in Panama caterpillars, spiders (Araneae) and pseudoscorpions (Pseudoscorpiones). Usually in pairs or family parties. Forages mainly 0·2–5 m above ground, occasionally higher, more rarely on ground; often seeks food in subcanopy vines.
Breeding. Season protracted, Jan–Sept in Suriname, Jan to at least Jun in Venezuela. Co-operative breeding recorded in Panama, with small proportion of young of previous year remaining on parents' territory and at least one such bird provisioning nestlings. Nest, built by both sexes, is a globular structure of dead leaves, grass, etc., with short access tunnel to chamber; situated 1 m or more above ground, frequently in a palm; builds multiple nests. Eggs 2–3, white with small brown spots; incubation by both sexes (unusual among tropical wrens), period not recorded; no information on fledging period; fledglings remain with parents for prolonged time, and begin singing during this period. Frequently parasitized by American Striped Cuckoo (*Tapera naevia*).
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common in suitable habitat over much of its range; locally common to abundant, as, for example, in flooded palm forest mixed with mangroves in NE Venezuela (Delta Amacuro). Occurs in many protected areas, e.g. Henri Pittier National Park, in Venezuela, and Brasília National Park, Rio Cristalino Forest Reserve and Anavilhanas Ecological Station, in Brazil.
Bibliography. Ahumada (2001), Allen (1995), Anon. (1998b), Best *et al.* (1997), Chapman (1917), Dubs (1992), Eisenmann (1950), Farabaugh (1984), Friedmann (1948), Gill (2004), Gyldenstolpe (1950), Haffer (1975), Haverschmidt (1968), Haverschmidt & Mees (1994), Hellmayr (1934), Hilty (2003), Hilty & Brown (1986), Meyer de Schauensee (1982), Morton (1980), Oren & Parker (1997), Parker & Remsen (1987), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Schäfer & Phelps (1954), Sick (1993, 1997), Skutch (1968), Tostain *et al.* (1992), Wetmore *et al.* (1984), Willard *et al.* (1991), Willis & Eisenmann (1979), Wright *et al.* (1985), Zimmer *et al.* (1997).

55. Superciliated Wren

Thryothorus superciliaris

French: Troglodyte bridé **German**: Küstenzaunkönig **Spanish**: Cucarachero Cejón



Taxonomy. *Thryothorus superciliaris* Lawrence, 1869, Isla de Puná, Ecuador.

Forms a superspecies with *T. leucotis*, *T. guarayanus* and *T. longirostris*; sometimes treated as conspecific with first of those, but distinct in vocalizations and ecology. Two subspecies recognized.

Subspecies and Distribution.

T. s. superciliaris Lawrence, 1869 – W Ecuador (Manabí S to Guayas).

T. s. baroni (Hellmayr, 1902) – S Ecuador (El Oro, Loja) and W Peru (S to Ancash).

Descriptive notes. 14·5 cm. Nominate race has grey lores, prominent white supercilium, dark brown eyestripe, buffy-white ear-coverts; crown dark greyish-brown, back and shoulders rufous-brown, becoming more rufescent on rump; primaries and secondaries warm brown, blackish bars on outer webs; rectrices reddish-brown with transverse black bars; chin and throat pale buffy white, darker on lower chest, more buff-grey on flanks; eye brown; bill black above, grey below, dark tip; legs grey. Differs from *T. leucotis* in having white, not buff, chest, less well-marked ear-coverts. Sexes similar. Juvenile resembles adult, but less warm brown above, duller on crown. Race *baroni* is more rufescent than nominate, with rump and lower back brighter tawny-brown. Voice. Song a series of short repeated phrases of 2 or 3 notes, sometimes extending into longer phrases with trills, not so rich or so musical as that of *T. leucotis*; probably both sexes sing.

Habitat. Typically in dry woodland and scrub, hedgerows and brushland; less commonly in more humid woodland. Sea-level to 1500 m, locally to 1850 m.

Food and Feeding. Little information; stomach contents "insects". Usually in pairs; forages low down in vegetation, or on ground.

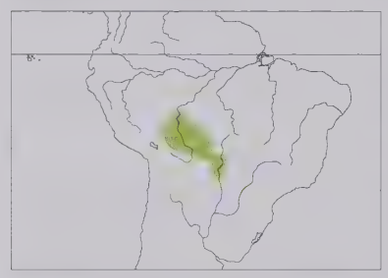
Breeding. Nests at least in Jan and Feb in Peru; may be double-brooded. Nest a retort-shaped, rather flimsy construction, lateral entrance covered by long frayed porch, egg-chamber lined with finer material and feathers, sited 1·6–3·2 m up in bush or tree, often close to wasp nest, more rarely under roof of old building; multiple nests built, only some used for breeding, others unlined. Eggs 2–3, white with slight greenish tinge; incubation period not recorded; fledging period, in nest shared with young Shiny Cowbird (*Molothrus bonariensis*), 10–13 days. Parasitism by cowbird very frequent.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. Restricted-range species: present in Tumbesian Region EBA. Quite common in some parts of range, less so in others. Seems able to tolerate moderately disturbed habitat.

Bibliography. Best & Kessler (1995), Best *et al.* (1997), Butler (1979), Clements & Shany (2001), Cracraft (1985), Hellmayr (1934), López & Gastezzi (2000), Marchant (1960), Meyer de Schauensee (1982), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Taczanowski (1884), Walker (2002).

56. **Fawn-breasted Wren**



Thryothorus guarayanus

French: Troglodyte des Guarayos **Spanish**: Cucarachero del Guarayos
German: Guarayoszaunkönig

Taxonomy. *Troglodytes guarayana* d'Orbigny and Lafresnaye, 1837, Guarayos, Santa Cruz, Bolivia.

Forms a superspecies with *T. leucotis*, *T. superciliaris* and *T. longirostris*; sometimes regarded as conspecific with first of those, although vocalizations quite distinct. Monotypic.

Distribution. Lowland areas of NE Bolivia (E Pando, E La Paz, E Cochabamba, Beni, Santa Cruz), adjacent Brazil (E Rondônia, SW Mato Grosso) and extreme NE Paraguay.

Descriptive notes. 13·5 cm; 13–14 g. Has narrow white supercilium behind eye; ear-coverts mottled grey-white and blackish; crown and upperparts unmarked medium-brown, becoming more rufescent on lower back and rump; primaries, secondaries and upperwing-coverts rufescent brown with narrow blackish bars; rectrices reddish-brown with 10–12 sharply defined black bars; chin whitish, narrow black malar stripe, blackish moustachial stripe on white background; chest warm orange-buff, belly and vent deep orange-buff; eye hazel; bill black above, lead-blue below; legs lead-blue. Distinguished from very similar *T. leucotis* by having more buff on throat, less rufescent upperparts, more strongly marked cheeks. Sexes similar. Juvenile has facial pattern less sharply demarcated than adult's. Voice. Song, given antiphonally by both sexes, male contribution a repeated series of notes, e.g. "cheerilo-choli" or faster "chililililoo", female "pew-pew, pew-pew"; more simple in form than that of *T. leucotis*. Calls include "pew-pew", often repeated, and various harsh clicking sounds.

Habitat. *Várzea* scrubland, and secondary growth, usually near water; to c. 400 m.

Food and Feeding. No published information on food items. Forages in pairs during dry season, in small family groups of up to four individuals after breeding. Seeks food from ground level to 2–4 m up, at times to 10 m, in dense creeper growth.

Breeding. Little available information; few nests described. Nest with eggs in late Jan in Bolivia. Nest a rather flimsy domed structure with side entrance, made from fine grasses and root hairs of *Cecropia* trees but no leaves, much less robustly constructed than that of *T. genibarbis*; c. 1–3 m up, sometimes above water, in weeds or bushes, or in spiny base of small palm. Eggs 2, white with fine spots around blunt end; no information on incubation and fledging periods. Sometimes parasitized by Shiny Cowbird (*Molothrus bonariensis*).

Movements. Apparently sedentary.

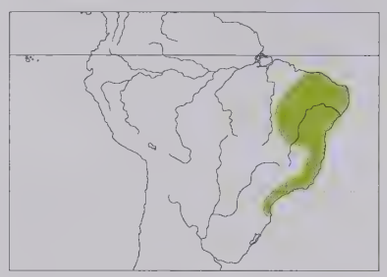
Status and Conservation. Not globally threatened. Locally common in parts of range; fairly common in E Bolivia (Santa Cruz).

Bibliography. Brace *et al.* (1997), Davis (1993), Dubs (1992), Flores, Rumiz & Cox (2001), Flores, Rumiz, Fredericksen & Fredericksen (2002), Guerrero & Arambiza (2001), Hellmayr (1934), Hennessey *et al.* (2003), Meyer de Schauensee (1982), Pearson (1975), Ridgely & Tudor (1989), Short (1975), Sick (1993, 1997).

57. **Long-billed Wren**

Thryothorus longirostris

French: Troglodyte à long bec **Spanish**: Cucarachero Piquilargo
German: Langschnabel-Zaunkönig



Taxonomy. *Thryothorus longirostris* Vieillot, 1819, Brazil.

Forms a superspecies with *T. leucotis*, *T. superciliaris* and *T. guarayanus*; treated by some authors as conspecific with first of those. Race *bahiae* possibly a separate species, differing from nominate in plumage, voice and habitat. Two subspecies recognized.

Subspecies and Distribution.

T. l. bahiae (Hellmayr, 1903) – NE Brazil, from Ceará and Piauí S to Bahia and N & E Minas Gerais.

T. l. longirostris Vieillot, 1819 – coastal region of E Brazil, from SE Bahia S to E Santa Catarina.

Descriptive notes. 19–21·5 cm; 20–21 g. Nominate race has greyish lores, off-white supercilium, medium dark brown eyestripe; ear-coverts and area under eye mottled off-white and dark grey; crown and nape rich dark brown, becoming more rufescent on lower back, where obscurely barred darker; rump reddish-brown; primaries, secondaries and tertials deep reddish-brown, narrowly barred black; rectrices reddish-brown with transverse darker bars, broader distally; chin off-white, narrow blackish malar stripe, throat pale buff to whitish (variable, lower throat sometimes as chest); chest reddish-buff, belly deep rich buff; eye brown to reddish-brown; bill blue-grey, darker or black above; legs dull grey. Differs from very similar *T. leucotis* in having longer bill and more rufescent underparts. Sexes similar. Juvenile is very like adult, but facial markings and malar stripe less well defined, eye grey, bill shorter. Race *bahiae* is somewhat paler than nominate above, especially on rump, rectrices with broader dark barring, underparts much less saturated, with whiter, less boldly streaked auriculars. Voice. Song loud and varied, by both sexes, male and female having slightly differing phrases, superimposed in duet, loud "choop-chip-chip", "chee-wah-lii", and similar; also a quieter, individual song, by both sexes but without synchronization. Songs of an individual may change during course of a day (according to popular local belief, in response to weather conditions).

Habitat. Secondary forest, shrubby clearings and forest edge, arboreal *caatinga* (deciduous forest with cacti and bromeliads), mangroves; locally common in fairly tall, dense *restinga* (white-sand vegetation near coasts). Much less closely associated with water than is *T. leucotis*. Sea-level to 900 m.

Food and Feeding. No published data on diet. Seems always to forage in pairs or singly, within 5 m of ground, more usually at less than 2 m.

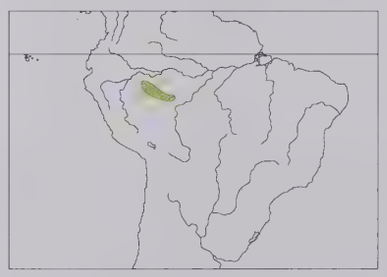
Breeding. Juveniles in Feb to late Mar, and adult male with enlarged testes in Sept, suggesting that breeding coincides with local rainy season. Nest domed, with downward-sloping entrance port; also builds simpler dormitory nests. No other information.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. Frequently common or abundant. Common in SE of range, including on offshore islands; rather rare in S (Santa Catarina). Occurs in a number of protected areas, e.g. Cavernas do Peruaçu National Park, in Minas Gerais.

Bibliography. Buzzetti (2000), Cracraft (1985), Goerck (1999), Guix *et al.* (1992), Hellmayr (1929, 1934), Hinkelmann & Fiebig (2001), Kirwan *et al.* (2004), Mallet-Rodrigues & Marinho (2003), Marsden *et al.* (2003), Meyer de Schauensee (1982), Naka *et al.* (2001), Parker & Goerck (1997), Pinto & Camargo (1961), Ridgely & Tudor (1989), do Rosário (1996), Sick (1993, 1997).

58. **Grey Wren**



Thryothorus griseus

French: Troglodyte gris **German**: Grauzaunkönig **Spanish**: Cucarachero Gris
Other common names: Amazon Wren

Taxonomy. *Thryophilus griseus* Todd, 1925, Hiutanaã, River Purús, Amazonas, Brazil.

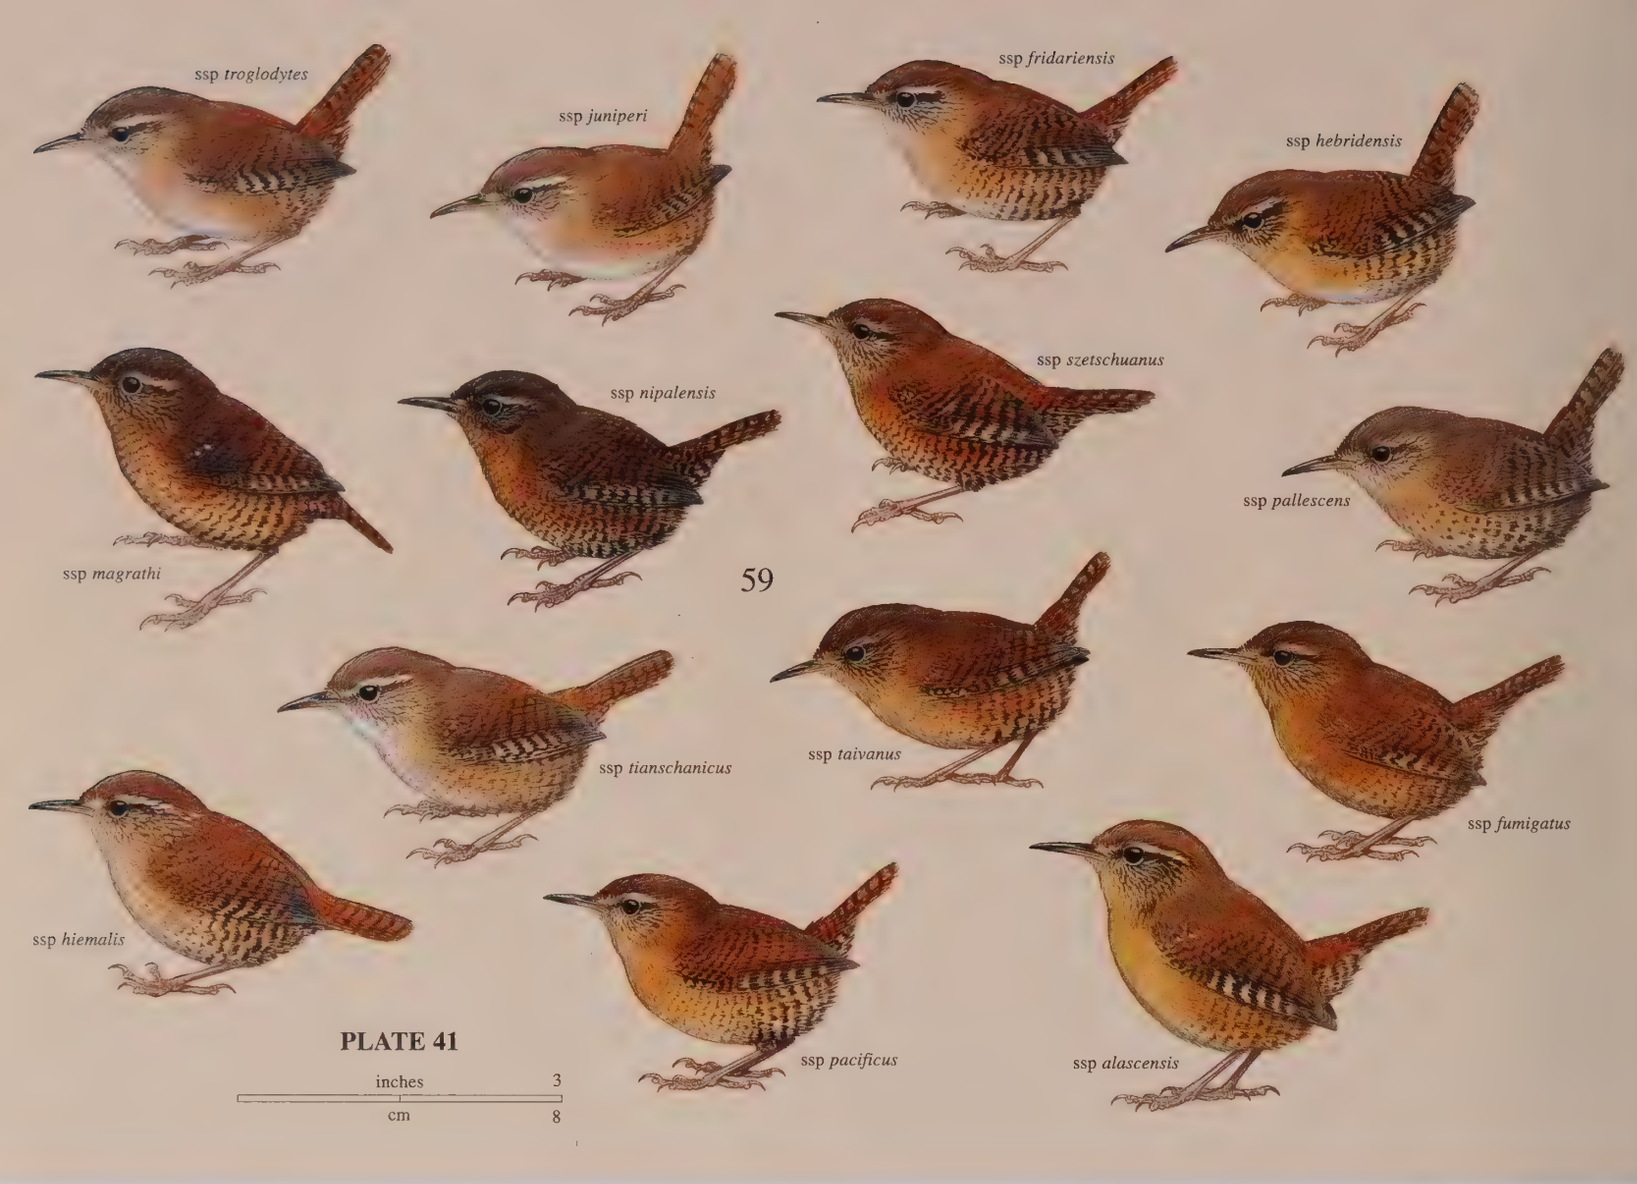
Exhibits a number of features (e.g. small size, short tail, grey plumage without prominent facial markings) that are not typical of present genus; although traditionally included here, may well merit separate generic status. Study of its breeding biology and social structure, virtually nothing of which is known, could shed light on its true taxonomic status. Monotypic.

Distribution. SW Amazonas (along R Javari, upper R Juruá, upper R Purús), in W Brazil.

Descriptive notes. 11·5 cm. Has inconspicuous whitish eyestripe, grey ear-coverts obscurely mottled darker; crown and upperparts uniform unmarked lead-grey; primaries and secondaries blackish-grey on inner webs, outer webs dull lead-grey with very obscure dark bars; rectrices dull grey with broad blackish bars; chin and throat whitish-grey, chest grey, lower belly slightly buff-grey; eye brown; bill blackish above, dull horn below; legs dull blue-grey. Sexes similar. Juvenile undescribed. Voice. Song a repeated phrase of 2 or 3 notes, "chu-choww" or "chippit, chippit", becoming louder with repetition, simpler in form than is typical for this genus; whether both sexes sing is not known.

Habitat. Tangled undergrowth at edge of *várzea* and overgrown clearings; to 200 m.

Food and Feeding. No published data on food items. Usually forages in pairs or family parties in tangled undergrowth.



Breeding. No information.

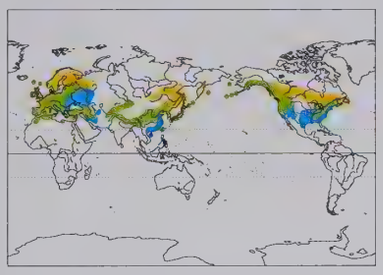
Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. Poorly known; apparently quite common in some locations within its limited range. Requires much further study.

Bibliography. Cracraft (1985), Gyldenstolpe (1950), Hellmayr (1934), Meyer de Schauensee (1982), Ridgely & Tudor (1989), Sick (1993, 1997), Zimmer & Mayr (1943).

PLATE 41 ➤

Genus *TROGLODYTES* Vieillot, 1809



59. **Northern Wren**

Troglodytes troglodytes

French: Troglodyte mignon **German**: Zaunkönig **Spanish**: Chochín Común
Other common names: Wren, Common/Holarctic Wren; Winter Wren (America)

Taxonomy. *Motacilla Troglodytes* Linnaeus, 1758, Sweden.
It has been proposed, on the basis of DNA analysis, that this species is sufficiently distinct from its congeners (all confined to New World) to warrant placement in its own monotypic genus, for which the name *Nannus* is available. Recent DNA work suggests that it contains six distinct clades, in, respectively, W Nearctic, E Nearctic, Europe, E Asia, Nepal, and Caucasus, indicating cryptic speciation. Also, vocal differences exist between birds in W Nearctic and those in E, and both differ also from Old World birds, suggesting that at least three species may be involved. Numerous races of doubtful validity have been described. Race *orii* (Daito Is, in Japan) extinct. Forty-four extant subspecies recognized.
Subspecies and Distribution.
T. t. islandicus Hartert, 1907 – Iceland.
T. t. borealis Fischer, 1861 – Faroe Is.
T. t. zetlandicus Hartert, 1910 – Shetland Is.
T. t. fridariensis Williamson, 1951 – Fair I (S of Shetland Is).
T. t. hirtensis Seebohm, 1884 – St Kilda, in Outer Hebrides, off W Scotland.
T. t. hebridensis Meinertzhagen, 1924 – Outer Hebrides (except St Kilda).
T. t. indigenus Clancey, 1937 – Britain (except Shetland Is and Outer Hebrides) and Ireland.
T. t. troglodytes (Linnaeus, 1758) – much of mainland Europe, from Scandinavia E to Urals, S to Iberia, Italy and Greece.
T. t. kabylorum Hartert, 1910 – Balearic Is and N Africa (Morocco E to Tunisia), perhaps also S Spain.
T. t. koenigi Schiebel, 1910 – Corsica and Sardinia.
T. t. juniperi Hartert, 1922 – NE Libya (from about Tocra Pass E to Darnah).
T. t. cypriotes (Bate, 1903) – Cyprus and N Middle East (S to N Israel).
T. t. hyrcanus Zarudny & Loudon, 1905 – Crimea, Caucasus, N Turkey and N Iran.
T. t. zagrossiensis Zarudny & Loudon, 1908 – W Iran (Zagros Mts).
T. t. tianschanicus Sharpe, 1882 – mountains from Tien Shan (possibly from Altai) S to Pamir and NE Afghanistan.
T. t. subpallidus Zarudny & Loudon, 1905 – NE Iran E to S Uzbekistan and NW Afghanistan.
T. t. magrathi (Whitehead, 1907) – SE Afghanistan and adjacent W Pakistan.
T. t. neglectus W. E. Brooks, 1872 – W Himalayas (Gilgit E to W Nepal).
T. t. nipalensis Blyth, 1845 – C & E Himalayas (Nepal E to NE India and S Tibet).
T. t. idius (Richmond, 1907) – NC China (NE Qinghai and Gansu E to Hebei).
T. t. szetschuanus Hartert, 1910 – WC China (E Xizang, SE Qinghai, W Sichuan).
T. t. talifuensis (Sharpe, 1902) – S China (S Sichuan, N Yunnan) and NE Myanmar.
T. t. dauricus Dybowski & Taczanowski, 1884 – SE Siberia, NE China, Korea, and Tsushima I (SW Japan).
T. t. pallescens (Ridgway, 1883) – Kamchatka Peninsula and Commander Is.
T. t. kurilensis Stejneger, 1889 – N Kuril Is.
T. t. fumigatus Temminck, 1835 – S Kuril Is, Sakhalin, and Japan (including islands of Quelpart and Iki).
T. t. mosukei Momiyama, 1923 – Izu Is, off SE Honshu (Japan).
T. t. ogawae Hartert, 1910 – Tanegashima and Yakushima islands, off S Kyushu (Japan).
T. t. taivanus Hartert, 1910 – Taiwan.
T. t. alascensis S. F. Baird, 1869 – Pribilof Is (St George, St Paul, Otter).
T. t. meligerus (Oberholser, 1900) – W Aleutian Is (Attu, Buldir).
T. t. kiskensis (Oberholser, 1919) – W Aleutians (Kiska, Little Kiska, Amchitka, Oglinga).
T. t. tanagensis (Oberholser, 1919) – WC Aleutians (Tanaga, Adak, Atka).
T. t. seguamensis Gabrielson & Lincoln, 1951 – C Aleutians (Seguam, Amutka, Yunaska).
T. t. petrophilus (Oberholser, 1919) – Unalaska, in E Aleutians.
T. t. stevensoni (Oberholser, 1930) – W Alaska Peninsula, including Amak I and Amagat I.
T. t. ochroleucus Rea, 1986 – islands of Baranoff, Admiralty, Chichagof, Mitkof and Kupreanof, off S Alaska Peninsula.
T. t. semidiensis (Brooks, 1915) – Semidi Is, off S Alaska Peninsula.
T. t. helleri (Osgood, 1901) – Kodiak I and Afognak I, off S Alaska.
T. t. pacificus S. F. Baird, 1864 – breeds W North America from SE Alaska, SW Yukon, British Columbia and SW Alberta S in USA to Oregon; non-breeding S to Arizona and S California.
T. t. muiri Rea, 1986 – coastal W USA from SW Oregon S to C California.

T. t. obscurior Rea, 1986 – interior W USA from Oregon (S from Cascades) S to EC California (also on C coast S from San Francisco Bay) and Nevada.
T. t. hiemalis Vieillot, 1819 – breeds E North America from C Canada E to Newfoundland and in NE USA (Wisconsin E to New York and Pennsylvania); non-breeding from S Canada (S Ontario) S to Texas and Florida, rarely to NE Mexico.
T. t. pullus (Burleigh, 1935) – breeds in Appalachians (from Virginia and West Virginia S to Georgia); non-breeding range not known.

Descriptive notes. 9–10 cm; 6–12 g. Nominate race has pale buff supercilium, brown lores and ear-coverts, spotted off-white; crown dark brown, back warmer brown, rump more rufous-brown; shoulders and upperwing-coverts rufous-brown with darker barring; primaries and secondaries brown, barred darker; rectrices warm brown with dark transverse bars; chin and throat pale buff-brown, centre of throat sometimes whiter; chest and belly warmer rufous-brown, central belly uniform buff-white, flanks darker rufous-brown, blackish barring on lower flanks; eye brown; bill brown, pale base; legs light brown. Differs from e.g. *T. aedon* (the most widely distributed sympatric species) in smaller size, shorter tail, and generally darker and more rufous coloration, especially below. Sexes similar. Juvenile has indistinctly mottled breast, more obscure barring on flanks. Races differ mainly in size, general coloration, and extent of barring, and American races fall into three broad groups (large, long-billed and pale birds in Alaska and islands, small, short-billed and dark-coloured W races, and medium, reddish-brown birds with pale throat in E): *islandicus* is substantially larger than nominate, bill heavier, generally darker brown, barring more pronounced, especially below; *indigenus* is darker, duller and less rufous than nominate; *hirtensis* is similar to previous but larger, more grey-brown above, pale and well barred below; *zetlandicus* is much darker above and below than previous, more rufous-brown; *fridariensis* resembles last but paler above and below; *borealis* is also paler, and more heavily barred; *hebridensis* is more buffy, less heavily barred and with less stout bill; *koenigi* is darker, more earth-brown and less rufous, than nominate; *kabylorum* is paler above and below than nominate; *juniperi* is like previous, but bill longer, feet dark-coloured; *cypriotes* is more extensively barred below than last; *hyrcanus* is more greyish-brown than nominate, with pale throat, more extensively barred underparts; *zagrossiensis* resembles previous but paler; *tianschanicus* is also paler and greyer, and with fainter barring; *pallescens* is dull and grey, with long bill; *kurilensis* is darker than last; *fumigatus* has shorter bill than previous; *mosukei* is similar to previous, but darker and more reddish-brown; *ogawae* is darker, duller and more sooty; *taivanus* is greyer and less rufous than last; *magrathi* has dense barring extending over mantle and breast; *neglectus* is similar to previous but darker, with smoky-brown throat; *subpallidus* differs from last in paler coloration; *nipalensis* differs in having still darker plumage; *talifuensis* differs in paler plumage with reduced barring; *szetschuanus* is more olive than previous, with heavier barring; *idius* is smaller and greyer than previous; *dauricus* is similar to last but darker; *seguamensis* is paler and greyer than other Aleutian races, with little or no rufescence on breast and belly; *meligerus* is large, with dull dark, dusky brown upperparts; *kiskensis* is similar to previous, but lighter and less rufescent above; *tanagensis* is longer-winged, and lighter and less rufescent above, than last; *alascensis* is large, bill medium length, throat and breast medium brown; *petrophilus* is like previous but sooty greyish below; *stevensoni* is similar to previous, but underparts still more sooty grey; *semidiensis* is also similar, but with darker and more grey upperparts; *ochroleucus* is rather small and pale (less rufous than *pacificus*), with lighter flanks; *helleri* has longer bill, upperparts medium-brown; *pacificus* has short bill, rufous-brown throat, dark rufous-brown upperparts; *obscurior* is darker and less rufescent than previous; *muiri* is small and pale, with fewer vermiculations than other W American races; *hiemalis* is more reddish-buff than nominate and with heavier flank barring; *pullus* is more reddish above than last, and has shorter bill. Voice. Male has remarkable song, long and complex, a series of tinkling trills one after the other for seconds on end; female not known to sing. In North America two different singers, those in E with simpler songs and smaller repertoires than those in W (non-learnt calls also differ between East and West); also, races in Old World sing differently from those in America. Calls include various sharp "tac" notes and loud churrs; in America, sharp, high-pitched note in W but lower-pitched, richer note in E.

Habitat. Very varied. In North America, breeds primarily in boreal moist coniferous forest with extensive understorey; also on offshore islands with very stunted vegetation. In Old World more catholic in habitat selection, but still almost exclusively in damp situations; in W Europe, commonest in deciduous and mixed woodland, well-vegetated suburbs, urban parks and gardens, moorland scrub, and offshore islands with very scanty cover. In some parts of range more restricted; e.g. in N Africa found mostly in forested stream valleys at elevations of 1200–1800 m. From sea-level to above-tree-line; to 4575 m in Himalayas.

Food and Feeding. Bulk of food invertebrates; arthropods, including spiders (Araneae), beetles (Coleoptera), earwigs (Dermaptera), orthopterans, etc. Also small invertebrates, such as small fish, tadpoles and young frogs. Some vegetable matter, including various berries and some seeds; sometimes seaweed. Usually forages low in vegetation, singly or in pairs; will also flycatch, and has been seen to wade in shallow water, immersing head in search of prey. Recorded also as associating with foraging badgers (*Meles meles*), capturing prey disturbed by them.

Breeding. Egg-laying from late Mar or early Apr in W Europe, a week or more later in C Europe, early Apr to May in Cyprus, and second half May in European Russia; in Canada, from mid-May to mid-Jun in Ontario, late Jun in Labrador; from late May to Jul in Alaska; usually double-brooded in Britain, double-brooded in Israel, and two or sometimes three broods in W North America. Polygamy quite frequent in some W European populations; apparently less so in America, but in one Alaskan study (of race *pacificus*) majority of males nested polygynously at one site with abundant food resources, whereas polygyny was rare at others. Nest domed, with side entrance hole, made of grass and fibres (often wet when placed in position, giving very tight structure on drying), average dimensions c. 11·3 cm high, 13 cm wide and 14·5 cm deep, internal chamber 6·2 cm in diameter and 5·6 cm high; male builds surplus nests, female selects the one to be used and adds lining herself; located in variety of sites, frequently in dense vegetation but also in cavity or crevice, often artificial, as well as odd sites such as pocket of a hanging coat, in rocky locations often in crevice in rock face, on St Kilda (race *hirtensis*) often in crevice in ruin; usually low down, although race *pacificus* in SE Alaska occasionally as high as 18 m in moss-covered tree in response to heavy predation by American red squirrels (*Tamiasciurus hudsonicus*); nest may be reused in subsequent years, sometimes by individuals other than original builders. Clutch 3–9 eggs, usually 5–8, larger clutches (of up to 17) probably the result of two females laying in one nest, island races tend to lay smaller clutches; eggs clear white, spotted with pale brown or reddish-brown, especially around blunt end, more rarely almost immaculate, race *meligerus* (W Aleutian Is) pure unspotted white; incubation by female alone, period c. 16 days; young fed by both parents, brooded only by female, nestling period 14–19 days, average c. 17 days; fledglings cared for for a further 9–18 days before becoming totally independent. Nests parasitized only rarely, by cuckoos (*Cuculus*) in Old World and Brown-headed Cowbird (*Molothrus ater*) in America.

Movements. Resident, migratory and partially migratory. Movements nocturnal. In Britain and Ireland largely sedentary, with most ringing recoveries showing movements of 50 km or less, although several recoveries from S coast into C & S France; races on offshore islands in Britain largely sedentary, but one record of *zetlandicus* from mainland Scotland (Aberdeenshire). N populations in continental Europe highly migratory; individuals ringed in Norway, in Sweden and on E Baltic coast recovered in, respectively, Belgium and Germany, S Spain, and SW France; largely absent from Scandinavia and N European Russia in winter. Farther S in Europe, movements seem to be mostly altitudinal in nature. In E Asia, breeding areas in E Siberia, Kamchatka and Sakhalin vacated in winter, but island populations appear to be sedentary; in C Asia most movements altitudinal, although detailed data lacking. Most North American populations migratory, and majority of breeding range in E & C parts of the continent, as far W as interior British Columbia, vacated in winter, non-breeding range of E populations reaching as far S as NE Mexico; apparently sedentary in coastal W North America and island groups of Alaska, with some altitudinal movement in mountains; no very informative ringing recoveries in North America.

Status and Conservation. Not globally threatened. Common or abundant over much of range. European population estimated at 20,500,000–26,500,000 pairs, of which at least 7,000,000 in UK. Some island populations may be very small; for example, totals of singing males of *fridariensis* on Fair Isle (7·6 km²) have oscillated between ten and 50. Designation of St Kilda race *hirtensis* as a separate species in 1884 led to a frenzy of collecting activity, although this did not, in all likelihood, put the race in serious danger; it currently numbers 200–300 pairs. Estimates of *borealis* (Faroe Is) are in the region of 250–500 pairs. No recent published population estimates for isolated Aleutian races. In Japan, race *mosukei* (Izu Is) is listed as Endangered, and *orii* (Daito Is) has recently become extinct. Generally, a highly successful species. Has great ability, especially in Europe, to adapt to modified habitat, and at peaks of abundance may be one of the three commonest species in Britain. Hard winters with prolonged snow cover can cause catastrophic declines in numbers in non-migratory populations, but these normally very temporary, and recovery typically very swift.

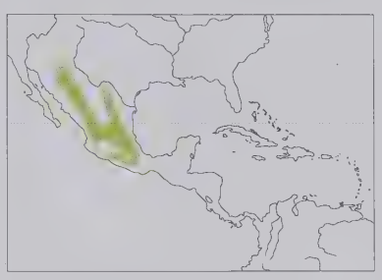
60. Northern House Wren

Troglodytes aedon

French: Troglodyte familier **German**: Nördlicher Hauszaunkönig **Spanish**: Chochín Criollo
Other common names: House Wren (when combined with other members of superspecies)

Taxonomy. *Troglodytes aëdon* Vieillot 1809, "North America" = New York City, USA.
Forms a superspecies with *T. brunneicollis*, *T. musculus*, *T. tanneri*, *T. beani* and *T. cobbi*; all have often been treated as conspecific, as suggested by field observations, but recent DNA analyses indicate that present species and first two are three separate species; the others, isolated on islands, likely also to be distinct. Intergrades with *T. brunneicollis* in S Arizona. Birds breeding in E part of range (from Michigan and Quebec S to Kentucky and West Virginia) described as race *baldwini*, but poorly differentiated from, and therefore merged with, nominate. Species name *domesticus* has priority, but use of *aedon* almost universal; this has led to the proposal that the name *domesticus* be officially suppressed in order to favour stability in nomenclature. Two subspecies recognized.
Subspecies and Distribution.
T. a. parkmanii Audubon, 1839 – breeds S Canada (British Columbia E to W Ontario) S to extreme NW Mexico (N Baja California) and in USA to W Texas and W Kentucky; non-breeding from SW & S USA (California and Texas) S to S Mexico (S to Oaxaca).
T. a. aedon Vieillot, 1809 – breeds SE Canada (Ontario E to S Quebec) and S in USA to Kentucky and Virginia; non-breeding SE USA (Carolinas S to Texas) and NE Mexico.



Descriptive notes. 11·5–12·5 cm; 8·9–14·2 g. Nominate race variable: side of face grey-brown, obscurely mottled; crown and upperparts medium brown to grey-brown, becoming warmer brown on back and rump, with obscure darker bars; primaries and secondaries barred buff and dark brown on outer webs, tertials with barring across both webs; rectrices rufescent brown, narrowly barred dark brown; throat and chest buffy white to greyish-white, lower underparts more rufous-buff to greyish-buff, belly greyish-white, undertail-coverts barred off-white and dark brown; eye brown; bill dusky brown above, pale horn below; legs dark brown. Sexes similar. Juvenile has dusky mottling on breast, indistinct barring on flanks. Race *parkmanii* is larger, paler and greyer than nominate. Voice. Male has large repertoire of songs, each a bubbling, cascading series of complex phrases, given especially persistently both by unmated male and by already mated male attempting to attract additional female to nest-site; female also sings, usually a shorter sequence, occasionally identical to male. Various low short calls, churrs and rattling notes, also high squeaky calls.
Habitat. Quite varied. Generally semi-open country, including forest edge, second growth, abandoned farmland, orchards and well-vegetated suburban areas; in open woodland, both deciduous and coniferous, in W of range. Sea-level to 3000 m.
Food and Feeding. Food predominantly invertebrates, including bugs (Hemiptera), caterpillars, grasshoppers (Orthoptera), beetles (Coleoptera), spiders (Araneae) and others; vegetable matter only a minor component (2% of diet). Forages generally low down in tangled vegetation. Frequently destroys eggs of other species, especially cavity-nesters (occasionally to extent that it may be a limiting factor on populations of the victimized species), but appears not to eat these eggs routinely.
Breeding. Season May–Aug; single-brooded at N edges of range and at higher altitudes, two broods, occasionally three, farther S. Generally monogamous, but in some populations significant amount of polygamy, especially when surplus nest-sites available; although secondary females less successful than those in monogamous pairing, some females seem preferentially to choose already mated males. Cavity-nester; nest base built by male, of coarse twigs, on which female builds cup lined with hair, wool and feathers, usually filling cavity almost to the top; natural sites include woodpecker (Picidae) hole, cavity in tree, disused hanging nest of Northern Oriole (*Icterus galbula*), mud nest of Cliff Swallow (*Petrochelidon pyrrhonota*), burrow of Belted Kingfisher (*Megaceryle alcyon*) and base of Osprey (*Pandion haliaetus*) nest, but in many areas majority are in artificial sites, including nestboxes and other cavities; male builds surplus nests, not used for breeding. Eggs 4–8, rarely 3–10, white, pinkish or greyish-white with small reddish-brown or lavender spots and blotches; incubation by female alone, period 12–14 days; chicks fed by both sexes, nestling period 16–18 days; young cared for by parents for up to 13 days after fledging.
Movements. Migratory; occurs throughout year only in extreme SW of breeding range (S California). Ringing returns indicate that those breeding in Ontario and E USA migrate SW & S to wintering areas in S states from Texas E to Georgia and N Florida (those from E seaboard move S to Florida), whereas birds breeding in Prairie Provinces and Great Plains tend to have a more SE displacement in winter; no recoveries of any significance involving birds from Pacific drainage. Nocturnal migrant; leaves non-breeding grounds in late Apr or early May, earlier in S Mexico, and arrives at N limits of breeding area by mid-May. Recorded as vagrant in Cuba.
Status and Conservation. Not globally threatened. Abundant in much of its range. Breeding Bird Surveys over the last 30 years indicate a steady increase in population of c. 1·6% per annum. Has clearly benefited from many man-made habitat changes, from the clearing of forest for agriculture to the provision, either deliberately or inadvertently, of nest-sites. Has expanded its range historically; for example, colonized West Virginia in late 19th century and South Carolina by 1940s.

61. Brown-throated Wren

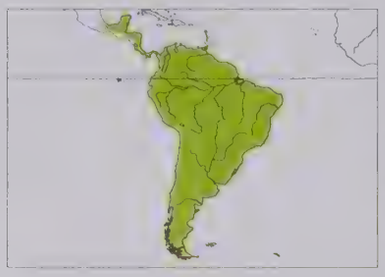
Troglodytes brunneicollis

French: Troglodyte à gorge brune **German**: Fahlkehl-Zaunkönig **Spanish**: Chochín Gorgicafé
Other common names: Brown-throated House Wren

Taxonomy. *Troglodytes brunneicollis* P. L. Sclater, 1858, La Parada, six leagues [c. 25-30 km] from Oaxaca city, Mexico.
Forms a superspecies with *T. aedon*, *T. musculus*, *T. tanneri*, *T. beani* and *T. cobbi*; all have often been treated as conspecific, as suggested by field observations, but recent DNA analyses indicate that present species and first two are three separate species; the others, isolated on islands, likely also to be distinct. Intergrades with *T. aedon* in S Arizona. Birds from NC Mexico were separated as race *compositus*, but apparently on basis of merely individual variation. Three subspecies recognized.
Subspecies and Distribution.
T. b. cahooni Brewster, 1888 – S USA (S Arizona) and C Mexico (S to Zacatecas and Michoacán).
T. b. brunneicollis P. L. Sclater, 1858 – E Mexico from San Luis Potosí and Hidalgo S to Oaxaca.
T. b. nitidus Nelson, 1903 – Mt Zempoaltepec, in Oaxaca.

Descriptive notes. 11·5–12·5 cm; 9·7–11·8 g. Nominate race has buff supercilium, ear-coverts mottled grey-brown; dark greyish-brown crown, warmer brown back and rump with obscure darker barring; primaries and secondaries barred medium brown and blackish-brown, rectrices warm brown with narrow darker bars; chin and throat grey-brown mottled greyish-buff, chest warm buff-brown, flanks rufous-brown with dark bars, belly whitish; eye dark brown; bill blackish-brown above, paler brown below, legs brown. Distinguished from very similar *T. aedon* by buff supercilium, more buffy underparts. Sexes similar. Juvenile similar to adult but more uniform below, with only faint dark markings. Race *cahooni* is greyer above and paler below than nominate; *nitidus* is deeper in colour than nominate. Voice. Song a bubbling, cascading series of trills and rattles, very similar to that of *T. aedon*, sometimes with initial high trill; also a bright springy trill, reminiscent of that of *Salpinctes obsoletus*.
Habitat. Open mountain forests and forest edge of various types, in N of range including ponderosa pine (*Pinus ponderosa*) woodland; pine–oak (*Pinus–Quercus*) forest in much of range. 1600–3000 m.
Food and Feeding. No published data on food items. Generally forages low down in vegetation.
Breeding. Very little documented. Nest a stick base and a cup of finer material, built in cavity in tree such as sycamore (*Platanus*) or oak. No information on clutch size; eggs white or greyish-white with blotches and speckles of brown or reddish-brown, identical to those of *T. aedon* (despite some published statements to the contrary). No other information.
Movements. Apparently sedentary; possibly some minor altitudinal movements in N of range.
Status and Conservation. Not globally threatened. Abundant in many parts of its range. Can tolerate some disturbance of habitat, provided that substantial cover allowed to remain.
Bibliography. Binford (1989), Blake (1953), Blake & Hanson (1942), Brumfield & Capparella (1996), Burleigh & Lowery (1942), Hellmayr (1934), Howell & Webb (1995), Lanyon (1960), Marshall (1956), Oberholser (1904), Phillips *et al.* (1964), Rice *et al.* (1999), Ridgway (1904), Rogers (1981), Rowley (1966), Russell & Monson (1998), Sousa *et al.* (1982), Udvardy (1963), Urban (1959), Young (1994b).

62. Southern House Wren



Troglodytes musculus

French: Troglodyte austral **German**: Südlicher Hauszaunkönig **Spanish**: Chochín Ratón
Other common names: House Wren (when combined with other members of superspecies); Antillean House Wren ("*martinicensis* group")

Taxonomy. *Troglodytes musculus* J. F. Naumann, 1823, Bahia, Brazil.
Forms a superspecies with *T. aedon*, *T. brunneicollis*, *T. tanneri*, *T. beani* and *T. cobbi*; all have often been treated as conspecific, as suggested by field observations, but recent DNA analyses indicate that present species and first two are three separate species; the others, isolated on islands, likely also to be distinct. The six Lesser Antilles races of present species (the "*martinicensis*" group) possibly warrant separation as an additional full species. Race *martinicensis* (Martinique) presumed extinct. Twenty-five extant subspecies recognized.
Subspecies and Distribution.
T. m. intermedius Cabanis, 1861 – S Mexico (SE Oaxaca, Tabasco) S to C Costa Rica.
T. m. inquietus S. F. Baird, 1864 – extreme SW Costa Rica and Panama (E to Darién).
T. m. carychrous Wetmore, 1957 – Coiba I, off S Panama.
T. m. pallidipes A. R. Phillips, 1986 – Pearl Is (San Jose and Pedro González, possibly also Bayoneta and Santelmo), off SE Panama.
T. m. guadeloupensis (Cory, 1886) – Guadeloupe, in N Lesser Antilles.
T. m. rufescens (Lawrence, 1877) – Dominica.
T. m. mesoleucus (P. L. Sclater, 1876) – St Lucia.
T. m. musicus (Lawrence, 1878) – St Vincent.
T. m. grenadensis (Lawrence, 1878) – Grenada, in S Lesser Antilles.
T. m. tobagensis Lawrence, 1888 – Tobago.
T. m. atopus Oberholser, 1904 – N Colombia.
T. m. effutitus Wetmore, 1958 – NE Colombia (Guajira Peninsula and extreme NE Magdalena).
T. m. striatulus (Lafresnaye, 1845) – W & C Colombia and W Venezuela.
T. m. columbae Stone, 1899 – E Andes in Venezuela and Colombia.
T. m. clarus Berlepsch & Hartert, 1902 – Venezuela (except W), Trinidad, the Guianas and E Colombia S to NE Peru and N & W Brazil.

On following pages: 63. Clarion Wren (*Troglodytes tanneri*); 64. Cozumel Wren (*Troglodytes beani*); 65. Cobb's Wren (*Troglodytes cobbi*).

T. m. albicans Berlepsch & Taczanowski, 1884 – SW Colombia and W Ecuador.
T. m. musculus J. F. Naumann, 1823 – C, E & S Brazil (S to Mato Grosso), E Paraguay & NE Argentina (Misiones).
T. m. bonariae Hellmayr, 1919 – NE Argentina, Uruguay and extreme SE Brazil.
T. m. puna Berlepsch & Stolzmann, 1896 – N & E Peru and NW Bolivia.
T. m. audax Tschudi, 1844 – arid W coast of Peru (from Trujillo S to Pisco).
T. m. carabayae Chapman & Griscom, 1924 – C & S Peru (Junín S to Puno).
T. m. tecellatus d'Orbigny & Lafresnaye, 1837 – extreme SW Peru and N Chile (Lluta Valley).
T. m. rex Berlepsch & Leverkühn, 1890 – C & E Bolivia, N Argentina and W Paraguay.
T. m. atacamensis Hellmayr, 1924 – N Chile.
T. m. chilensis Lesson, 1830 – from C Chile (S from Aconcagua) and C Argentina S to Tierra del Fuego.

Descriptive notes. 11·5–12·5 cm ; c. 12 g. Nominate race has lores and ear-coverts grey-brown, obscure postocular supercilium paler grey-brown; crown greyish-brown, back warmer brown, rump rufous-brown; shoulders, upperwing-coverts and tertials rufous-brown with darker transverse bars; primaries and secondaries barred with warm buff-brown and darker brown; rectrices rufous-brown with narrow darker bars; chin, throat and chest pale buffish-brown, flanks warmer buff-brown; eye brown; bill dark brown, paler base; legs brown or pinkish-brown. Sexes similar. Juvenile has conspicuous darker scalloping on underparts from chin to belly. Race *puna* is larger than nominate, with deeper cinnamon-buff underparts; *clarus* has paler underparts than nominate; *tobagensis* is similar to previous but with longer wings, heavier bill, whiter underparts; *carabayae* is also similar, but back has distinct narrow darker bars, underparts buffer; *striatulus* is larger and more greyish-brown than nominate, more whitish below; *atopus* is similar to previous but deeper ochraceous below; *effutitus* resembles last, but paler above and below, more greyish-brown on back, lighter brown rump and uppertail-coverts; *albicans* is smaller, with warmer rufous upperparts, sandy-coloured underparts; *columbae* has darker greyish-brown upperparts finely barred dusky, darker underparts; *audax* is warm rufous above, most like *albicans* but with longer tail, more uniformly ochraceous underparts; *tecellatus* is similar to previous, but more greyish above, distinct broad blackish bars on back; *bonariae* is brownish-grey above with faint darker barring on back, while rump and tail less rufescent than in most other races, pale isabelline on most of underparts, with barring restricted to undertail-coverts; *chilensis* has paler upperparts than previous; *atacamensis* is very similar to previous, but with longer and more slender bill, paler upperparts without bars; *rex* is also similar, but with longer and heavier bill, brighter isabelline underparts; *intermedius* differs from nominate in having ventral surface uniform deep cinnamon-buff; *carychrous* is overall brighter in colour than previous; *inquietus* is larger, less buff below and more grey above; *pallidipes* is similar to last, but more rufescent on flanks and rump; *mesoleucus* has strong rufescent tinge above, white underparts; *musicus* is larger than previous, more rust-coloured above, back with obscure darker bars; *guadeloupensis* is smaller and more rufous above than last; *grenadensis* is closest to previous but larger and paler, with no bars on back; *rufescens* resembles last, but overall much darker, crissum with dark bars. Voice. Male song a rather variable series of rapid notes, sometimes preceded by slower warbling sequence, resembles that of *T. aedon*; in S parts of range tends to conclude with a series of harsh rising notes. Female song distinct, a low, rapid twittering, at times followed by high clear trill. Call (at least in Ecuador) a nasal "jeeyah", differing from that of *T. aedon*; alarm calls also differ from latter's.

Habitat. Very varied; generally, in open or semi-open bushland, forest edge and clearings, abandoned farmland, hedgerows, scrub, around settlements and in well-vegetated suburban areas. Generally absent from unbroken forest, but rapidly colonizes rough clearings. From sea-level up to 4000 m.

Food and Feeding. Food seems to consist largely or entirely of invertebrates; observed prey items include caterpillars, spiders (Araneae), crickets and grasshoppers (Orthoptera), cockroaches (Blattodea), bugs (Hemiptera) and wasps (Hymenoptera). Generally forages low down in tangled vegetation; will also examine lower levels of tree trunks in manner of a woodcreeper (Dendrocolaptidae).

Breeding. Season very protracted in tropical parts of range, in every month except Oct and Nov in Costa Rica, more or less throughout year in Suriname (peaks in Jan and Jul) and Trinidad (peak May); austral spring in temperate South America, e.g. in Oct and Nov in Uruguay, and in Chile from Aug in N and from Sept in S, Oct–Dec in Argentina; multiple-brooded in tropics, partners usually remaining together for subsequent broods. Generally monogamous; several instances of polygamy recorded in Panama, but in detailed study in Colombia monogamy the invariable rule. Nest a base of coarse twigs, made mostly by male, with cup of finer material added by female, similar to that of *T. aedon*; usually situated in cavity 0·5–11 m above ground, mostly c. 2–3 m, occasionally in shrubbery or even on ground. Clutch 4 eggs (rarely 5) in Costa Rica, 4–5 in Trinidad, 2–4 in Colombia, usually 5 (up to 7) in Argentina; eggs whitish, densely flecked all over with fine brown, reddish-brown or cinnamon (rarely, unmarked white); incubation by female alone, period 14·5–15·5 days, rarely 17 days; young fed by both sexes, fledging period 18–19 days, rarely 17 or 20 days, but in Argentina normally 16–17 days; destruction of nest contents of different paternity by incoming male observed in Panama. Frequently parasitized by Shiny Cowbird (*Molothrus bonariensis*).

Movements. Sedentary in tropical parts of range; in study in Colombia, high degree of permanent faithfulness to breeding sites. Migratory in extreme S South America, but extent of non-breeding range imperfectly known; leaves I Grande (Tierra del Fuego) after breeding, but found throughout year as far S in Chile as Torres del Paine.

Status and Conservation. Not globally threatened. Common or abundant over most of its huge range. Can tolerate, and frequently benefits from, human changes to habitat, such as the clearing of deep forest. In contrast, isolated races in Lesser Antilles (possibly warranting full species status) have suffered severely from habitat destruction and from predation by introduced mongooses (Herpestidae). Thus, *martinicensis* on Martinique presumed extinct, having not been observed since c. 1900; *guadeloupensis* was believed extinct in 1914, but small numbers rediscovered in 1969 and 1973, although not seen recently; tiny population of *mesoleucus* still present on St Lucia in 1984, while on St Vincent *musicus* is uncommon; seems still to be common, at least in some areas, on Grenada (*grenadensis*) and Dominica (*rufescens*).

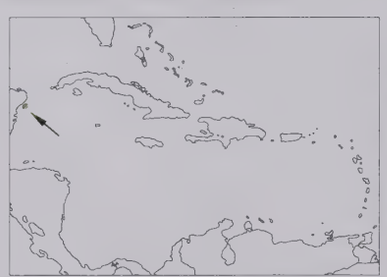
63. Clarion Wren

Troglodytes tanneri

French: Troglodyte de Clarion **German**: Clarionzaunkönig **Spanish**: Chochín de la Clarión

Taxonomy. *Troglodytes tanneri* C. H. Townsend, 1890, Clarión Island, in Revillagigedo Group, off west Mexico.
Forms a superspecies with *T. aedon*, *T. brunneicollis*, *T. musculus*, *T. beani* and *T. cobbi*, and all often treated as conspecific. Monotypic.
Distribution. Clarión I, in Revillagigedo Group, off W Mexico.



Descriptive notes. 12·5–14 cm. Has grey-brown lores, buffy-white supercilium, grey-brown ear-coverts obscurely mottled lighter brown; crown and nape dull blackish-brown, back dull grey-brown, rump rufescent brown; primaries and secondaries barred light and dark brown on outer webs; rectrices alternately barred dark brown and greyish-brown; throat and chest buffy white, lower belly and flanks deeper buff; eye brown; bill dark brown, pale horn-brown base; legs brownish. Sexes similar. Juvenile has underparts faintly scalloped brownish. Voice. Song usually begins with 2 or more gruff "chut" notes, then continues as a warble, resembles that of *T. aedon*, lower and with more gruff chattering than song of *T. sissonii*; prolonged scratchy warble in post-breeding period. Call a dry, insect-like churring rattle.
Habitat. Arid scrub and cactus bush.
Food and Feeding. No published information.
Breeding. Probably breeds in Jan; numerous flying young seen in May. One nest described in 1898 as being made of material such as is used by *T. aedon*, but in shape and location like that of a Song Sparrow (*Melospiza melodia*), i.e. an open cup on ground; several nests found in 1990, each in radiator or glove compartment of derelict vehicle, no other details. No other information.
Movements. Sedentary.
Status and Conservation. VULNERABLE. Confined entirely to Clarión I, a small island (8 km long) in Revillagigedo Group, off W Mexico; described in 1898 as "not uncommon". Notwithstanding substantial habitat change, caused by burning and the introduction of goats, hares (*Lepus*) and pigs, it seems still to be reasonably common. Recent population estimates of 170–200 pairs; density seems to be greater near buildings than elsewhere on island. The Revillagigedo Archipelago is now a Biosphere Reserve, with strictly controlled access.
Bibliography. Anon. (1998b), Anthony (1898), Arizmendi & Márquez (2000), Baptista & Martínez (2002), Blake (1953), Brattstrom & Howell (1956), Collar & Andrew (1988), Collar *et al.* (1994), Everett (1988), Hellmayr (1934), Howell & Webb (1989, 1995), Johnson & Stattersfield (1990), Ridgway (1904), Santaella & Sada (1991), Stattersfield & Capper (2000).

64. Cozumel Wren

Troglodytes beani

French: Troglodyte de Cozumel **German**: Cozumelzaunkönig **Spanish**: Chochín de Cozumel
Other common names: Cozumel House Wren

Taxonomy. *Troglodytes beani* Ridgway, 1885, Cozumel Island, Quintana Roo, Mexico.
Forms a superspecies with *T. aedon*, *T. brunneicollis*, *T. musculus*, *T. tanneri* and *T. cobbi*, and all often treated as conspecific. This species possibly closest to Lesser Antilles races ("*martinicensis* group") of *T. musculus*. Monotypic.
Distribution. Cozumel I (Quintana Roo), off SE Mexico.

Descriptive notes. 12–12·5 cm. Has crown warm grey-brown, becoming rufescent brown on back and warm rufous-brown on rump; upperwing-coverts rufescent brown; primaries and secondaries barred dark brown and rufous-brown on outer webs; rectrices deep rufous-brown with narrow darker bars; throat and chest buffy white, flanks grey-buff, lower flanks rufous-buff; eye brown; bill brown, pale base; legs brown or pinkish-brown. Sexes similar. Juvenile undescribed. Voice. Song typically begins with scolding "chih-chih", breaking into short rich warble, then ending with bright "wheet-wheet-wheet-wheet", resembles that of *T. musculus* but fuller and richer, without trills, and often interspersed with persistent "wha-wha" note. Calls include scolding "shch-shch" and rolled "jirr-r-r-r".
Habitat. Brushland, farmland edges and broken bush, including areas around habitation.
Food and Feeding. Few data on food items; stomach contents "insects". Forages in bush and tangles.
Breeding. No information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Common in suitable habitat; despite its tiny range (Cozumel is c. 45 km long and 20 km wide), not apparently in any danger. Adapts well to disturbed habitat, provided that some cover remains. Cozumel is subject to hurricanes, which periodically sweep over the island; in contrast to Cozumel Thrasher (*Toxostoma guttatum*), it seems to recover very well from the effects of these.
Bibliography. Arizmendi & Márquez (2000), Hellmayr (1934), Howell & Webb (1995), Klaas (1968), Paynter (1955), Phillips (1986), Ridgway (1904), Wheatley & Brewer (2001).

65. Cobb's Wren

Troglodytes cobbi

French: Troglodyte de Cobb **German**: Falklandzaunkönig **Spanish**: Chochín Malvinero
Other common names: Rock Wren(!)

Taxonomy. *Troglodytes cobbi* Chubb, 1909, Carcass Island, north-west of West Falkland, Falkland Islands.
Forms a superspecies with *T. aedon*, *T. brunneicollis*, *T. musculus*, *T. tanneri* and *T. beani*, and all often treated as conspecific. Present species distinct from others, however, in large size, different plumage and markedly different ecology. Monotypic.
Distribution. Small offshore islands in Falkland Is.

Descriptive notes. 13–14 cm; 17–20 g. Partial albinism, e.g. with some white or grey on head, quite common. Lores, cheeks and ear-coverts are unmarked grey-brown, with no obvious eyestripe or supercilium; crown and nape grey-brown, back and shoulders warmer brown, rump brighter rusty-brown; outer webs of primaries and secondaries barred blackish-grey and warm brown; rectrices warm brown with narrow blackish-grey bars; underparts grey-brown, palest on centre of throat and upper breast, becoming richer and warmer on flanks and vent; eye brown; bill blackish; legs dark brown. Sexes similar. Juvenile is more richly coloured than adult, with buff underparts. Voice. Song, delivered from conspicuous perch on beach boulder or completely hidden site in tussac grass, usually a loud phrase of rapid trills and whistles mixed with low buzzing notes, duration c. 2 seconds; individuals males with distinctive songs varying in pattern, slow trills repeated at 10-second intervals or continuous warbling lasting up to 20 seconds. Call notes harsh and buzzing trills, becoming higher-pitched, staccato and explosive when agitated.
Habitat. Usually associated with tussac grass (*Parodiochloa flabellata*), a characteristic very tall and dense Falkland plant; also occurs away from tussac stands in areas where no introduced predators. Also piles of washed-up kelp on shorelines.
Food and Feeding. Invertebrates; no published data on prey items. Usually forages in tussac grass; also in crevices in boulders and among washed-up kelp on beaches.
Breeding. Only a few nests described. Sept/Oct–Dec, but song heard between late Aug and mid-Apr; probably double-brooded. Strongly territorial during breeding, faithful to territory from year to year. Nest an ovoid ball, with side entrance pointing slightly upwards, made of tussac grass and seal hairs, thickly lined with feathers, usually on or close to ground, maximum height above it 0·9 m, in base of tussac clump, sometimes in rock crevice or beneath large boulder, once in sheepskin hanging on fence. Eggs 3 or 4, pinkish, heavily spotted with red or light brown; no information on incubation and fledging periods.
Movements. Sedentary; the only inter-island movement seems to be between closely adjacent islands.
Status and Conservation. VULNERABLE. Restricted-range species: present in Southern Patagonia EBA. Confined to offshore islands, varying in size from 5 ha to 3000 ha, in Falklands. Total population in late 1990s estimated at 4000–8000 pairs, distributed among c. 31 separate islands; recent observations, however, have extended range to several additional islands. Density can be quite high, with up to 4 territorial males/ha in optimum habitat and 2/ha in less suitable conditions. Probably occurred throughout the archipelago prior to human colonization; in 1771, "great numbers of wrens like those in France" reported near present-day Stanley, on East Falkland, but by 1833–1834, following colonization and the introduction of huge numbers of grazing stock, Darwin saw no wrens at all. Highly vulnerable to introduced predators, especially rats (*Rattus*) and cats, and to the destruction of tussac grass habitat by burning and unwise grazing practices; doubtless, its easily accessible nests add to its vulnerability. Efforts are currently being made to eliminate rats from several of the more suitable islands.

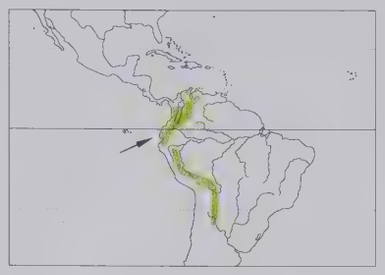
66. Socorro Wren

Troglodytes sissonii

French: Troglodyte de Socorro **German**: Socorrozaunkönig **Spanish**: Chochín de la Socorro
Other common names: Revillagigedo Wren

Taxonomy. *Thryothorus sissonii* Grayson, 1868, Socorro Island, in Revillagigedo Group, off west Mexico.
Although traditionally placed in genus *Thryomanes*, and sometimes in *Thryothorus*, it is generally agreed among ornithologists familiar with this species that it exhibits features typical of present genus; recent work using mitochondrial DNA supports its placement in present genus, close to *T. aedon* and *T. musculus*; in past, considered by some to form a superspecies with *Thryomanes bewickii*, with suggestion that they might even be conspecific. Species name *insularis* commonly used prior to 1951, when *sissonii* was shown to have priority; proposal for treatment of latter as a *nomen oblitum* has generally been ignored, and since 1951 *sissonii* has been used almost universally. Monotypic.
Distribution. Socorro I, in Revillagigedo Archipelago, off W Mexico.



Descriptive notes. 11–12 cm. Has buffy lores, pale buff supercilium, ear-coverts mottled grey-buff; crown grey-brown with some darker feather centres, shoulders and back grey-brown with obscure fine bars, rump warmer brown; outer webs of primaries and secondaries barred blackish-grey and greyish-white; rectrices grey-brown, barred dark greyish-black; chin and throat buffy white, becoming somewhat deeper in colour on chest, belly whitish, flanks and vent buffy; eye dark brown; bill dark brown above, paler below; legs brown. Sexes similar. Juvenile is like adult, but with conspicuous darker scalloping on underparts. Voice. Song usually starts with 2 or more gruff "chuk" notes, breaks into short, rich, slightly scratchy warble and often ends with rich chortle or clear "sweet-weet-weet"; female countersings with male, contributing gruff chatters; song more reminiscent of other *Troglodytes* than of *Thryomanes bewickii*. Scolding "chuk chuk" calls, also rapid "jihr-jihr".
Habitat. Woodland and brushy hillsides.
Food and Feeding. No data available on food items taken. Forages low down in vegetation and also on the ground, turning over leaves; also climbs on tree trunks in the manner of a treecreeper (*Certhia*).
Breeding. Apparently breeds early, though no precise data available; families with fledged young in Apr. One nest was located in knothole of decayed tree, but no further details given. No other information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Socorro Island EBA. Quite common; stated to be the second most abundant bird species on Socorro I. Despite severe ecological damage to the island's habitats, caused primarily by introduced cats and sheep, this species appears not to have suffered to same extent as have other endemic members of the fauna; woodland destruction by sheep may limit its range on parts of the island. Its population is said to have increased as a result of the near-extinction, owing mainly to predation by cats, of Socorro Mockingbird (*Mimodes graysoni*); whether the latter was a predator of small passerines is, however, open to dispute.
Bibliography. Anon. (1998b), Anthony (1898), Arizmendi & Márquez (2000), Banks & Browning (1995), Baptista & Martínez (2002), Blake (1953), Brattstrom & Howell (1956), Collar & Andrew (1988), Grayson (1868), Howell & Webb (1995), Jehl & Parkes (1982), Johnson & Stattersfield (1990), Martínez *et al.* (2005), McLellan (1926), Santaella & Sada (1991), Stattersfield & Capper (2000), Taylor (1951).

67. Mountain Wren

Troglodytes solstitialis

French: Troglodyte montagnard **German**: Andenzaunkönig **Spanish**: Chochín Montañés
Other common names: Equatorial Wren

Taxonomy. *Troglodytes solstitialis* P. L. Sclater, 1859, Matos and Pinipi, near Riobamba, Chimborazo, Ecuador.
Sometimes considered to include *T. monticola*, *T. ochraceus*, *T. rufociliatus* and *T. rufulus* as races; recent DNA work, however, strongly indicates that last three of those, at least, are distinct from present species. Five subspecies recognized.
Subspecies and Distribution.
T. s. solitarius Todd, 1912 – mountains of Colombia (except extreme S) and W Venezuela (Perijá Mts and Andes S from S Lara).
T. s. solstitialis P. L. Sclater, 1859 – extreme S Colombia S to NW Peru.
T. s. macrourus Berlepsch & Stolzmann, 1902 – E slope of Peru S from San Martín.
T. s. frater Sharpe, 1882 – extreme SE Peru (Puno) and Bolivia.
T. s. auricularis Cabanis, 1883 – NW Argentina (S to Tucumán).
Descriptive notes. 10·5–11·5 cm; mean 11·8 g. Nominate race has reddish-brown lores, buff-brown supercilium before and behind eye, area behind eye darker brown, ear-coverts warm buff-brown; crown and forehead rufous-brown, nape, shoulders, back and rump less rufescent; primaries and secondaries barred light rufescent brown and dark chocolate-brown on outer webs; rectrices rufous-brown, narrowly barred blackish; throat and chest warm buff, belly paler buff, flanks buff-brown with indistinct darker barring, vent greyish-white with indistinct darker bars; eye dark brown; bill blackish; legs greyish or greyish-brown. Sexes similar. Juvenile is quite distinct from adult, supercilium less warm buff, upperparts less warm in colour, underparts dull grey-brown, chin to upper belly diffusely speckled dark grey-brown. Race *solitarius* has darker upperparts than nominate, auricular patch deeper brown, throat paler buff, flanks less rufescent, tail longer; *macrourus* is larger and longer-tailed, middle of breast white; *frater* is closest to previous, but with white or buffy-white supercilium; *auricularis* is very similar to last, but with shorter tail, less rufescent upperparts. Voice. Song is rather quiet, a series of high notes, "treee-treeeee-tititiki"; call, constantly given, a characteristic "dzz" or "di-di".

Habitat. Humid forest and forest edge and cloudforest, up to tree-line; sometimes in bamboo thickets. Mostly 1700–3500 m, but down to 700 m in N Argentina.
Food and Feeding. No published data available on food items consumed. Usually in pairs or family parties; occasionally associates with other species in mixed flocks. Forages in low vegetation, sometimes climbing into moss-covered trees.
Breeding. Season quite protracted, varying widely in different parts of range; fledglings observed in almost all months of year in Colombia, Feb–Dec in Peru, Nov and Feb in Bolivia; eggs in Nov in N Argentina; probably multiple-brooded, but confirmation needed. Few observations of nests; one described as a bulky structure, with side entrance but no roof, made of fibrous roots, lined with narrow dry leaves; one in Ecuador located in pile of brush c. 2 m up in crotch of tree, another in natural cavity 10 m up in tree trunk. Clutch 2 eggs, white, but in Argentina reported as 4–5 eggs, whitish with chestnut spots mainly at blunt end; no information available on incubation and fledging periods.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Common or abundant in suitable habitat in much of its range. Occurs in several protected areas, e.g. Sierra Nevada National Park, in Venezuela, and Podocarpus National Park, in Ecuador.
Bibliography. Allen (1998), Babarskas *et al.* (1995), Baez *et al.* (1997), Becker & López (1997), Best *et al.* (1997), Blake (1958), Bloch *et al.* (1991), Canevari *et al.* (1991), Chapman (1917), Chebez *et al.* (1999), Clements & Shany (2001), Cresswell *et al.* (1999), Davies *et al.* (1994), Dobbs *et al.* (1998), Fjeldså & Krabbe (1990), Fjeldså & Maijer (1996), Hellmayr (1934), Hennessey *et al.* (2003), Hilty (2003), Hilty & Brown (1986), Kirwan & Marlow (1996), Mazar Barnett & Pearman (2001), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Parker *et al.* (1985), de la Peña (1989), Remsen (1985), Ridgely & Gaulin (1980), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Salaman (1994), Sclater & Salvin (1879), Skutch (1960), Varty *et al.* (1986), Walker (2001), Williams & Tobias (1994).

68. Santa Marta Wren

Troglodytes monticola

French: Troglodyte des Santa Marta **Spanish**: Chochín de Santa Marta
German: Santa Marta-Zaunkönig
Other common names: Paramo Wren

Taxonomy. *Troglodytes monticola* Bangs, 1899, Páramo de Chiruqua, 15,000 feet [c. 4570 m], Santa Marta Mountains, Colombia.
Frequently treated as a race of *T. solstitialis*, although morphologically closer to *T. ochraceus*; relationships with other montane congeners of Central and South America uncertain, and no DNA analysis yet undertaken. Monotypic.
Distribution. Upper elevations in Santa Marta massif, in N Colombia.

Descriptive notes. 11·5 cm. Has buffy supercilium, buffy-white eyering; crown and upperparts rufous-brown, lower back, primaries and secondaries barred blackish; rectrices brown, transversely barred black; chin pale buff, becoming buffy brown on throat and chest, flanks buffy-white with obvious dark brown bars, vent white with blackish bars; eye brown; bill dark brown, paler base; legs brownish. Sexes similar. Juvenile is similar to adult, but with dark feather tips on back and underparts. Voice. No documented information on song; call, constantly given, a characteristic "di-di".
Habitat. Edges of elfin forest, tree-line scrub, *páramo*; 3200–4800 m.
Food and Feeding. No data on prey items. Forages from ground to middle levels; joins mixed-species flocks.
Breeding. No information.
Movements. Apparently sedentary; not known if altitudinal movements occur.
Status and Conservation. Not globally threatened. Restricted-range species: present in Santa Marta Mountains EBA. Known range is largely contained within the Sierra Nevada de Santa Marta National Park. This area now rarely visited by ornithologists, but recent observations in Frío Valley suggest that this species may be under threat; population density appears to be low. Despite supposedly protected status of the area, forest destruction, overgrazing and burning continue almost unabated. More data needed from other parts of the Santa Marta massif. The species' conservation status requires reassessment.
Bibliography. Cracraft (1985), Hellmayr (1934), Hilty & Brown (1986), Ridgely & Tudor (1989), Stattersfield *et al.* (1998), Strewe & Navarro (2004), Todd & Carriker (1922).

69. Ochraceous Wren

Troglodytes ochraceus

French: Troglodyte ocré **German**: Fahlstreif-Zaunkönig **Spanish**: Chochín Ocráceo
Other common names: Irazu Wren

Taxonomy. *Troglodytes* (?) *ochraceus* Ridgway, 1882, Volcán Irazú, Cartago, Costa Rica.

On following pages: 70. Rufous-browed Wren (*Troglodytes rufociliatus*); 71. Tepui Wren (*Troglodytes rufulus*); 72. Timberline Wren (*Thryorchilus browni*); 73. White-bellied Wren (*Uropsila leucogastra*); 74. Grey-breasted Wood-wren (*Henicorhina leucophrys*); 75. Munchique Wood-wren (*Henicorhina negreti*); 76. White-breasted Wood-wren (*Henicorhina leucosticta*); 77. Bar-winged Wood-wren (*Henicorhina leucoptera*).

Formerly considered a race of *T. solstitialis*, but recent DNA work strongly supports treatment as a separate species. Three races recognized.
Subspecies and Distribution.
T. o. ochraceus Ridgway, 1882 – highlands of Costa Rica (Tilarán and Talamanca ranges and mountainous areas in between).
T. o. ligea Bangs, 1908 – mountains of W Panama.
T. o. festinus Nelson, 1912 – Cerro Pirre, in E Panama; possibly also adjacent NW Colombia.

Descriptive notes. 9·5–10 cm; 8–10 g. Nominate race has buff-brown lores, prominent ochraceous buff postocular supercilium, widening posteriorly, ear-coverts contrastingly darker; crown and upperparts rich medium brown, forehead slightly more orange, rump slightly more rufous; primaries and secondaries barred orange-brown and duller dark brown, tertials deep brown with blackish-brown bars; rectrices dull brown, barred blackish-brown; chin, throat and chest buffy brown, lower breast and upper belly buffy white, flanks and lower belly darker buffy brown; eye brown; bill dark brown, pale base of lower mandible; legs brown. Sexes similar. Juvenile has underparts scaled darker brown, supercilium less rich in colour. Race *ligea* is duller above than nominate, with heavier bill; *festinus* is smaller, lighter below than nominate, larger bill. VOICE. Song a rather subdued medley of varied liquid trills and high, thin slurred whistles; calls a rolling, thin high-pitched "peeer" or "peeew" and low, weak "churr".
Habitat. Humid mountain forest with epiphytes, also areas of scattered trees at forest edge in grazed land. Mostly 900–2450 m; rarely, down to 600 m and up to 3000 m.
Food and Feeding. No data available on prey items. Forages mostly on mossy trunks and in epiphytes.
Breeding. Apparently Apr–Jul (nestlings being fed early May, nest construction observed late May) in Costa Rica. Only three nests described, none of which could be examined, but each apparently in cavity of dead branch or among free-swinging epiphytes on broken-off, heavily overgrown branch supported by creepers and aerial roots. Family groups of adults and two young observed. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Costa Rica and Panama Highlands EBA. Fairly common. Considerable portions of its range lie within national parks, such as those of La Amistad, Tapantí and Volcán Poás, and biological reserves.
Bibliography. Angehr (2003), Anon. (1998b), Blake (1958), Buskirk (1981), Buskirk *et al.* (1972), Hartman & Brownell (1961), Hellmayr (1934), Nadkarni & Matelson (1989), Powell (1979), Ridgely & Gwynne (1989), Ridgway (1904), Robbins *et al.* (1985), Sillett (1994), Skutch (1940, 1960), Slud (1964), Stiles & Skutch (1989), Young *et al.* (1998).

70. **Rufous-browed Wren**

Troglodytes rufociliatus

French: Troglodyte à sourcils roux **Spanish**: Chochín Cejirrufo
German: Rostbrauen-Zaunkönig

Taxonomy. *Troglodytes rufociliatus* Sharpe, 1882, Volcán de Fuego, 10,000 feet [c. 3050 m], Sacatepéquez, Guatemala.
Frequently regarded as conspecific with *T. solstitialis*; recent DNA work, however, strongly indicates that it is a distinct species, and closer to the *T. aedon* superspecies than to other members of the genus in Central and South America. Four subspecies recognized.
Subspecies and Distribution.
T. r. chiapensis Brodkorb, 1943 – high mountains of Chiapas, in S Mexico.
T. r. rufociliatus Sharpe, 1882 – E Guatemala and N El Salvador.
T. r. nannoides Dickey & van Rossem, 1929 – Volcán Santa Ana, in El Salvador.
T. r. rehni Stone, 1932 – mountains of Honduras and NW Nicaragua.

Descriptive notes. 10–11·5 cm; 11 g. Nominate race has buff lores marked with darker brown, pale buff supercilium contrasting with dark brown upper ear-coverts; crown and back warm brown, obscure darker bars on back, rump warm brown with darker bars, shoulders warm brown with some greyish-white streaks; primaries and secondaries barred greyish-black, buff and brown; rectrices warm brown, barred blackish-brown; chin buffy, throat and chest ochraceous buff, deepening on sides to ochraceous tawny with obscure darker barring; flanks barred grey, warm brown and dark brown; centre of belly sometimes obscurely spotted, lower belly and vent barred; eye brown; bill dark horn with pale base to lower mandible; legs dark grey-brown. Sexes similar. Juvenile is like adult, but flank barring more obscure, chest feathers with fine dusky edgings. Race *chiapensis* is darker brown above than nominate, throat richer rufous, belly almost pure white, crissum greyish; *nannoides* is darker on back, barring on flanks heavier; *rehni* is more reddish-brown above, throat ochraceous, belly buffy. VOICE. Song a varied, scratchy warble running into tinkling trill; call a loud nasal "zhweet".
Habitat. Wet epiphyte-laden mountain forest; in El Salvador, found only in dampest, darkest sections of cloudforest. More varied habitat, including mixed oak–pine (*Quercus–Pinus*) forest and epiphytic cypress (*Cupressus*) forest, in Guatemala.1700–3500 m; recently found at 1250 m in Nicaragua.
Food and Feeding. Few data available on food items consumed; has been seen to take caterpillars. Forages, usually in pairs, low down in thick epiphytes and piles of brush; also in epiphytes on tree branches.
Breeding. Nests from third week Apr to early Jul in Guatemala; birds in breeding condition in May in El Salvador. Only three nests described, all from Guatemala: a cup made of dry grasses and pine needles, located in cavity in dead tree stump (the highest 1 m up) or in hole in ground; 3 eggs, white, speckled all over with cinnamon; incubation by female alone, sometimes fed on nest by male (unusual for a wren). No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in the North Central American Highlands EBA. Quite common in many areas where habitat undisturbed. Race *nannoides* now restricted to 600-ha area of Volcán Santa Ana (El Salvador), which is in a national park; total population of this race estimated at c. 4000 individuals.
Bibliography. Anon. (1998b), Arizmendi & Márquez (2000), Blake (1953), Dickey & van Rossem (1938), Gómez de Silva *et al.* (1999), Hellmayr (1934), Howell & Webb (1995), Komar (1998, 2002), Komar *et al.* (1998), Land (1970), Martínez-Sánchez (1989), Monroe (1968), Rice *et al.* (1999), Ridgway (1904), Skutch (1940, 1960, 1985b), Wetmore (1941), Wheatley & Brewer (2001).

71. **Tepui Wren**

Troglodytes rufulus

French: Troglodyte des tépuis **German**: Tepuizaunkönig **Spanish**: Chochín de Tepuí
Other common names: Roraima Wren

Taxonomy. *Troglodytes rufulus* Cabanis, 1849, Cerro Roraima, Bolívar, Venezuela.
Sometimes regarded as conspecific with *T. solstitialis*, but recent DNA work indicates that it is a separate species. Six subspecies recognized.
Subspecies and Distribution.
T. r. yavii Phelps, Sr & Phelps, Jr, 1949 – tepuis of N Amazonas (Sipapo, Guanay, Yavi), in S Venezuela.
T. r. marahuacae Phelps, Jr & Aveledo, 1984 – Cerro Marahuaca, in C Amazonas.
T. r. duidae Chapman, 1929 – tepuis of C Amazonas (Duida, Parú, Huachamacari) and S Bolívar (Jaua, Sarisariñama).
T. r. wetmorei Phelps, Sr & Phelps, Jr, 1955 – Cerro de la Neblina, in S Amazonas, presumably also in immediately adjacent N Brazil.
T. r. fulvigularis J. T. Zimmer & Phelps, Sr, 1945 – Auyán-tepui, Ptari-tepui, Chimantá-tepui and Sororopán-tepui, in SE Bolívar.
T. r. rufulus Cabanis, 1849 – subtropical zones of Mt Roraima and Uei-tepui, on Venezuela–Guyana border, presumably also in immediately adjacent N Brazil.

Descriptive notes. c. 11·5–12 cm; 16 g. Nominate race has grey lores, ochraceous buff supercilium, dark brown postocular area; crown and upperparts unmarked chestnut-brown, slightly more rufescent on lower back and rump; primaries and secondaries rather obscurely barred rufous-brown and blackish-brown on outer webs; rectrices dark rufous-brown with narrow blackish bars; throat and breast ochraceous buff deepening to rufous brown on sides, falnks and rear belly; vent buffy-brown, barred dark brown; eye dark brown; bill black, silvery base of lower mandible; legs medium grey. Sexes similar. Juvenile is darker, with underparts scaled. Race *wetmorei* is similar to nominate, but central underparts grey; *duidae* has whitish underparts, more pronounced bars on tail; *yavii* has whiter underparts; *fulvigularis* is darker and less rufous than nominate; *marahuacae* is similar to *wetmorei* but smaller, with very grey belly. VOICE. Song a series of high, thin whistled twitters, sometimes continuing for several seconds, sometimes in disjunct separate phrases.
Habitat. Humid forest on tepui mountains; also forest edge and bushland. At 1000–2800 m, mostly 1600–2400 m.
Food and Feeding. No published data on prey items. Spends most of its time in foraging very low in vegetation, or on ground.
Breeding. No information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in Tepuis EBA. Locally common; common on Mt Roraima. Much of habitat occupied by this species is very remote and largely untouched; many tepuis are also protected reserves.
Bibliography. Barnett *et al.* (2002), Chapman (1931), Cracraft (1985), Gilliard (1941), Hellmayr (1934), Hilty (2003), Mayr & Phelps (1967), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Ridgely & Tudor (1989), Sick (1993, 1997), Willard *et al.* (1991).

Genus *THRYORCHILUS* Oberholser 1904

72. **Timberline Wren**

Thryorchilus browni

French: Troglodyte des volcans **German**: Bergzaunkönig **Spanish**: Cucarachero del Bambú
Other common names: Irazu Wren

Taxonomy. *Troglodytes browni* Bangs, 1902, Volcán de Chiriquí, 10,000 feet [c. 3050 m], Chiriquí, Panama.
Resembles *Henicorhina* in many aspects (song, plumage, nest), but recent DNA work suggests that it is closer to *Troglodytes*; currently placed by most authors in its own genus, pending further investigation. Validity of races disputed, and species may be better considered monotypic. Three subspecies tentatively recognized.
Subspecies and Distribution.
T. b. ridgwayi Bangs, 1906 – highlands of C Costa Rica (Volcán Turrialba, Volcán Irazú and adjacent areas).
T. b. basultoi Ridgway, 1908 – Cordillera de Dota, in SC Costa Rica.
T. b. browni (Bangs, 1902) – W Panama (Volcán Barú, Volcán de Chiriquí, Cerro Copete).
Descriptive notes. 10 cm; mean 14 g. Nominate race has lores and supercilium conspicuously grey-white, wide postocular stripe rich chocolate-brown, cheeks to area behind ear-coverts grey-white with narrow black edgings; crown and upperparts rich chestnut-brown, some feathers in middle of upper back with concealed white centres; outer primaries edged white, remainder and secondaries barred dark brown and rufous-brown; rectrices rufous-brown with narrow dark bars;

throat and chest grey-white, belly mottled grey-white, lower belly dull brown, flanks and vent rufous-brown; eye brown; bill dull black above, flesh-horn below; legs dull pale brown. Sexes similar. Juvenile is more grey below than adult, with chest and belly feathers narrowly edged grey-black, giving scalloped appearance, and facial markings less clearly defined. Race *ridgwayi* is larger than nominate, deeper rufous-brown above; *basultoi* has broader supercilium, more extensive white markings on upperparts and sides of neck, and dusky crown, and is whiter below than others, with stouter bill. Voice. Song a series of half a dozen scratchy, warbling notes, lasting 2–3 seconds, the sequence usually rapidly repeated numerous times; quite unlike that of any *Troglodytes* species. Call a harsh scolding "churr".

Habitat. Upper edge of tree zone in *páramo* and near-*páramo*; found especially in bamboo thickets, also in isolated patches of bushes in sheltered areas. Mostly 2800–3600 m, locally down to 2200 m.

Food and Feeding. Recorded food items include spiders (Araneae), caterpillars and small insects. Feeds on or near ground, sometimes fluttering to pick prey from undersides of leaves; creeps along moss-covered branches.

Breeding. Poorly documented. Season Apr–Jun in Costa Rica. Nest is a hollow ball with a side entrance, made of bamboo leaves and lined with finer fibres, situated 1–3 m up in bamboo or shrub. Eggs 2, white, speckled all over with pale brown; no information available on incubation and fledging periods.

Movements. Sedentary; not known if altitudinal movements occur.

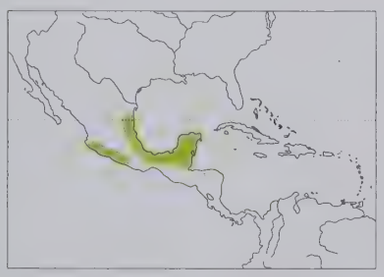
Status and Conservation. Not globally threatened. Restricted-range species: present in Costa Rica and Panama Highlands EBA. Common or abundant in suitable habitat. Most of its range lies in areas under little human pressure, and large parts are included in national parks, such as that of La Amistad, and other protected areas.

Bibliography. Angehr (2003), Anon. (1998b), Blake (1958), Hellmayr (1934), Rice *et al.* (1999), Ridgely & Gwynne (1989), Ridgway (1904), Slud (1964), Stiles & Skutch (1989).

Genus *UROPSILA* P. L. Sclater & Salvin, 1873

73. **White-bellied Wren**

Uropsila leucogastra



French: Troglodyte à ventre blanc **Spanish**: Cucarachero Ventriblanco
German: Weißbauch-Zaunkönig
Other common names: Gould's Wren

Taxonomy. *Troglodytes leucogastra* Gould, 1837, Tamaulipas, Mexico.

Different authorities have suggested that this species should be placed variously in *Troglodytes*, *Henicorhina* or *Thryothorus*; in absence of convicing argument, however, it is currently retained in its own monotypic genus. Population from S Quintana Roo to C Belize and N Honduras may be separable as race *australis*, with *hawkinsi* (Coyoles, Honduras) a synonym. Proposed race *grisescens* (E Mexico) apparently based on soot-discoloured specimens, and thus doubtfully valid. Six subspecies currently recognized.

Subspecies and Distribution.

U. l. pacifica (Nelson, 1897) – W Mexico (Colima, Michoacán, Guerrero).
U. l. leucogastra (Gould, 1837) – lowlands of E Mexico (S Tamaulipas and E San Luis Potosí S to N Oaxaca).
U. l. centralis A. R. Phillips, 1986 – S Mexico from N Puebla E to C Veracruz.
U. l. musica (Nelson, 1903) – S Mexico (NE Oaxaca, Tabasco, N Chiapas).
U. l. restricta A. R. Phillips, 1986 – SE Mexico (N Yucatán).
U. l. brachyura (Lawrence, 1887) – C & S Yucatán Peninsula (S to Guatemala and Belize) and N Honduras.

Descriptive notes. 9·5–10 cm; male 9·8–10·5 g, female 8–9·1 g. Nominate race has lores buffy grey, postocular supercilium grey-white, area behind eye mid-brown, ear-coverts mottled brown on grey; crown and upperparts medium brown, becoming slightly rufescent on rump; primaries and secondaries medium brown with obscure darker bars on outer webs; rectrices medium brown with many fine dark bars; throat, chest and upper belly grey, flanks, thighs and vent buff; eye brown; bill blackish-grey, paler at base; legs dull brown. Sexes similar. Juvenile has supercilium less well defined than adult, markings on ear-coverts more diffuse. Race *centralis* is paler than nominate; *pacifica* is paler above than nominate, with longer wings, shorter tarsi; *musica* is darker than nominate, upperparts deep russet-brown, flanks almond-brown; *restricta* is paler, greyer and generally duller than all others; *brachyura* has better-defined tailbars than nominate, undertail-coverts barred dusky. Voice. Song, often by both sexes in duet, a short series of 6 rapid up-and-down notes, descending at end, the whole with gurgling liquid quality; that of disjunct W race *pacifica* apparently lacks bubbly quality of other races. Calls include low "chek", scolding chatter, and hard dry cracking rattle.

Habitat. Woodland of various types, including semi-arid forest in W Mexico and much more humid rainforest in Yucatán; frequently in thickets of wild pineapple (*Bromelia pinguin*) in NE Mexico. Sea-level to 500 m.

Food and Feeding. Food items include insects and spiders (Araneae); has been seen to pilfer prey from spiderwebs. Forages in vegetation, from ground level to a considerable height; in *Bromelia* thickets takes prey from bases of leaf rosettes. In S part of range, where army ants occur, can be found in mixed bird flocks following swarms.

Breeding. Season appears to be late Mar to Jun; at present not known if species is multiple-brooded. Nest a peculiar structure shaped like old-fashioned chemical retort, with oval ball c. 12·5 × 20 cm containing egg-chamber, downward-pointing funnel c. 5 cm in length as entrance, beautifully woven from fine grasses, decorated on outside with lichens, spider egg cases, moss and similar material; more flimsy nests also built, probably for roosting; placed 3–4 m above ground, occasionally 1·5 m or as high as 15 m, usually in protective site in spiny *Bromelia* thicket, or in acacia (*Acacia*) protected by vicious symbiotic ants of genus *Pseudomyrmex* (55 of 59 nests in a study in Guatemala). Eggs usually 4, glossy, pale unmarked blue; incubation apparently carried out by both sexes (unusual for a wren), young fed by both parents; no information available on incubation and fledging periods.

Movements. Apparently sedentary.

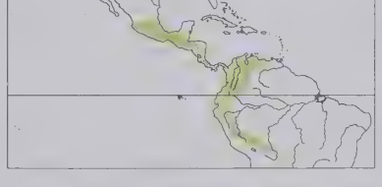
Status and Conservation. Not globally threatened. Reasonably common over much of its range. Able to tolerate moderate habitat disturbance. Occurs in several protected areas, including e.g. Maya Biosphere Reserve in Guatemala and contiguous parts of Mexico and Belize.

Bibliography. Anon. (1998b), Binford (1989), Blake (1953), England (2000), Gilardi & von Kugelgen (1991), González-García (1993), Gordon & Ornelas (2000), Hellmayr (1934), Howell & Webb (1995), Hutto (1980, 1992, 1994), Land (1970), Lee Jones (2004), Monroe (1963), Ornelas *et al.* (1993), Paynter (1955), Peterson, Navarro *et al.* (2003), Russell (1964), Sutton (1948), Waide (1980), Waide & Hailman (1977), Wauer (1998).

Genus *HENICORHINA* P. L. Sclater & Salvin, 1868

74. **Grey-breasted Wood-wren**

Henicorhina leucophrys



French: Troglodyte à poitrine grise **Spanish**: Cucarachero Pechigrís
German: Einsiedlerzaunkönig
Other common names: Highland Wood-wren

Taxonomy. *Troglodytes leucophrys* Tschudi, 1844, Montaña del Vitoc, Junín, Peru.

Has been thought to form a superspecies with *H. leucosticta*, but geographical and altitudinal overlap too extensive to justify such treatment. Possibly involves more than one species; *bangsi* and *anachoreta* are separated altitudinally in Santa Marta massif (N Colombia), and *brunneiceps* appears to have different song type from neighbouring races. Race *composita* perhaps not distinguishable from *castanea*. Eighteen subspecies recognized.

Subspecies and Distribution.

H. l. mexicana Nelson, 1897 – E Mexico (SE San Luis Potosí S to N Oaxaca).
H. l. minuscula A. R. Phillips, 1966 – W Mexico (SW Jalisco and Michoacán E to W México).
H. l. festiva Nelson, 1903 – SW Mexico from Michoacán S to Guerrero.
H. l. capitalis Nelson, 1897 – S Mexico (Veracruz and Puebla S to Oaxaca) and W Guatemala.
H. l. castanea Ridgway, 1903 – Atlantic slope of Guatemala.
H. l. composita Griscom, 1932 – N El Salvador, SC highlands of Honduras and adjacent NW Nicaragua.
H. l. collina Bangs, 1902 – C Costa Rica S to E Panama.
H. l. bangsi Ridgway, 1903 – Santa Marta Mts (below 2000 m), in N Colombia.
H. l. anachoreta Bangs, 1899 – upper levels of Santa Marta (2000–4000 m).
H. l. manastarae Aveledo & Ginés, 1952 – Perijá Mts, on N Colombia–Venezuela border.
H. l. sanluisensis Phelps, Sr & Phelps, Jr, 1959 – Sierra de San Luis, in C Falcón (NW Venezuela).
H. l. venezuelensis Hellmayr, 1903 – N Andes and coastal mountains of Venezuela (Lara, Yaracuy, and Carabobo E to Miranda).
H. l. meridana Todd, 1932 – Venezuelan Andes (Trujillo S to N Táchira).
H. l. tamae J. T. Zimmer & Phelps, Sr, 1944 – E Andes of SW Venezuela (SW Táchira) and E slope in Colombia.
H. l. brunneiceps Chapman, 1914 – W Colombia and NW Ecuador.
H. l. leucophrys (Tschudi, 1844) – subtropical zone in Colombia (E slope of W Andes E to W slope of E cordillera), Ecuador (except NW & SW) and Peru.
H. l. hilaris Berlepsch & Taczanowski, 1884 – subtropical zone of SW Ecuador.
H. l. boliviana Todd, 1932 – W Bolivia (La Paz, Cochabamba).

Descriptive notes. 10–11·5 cm; male average 18·1 g, female average 16·4 g. Nominate race has long grey-white supercilium, lores and wide postocular stripe black, black ear-coverts prominently streaked grey-white; crown feathers dull black with dark brown tips, nape and shoulders dark olive-brown, lower back and rump more chestnut; primaries and secondaries are barred on outer webs with dull chestnut-brown and darker brown, tertials dull red-brown with narrow darker bars; rectrices dull chestnut-brown, barred dull blackish-brown; chin and throat whitish-grey, chest and belly grey, side of belly and lower flanks brownish-buff; eye reddish-brown; bill black, dark grey base of lower mandible; legs dingy brownish-black. Sexes similar. Juvenile differs from adult in having facial markings more diffuse, throat greyish. Race *boliviana* is similar to nominate, but more streaked on throat, flanks less rufescent; *hilaris* is paler on foreneck and breast; *brunneiceps* has heavier bill than nominate, brighter upperparts, distinctly streaked throat, darker underparts; *meridana* has profusely streaked throat, slate-grey breast; *bangsi* is pale below, with pale grey-white throat and breast; *anachoreta* is similar to previous but has dusky throat streaking; *venezuelensis* is also similar, but with darker grey chest side, less rufescent flanks; *manastarae* is closest to previous, but sides, thighs and undertail-coverts a brighter brown colour; *sanluisensis* is darker and browner, less reddish, on back, and with darker, more greyish breast and abdomen; *tamae* has blackish streaks on throat; *castanea* is rather dark above and below, with diffuse throat streaking, small bill; *composita* is similar to previous, but paler cheeks; *collina* is also similar, but paler on back; *capitalis* is closest to last, but less chestnut above, with sooty-grey crown centre, more diffuse throat markings; *mexicana* is similar to previous, but with deeper and more rufescent flanks; *minuscula* is paler above, with duller crown; *festiva* is duller below, with crown and nape greyish-brown. Voice. Song, given both antiphonally and solo, a series of very loud, ringing musical phrases, frequently repeated, longer and more

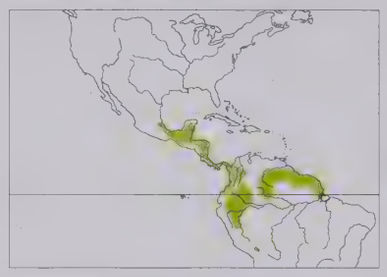
complex than *H. leucosticta* song; individual pairs often develop distinctive unique motifs, also considerable geographical variation in song type, e.g. much more tinkling in W Colombia (race *brunneiceps*). Calls also vary, in Mexico a sharp 'tek-tek-tek", in Costa Rica softer; alarm calls include harsh churrs and scolding notes.
Habitat. Inhabits humid mountain forest; found in a wide variety of forest types, including pine–oak (*Quercus–Pinus*) complexes, bamboo thickets and fringes of *páramo*. Usually above 1500 m; up to 4000 m in Colombia, but on Pacific slope down to 400 m; occasionally down to 600 m in Mexico.
Food and Feeding. Food seems to be entirely invertebrates; no evidence of vegetable matter being eaten. Forages singly, or in small parties (probably family groups), on ground or in lower levels of vegetation.
Breeding. Late Mar to early Jun in Costa Rica and Dec–Jun in Colombian Andes; possibly multi-brooded. Nest built by both sexes, a globular structure consisting of rounded chamber, roof of which projects forwards and downwards, giving downward-pointing antechamber at front (necessitating almost vertical mode of entry), made of fibrous rootlets, with moss attached to roof and walls, situated in low vegetation, frequently over bank or ravine; dormitory nests also built, these identical to breeding nests (in contrast to those of *H. leucosticta*). Eggs 2, pure white without markings; incubation by female alone, period 19–20 days; chicks fed by both sexes, fledging period 17–18 days.
Movements. Largely sedentary. Some evidence of altitudinal movements in response to rainfall in Guatemala.
Status and Conservation. Not globally threatened. Common or abundant in many habitats. Although significant habitat loss has occurred in many parts of its range, it is not at risk in any country. Occurs in several protected areas, e.g. Tapantí National Park, in Costa Rica, Henri Pittier National Park, in Venezuela, and Cock-of-the-Rock Lodge, in Peru.
Bibliography. Allen (1998), Anon. (1998b), Aveledo & Ginés (1952), Binford (1989), Blake (1953), Blake & Hanson (1942), Bloch *et al.* (1991), Chapman (1917), Clements & Shany (2001), Cracraft (1985), Davies *et al.* (1994), Fjeldså & Krabbe (1990), Hellmayr (1934), Hennessey *et al.* (2003), Hilty (1997, 2003), Hilty & Brown (1986), Howell & Webb (1995), Miller (1963), Monroe (1968), Orejuela *et al.* (1980), Parker *et al.* (1985), Phelps & Phelps (1959), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Ridgway (1904), Rowley (1966), Salaman (1994), Skutch (1940, 1960), Slud (1964), Sousa *et al.* (1982), Stiles & Skutch (1989), Walker (2001), Williams & Tobias (1994), Winnett-Murray (1987), Yanega (1996), Zimmer (1930).

75. Munchique Wood-wren

Henicorhina negreti

French: Troglodyte de Negret **German**: Negretzaunkönig **Spanish**: Cucarachero de Munchique

Taxonomy. *Henicorhina negreti* Salaman *et al.*, 2003. Tambito Natural Reserve, El Tambo, Cauca, Colombia.
Closely related to, and probably derived from, *H. leucophrys*. Monotypic.
Distribution. W Andes of Colombia: where departments of Chocó, Antioquia and Risaralda meet; and in Munchique massif (Valle de Cauca).



Descriptive notes. 10·8–11·7 cm; 15·2–16·7 g. Has narrow white supercilium, dull black lores, postocular area and auriculars, blackish cheeks and malar area mottled dull white to greyish-white; crown very dark brown, suffused with blackish, upperparts slightly brighter brown; outer webs of primaries and secondaries brown with narrow black bars, rectrices brown with irregular black bars; throat white, heavy black streaking posteriorly; breast medium grey, belly paler grey, flanks and crissum brown, abdomen and middle area of flanks with irregular dark grey to blackish bars; eye hazel-brown; bill black, basal half of lower mandible lead-grey; legs bluish slate-grey. Distinguished from *H. leucophrys* by, especially, its barred abdomen. Sexes similar. Juvenile is much darker overall than adult, with greyish-white supercilium, dark sooty-grey cheeks and malar region with only faint paler mottling, throat dark grey with dusky fringes, breast solid dark sooty-grey, flanks and abdomen unbarred dark dull brown. Voice. Repeated phrases of 6–12 pure notes, each phrase lasting c. 2 seconds, typical song containing more than ten repeated phrases, but often curtailed; very different from song of *H. leucophrys*. Call notes mostly churrs, similar to those of congeners.
Habitat. Apparently very specific in requirements, in contrast to more catholic *H. leucophrys*. Found in very wet, stunted epiphytic cloudforest characterized by almost continuous fog cover, at 2250–2640 m. Sharply separated ecologically from the two neighbouring races of *H. leucophrys*, one of which (nominate) occurs on drier E slopes of Munchique massif and the other (*brunneiceps*) on wetter Pacific slope but at lower altitudes (where fog cover much less prevalent, and vegetation generally taller) than present species. In some areas all three taxa occur within distance of 1 km, and breeding *brunneiceps* may be found only 200 m from present species, but no two of the three are found together.
Food and Feeding. Stomach contents exclusively arthropods, especially beetles (Coleoptera) and flies (Diptera). Forages close to forest floor, usually below 2 m; occasionally as high as 4 m to investigate epiphyte clusters. May associate with mixed flocks, but only briefly, when these pass through its territory.
Breeding. Juvenile on 25th Jul estimated to have fledged c. 2 weeks previously, implying egg date of about first week of Jun. No other information.
Movements. Presumably totally sedentary.
Status and Conservation. Not globally threatened. Conservation status not yet properly assessed, as species only recently discovered. When originally discovered, recommended status was Critical, on basis of total range of less than 100 km² and estimated population of fewer than 2500 individuals. However, very recently a second population was discovered c. 350 km to N, and there species appears to be common; extensive areas of apparently suitable habitat remain between these two nuclei, and these areas need surveying. Although southern portion of the species' range is nominally protected, lying within Munchique National Park and Tambito Nature Reserve, in practice forest clearance for agriculture continues in the absence of adequate wardening and enforcement of regulations. Very narrow and specific ecological requirements of this wren would render it vulnerable to climatic change. The Munchique area, which contains several species of very limited range, clearly merits classification as an Important Bird Area.
Bibliography. Anon. (2004a, 2004b), Ebels (2004), Kirwan (2004), Salaman *et al.* (2003), Suárez *et al.* (2005).

76. White-breasted Wood-wren

Henicorhina leucosticta

French: Troglodyte à poitrine blanche **Spanish**: Cucarachero Pechiblanco
German: Waldzaunkönig
Other common names: Lowland Wood-wren

Taxonomy. *Cyphorhinus leucosticta* Cabanis, 1847, Guyana.
Has been thought to form a superspecies with *H. leucophrys*, but geographical and altitudinal overlap too extensive to justify such treatment. Possibly represents three distinct species, with separation of *prostheleuca* and *pittieri* groups. Race *prostheleuca* intergrades with *smithei* in SE Mexico (extreme S Quintana Roo) and N Belize. Thirteen subspecies recognized.
Subspecies and Distribution.
H. l. decolorata A. R. Phillips, 1986 – E Mexico (San Luis Potosí S to N Veracruz and N Puebla).
H. l. prostheleuca (P. L. Sclater, 1857) – S & E Mexico (from Veracruz and N Chiapas) E to Belize.
H. l. smithei Dickerman, 1973 – S part of Yucatán Peninsula S to Guatemala.
H. l. tropaea Bangs & J. L. Peters, 1927 – Honduras and Nicaragua.
H. l. costaricensis Dickerman, 1973 – N & E Costa Rica.
H. l. pittieri Cherrie, 1893 – SW Costa Rica and W Panama.
H. l. alexandri A. R. Phillips, 1986 – E Panama and immediately adjacent NW Colombia.
H. l. darienensis Hellmayr, 1921 – E Panama (Darién) and W Colombia (S to Baudo Mts).
H. l. inornata Hellmayr, 1903 – W Colombia (S of R San Juan) S to extreme NW Ecuador.
H. l. albilateralis Chapman, 1917 – W Colombia (lower Cauca Valley, middle Magdalena Valley).
H. l. eucharis Bangs, 1910 – W Colombia (Valle).
H. l. leucosticta (Cabanis, 1847) – E & S Venezuela, Guyana, Suriname, French Guiana (one record), and N Brazil (S to N Pará).
H. l. hauxwelli Chubb, 1920 – tropical zone of upper Amazonia in S Colombia (S from Meta and Vaupés), E Ecuador and NE Peru.

Descriptive notes. 10–11·5 cm; mean 15·7 g. Nominate race has lores blackish-grey, supercilium greyish in front of eye, white behind; blackish area behind eye bordered with white spots at neck, black ear-coverts conspicuously spotted and streaked grey-white; crown and nape black, nape feathers tipped deep brown, back deep rich brown, rump rufescent brown; primaries and secondaries warm brown on outer webs, indistinctly barred darker brown; rectrices deep reddish-brown, narrowly barred blackish; chin, throat and chest white, chest side grey, belly and flanks warm ochraceous brown; eye brown; bill black, horn-coloured base of lower mandible; legs dark grey. Sexes similar. Juvenile has brown crown little different in colour from back, greyish (not white) throat and chest, grey belly, sometimes obscure darker bars below. Race *hauxwelli* is similar to nominate, but deeper rufous-chestnut on back, wings and tail, darker rufous-brown on flanks; *prostheleuca* has reddish-brown cap, not very rufescent above; *decolorata* is similar to previous but smaller, generally duller, paler and less rufescent, especially on wings and tail; *tropaea* is also similar, but is more rufescent on back and flanks, and has reddish-brown central crownstripe; *darienensis* is similar to last, but with black crown; *pittieri* is also similar, but brighter chestnut above, flanks more russet, median crownstripe rufescent; *smithei* is paler dorsally than other Central American races, greyer than previous, greyish-brown on crown; *costaricensis* is darker and less rufescent above than other Central American races, back dark chocolate-brown; *alexandri* is relatively pale and bright above, flanks with little reddish-brown tinge; *eucharis* is larger, rather dull above, with less black on cheeks, barring on primaries and secondaries more obscure; *albilateralis* differs from previous in having duller plumage, back cinnamon-brown, flanks with less grey; *inornata* is brighter above, with rufous crown, narrower white supercilium, deeper rufous-brown flanks, thicker bill. Voice. Song loud and powerful, consists of 3–5 clear whistles, constantly repeated as a phrase, often mixed with trills; both sexes sing, often antiphonally, female may sing while incubating. Call notes appear to vary geographically; in Veracruz (Mexico) a bright metallic "tick", in Costa Rica a hoarse "eerp".
Habitat. Inhabits wet lowland forest, from sea-level up to 1300 m; more rarely, up to 1800 m or even 2000 m.
Food and Feeding. Food mostly or entirely invertebrates; nestling diet entirely animal, especially grubs and larvae. Forages from ground level up to 2–3 m, rarely higher; especially fond of tangles surrounding fallen trees and ravines. Sometimes briefly joins mixed flocks of birds around ant armies, but not a true swarm-follower.
Breeding. Season Feb–May, rarely Jan, in Costa Rica and Feb–Jul in Suriname; newly fledged young in Dec in French Guiana, and birds in breeding condition Jan–Jul in Colombia. Nest ovoid in shape, rather taller than wide, with thick bottom, circular entrance hole at side protected above by visor-like projection, made of fibrous vegetable material, rootlets and similar material, camouflaged externally with moss, interior lined with feathers, placed on or close to ground and well concealed in thick vegetation or in tree stump; separate nests built for roosting much more flimsy than breeding nest, usually sited higher up and with less regard for concealment, placed in more slender vegetation which cannot be climbed by predator without shaking nest and alerting occupant. Eggs 2, usually immaculate glossy white, more rarely with few brown speckles; incubation probably by female alone, period c. 18 days; chicks fed by both sexes, fledging period probably 17–18 days.
Movements. Apparently entirely sedentary.
Status and Conservation. Not globally threatened. Considered common or abundant over much of its range. Although much of its habitat has been lost to agricultural and other development, this species is not at any risk in any of the countries in which it occurs. Present in several protected areas, including e.g. Braulio Carrillo National Park, in Costa Rica, and Darién National Park, in Panama.
Bibliography. Anon. (1998b), Blake (1953), Brenowitz & Kroodsma (1996), Brodkorb (1943), Canaday & Jost (1997), Carriker (1910), Chapman (1917), Clements & Shany (2001), Dickerman (1973), Haffer (1975), Haverschmidt (1968), Haverschmidt & Mees (1994), Hellmayr (1934), Hilty (2003), Hilty & Brown (1986), Howell & Webb (1995), Land (1970), Lee Jones (2004), Monroe (1968), Novaes (1974), Orejuela *et al.* (1980), Paynter (1957), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Ridgway (1904), Robbins *et al.* (1985), Salaman (1994), Skutch (1940, 1960, 1979), Slud (1964), Smithe (1966), Stiles & Skutch (1989), Tostain *et al.* (1992), Winker *et al.* (1996), Zimmer (1930).

77. **Bar-winged Wood-wren**

Henicorhina leucoptera

French: Troglodyte à ailes blanches **Spanish**: Cucarachero Aliblanco
German: Bindenflügel-Zaunkönig

Taxonomy. *Henicorhina leucoptera* Fitzpatrick *et al.*, 1977, Cajamarca, Peru.
Possibly more closely related to *H. leucophrys*; somewhat intermediate between that species and *H. leucosticta*. Monotypic.
Distribution. Recorded S Ecuador (Cordillera del Cóndor) and N Peru (Cajamarca, San Martín and La Libertad). Imperfectly known.
Descriptive notes. 11 cm; 14·5–16·5 g. Has white lores and supercilium, broken white eyering, wide black postocular stripe, side of face boldly streaked with black and white; crown grey at front, light brown at rear, back dark reddish-brown, becoming reddish laterally and amber on rump; primaries black, barred burnt umber, outermost fringed with white; rectrices blackish, finely barred fuscous on outer webs; chin, throat and upper breast off-white, darker laterally, lower breast white to grey, lower belly cinnamon, crissum cinnamon-brown; eye dark reddish-brown; bill mostly black; legs dark grey. Sexes similar. One juvenile known, face pattern more diffuse, lores grey, some brown on belly. Voice. Two song types, the first a series of loud ringing phrases, like song of *H. leucophrys* but faster, higher and with more ringing quality, the second consisting of longer phrases, beginning and ending with a trill; each sex sings an individual motif in syncopation with its partner. Call a rapid, high-pitched chatter.

Habitat. Originally discovered in impoverished forest types based on a quartz sand soil, with "sparse canopy of stunted trees"; more recently has been found in more varied habitat, from tall moist hill forest to fern-covered slopes in savanna woodland.
Food and Feeding. Stomach contents seem to consist entirely of invertebrates. Has finer bill and heavier legs than *H. leucophrys* and may differ in foraging habits, possibly specializing in vertical perches or in foraging near the ground.
Breeding. Juvenile in mid-Jul. No other information.
Movements. Probably sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in Andean Ridge-top Forests EBA and North-east Peruvian Cordilleras EBA. Has been described as common or abundant in some places. Distribution imperfectly known. Locations where it has been observed appear not to be currently under any pressure, being areas of poor soil and with little marketable timber.

Genus *MICROCERCULUS* P. L. Sclater, 1862

78. Southern Nightingale-wren

Microcerculus marginatus

French: Troglodyte siffleur **Spanish**: Cucarachero Ruiseñor Sureño
German: Schuppenbrust-Zaunkönig
Other common names: Scaly-breasted Wren/Nightingale-wren, Scaling Nightingale-wren; Whistling Wren (*luscinia*)

Taxonomy. *Heterocnemis marginata* P. L. Sclater, 1855, "Bogotá", Colombia.
Sometimes treated as conspecific with *M. philomela*, but differs substantially in vocalizations. Race *luscinia* regarded by some authorities as a full species; alternatively, this and other more northerly races (*squamulatus*, *corrasus*, *occidentalis*, *taeniatus*) together possibly form a separate species. In addition, recent DNA studies suggest that populations of nominate race N of Amazon may represent a different species from those S of the river, despite absence of obvious morphological differences. Race *occidentalis* sometimes merged with *taeniatus*. Six subspecies currently recognized.
Subspecies and Distribution.
M. m. luscinia Salvin, 1866 – C Costa Rica S to Panama (S to E Darién).
M. m. squamulatus P. L. Sclater & Salvin, 1875 – N Colombia (except Santa Marta) and mountains of NW & N Venezuela (E in coastal range to Distrito Federal).
M. m. corrasus Bangs, 1902 – Santa Marta region of N Colombia.
M. m. occidentalis Hellmayr, 1906 – W Colombia and NW Ecuador.
M. m. taeniatus Salvin, 1881 – tropical zone of W Ecuador.
M. m. marginatus (P. L. Sclater, 1855) – W Amazonia, from E Ecuador, E Colombia and S Venezuela (SW Amazonas) S to E Peru, W & C Brazil (E, S of Amazon, to Maranhão) and N & NE Bolivia.

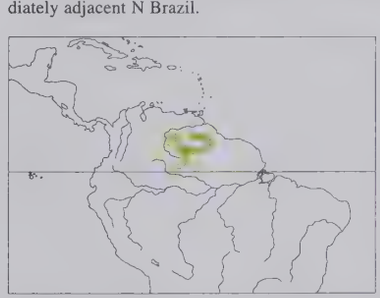
Descriptive notes. 11 cm; male 18·2–22 g, female 17–18 g. Nominate race has face dull grey-brown, crown and upperparts deep chocolate-brown, with rump slightly more rufescent; primaries, secondaries and tertials dark chocolate-brown, tertials with obscure darker barring; rectrices extremely short, dark chocolate-brown; chin to upper belly white, feathers on side of chest scalloped with blackish, lower flanks, belly and thighs deep chocolate-brown; eye dark brown; bill black, creamy base of lower mandible; legs greyish-black. Sexes similar. Juvenile has obscure darker barring on crown and back, dark brown feather tips below, flank barring more pronounced. Race *squamulatus* is similar to nominate, but with scaly markings on underparts; *taeniatus* is similar to previous, but deeper rufous-brown above, blackish barring below wider and better defined; *corrasus* is also similar, but purer white with narrower dark bars below, finer bill; *occidentalis* differs from nominate in having longer and thinner bill, darker upperparts and flanks, broad dark bars on abdomen; *luscinia* has throat whitish to pale grey becoming brownish-grey on breast and upper belly, with deep brown flanks and lower belly. Voice. Songs differ geographically. In Central America starts with series of c. 10–15 short notes that slow, lengthen, become louder and rise in pitch, followed by 2 loud upslurred notes, and then a series of pure, long-drawn-out high-pitched whistles, becoming longer and ending in a series of double whistles, entire sequence lasting up to 2·5 minutes; this song type occurs also from Panama S to W Amazonia, with minor differences in E Amazonia. Song in E Peru and N Bolivia consists of clear, pure notes given at random, with changes in pitch, length and volume. Call (in Costa Rica) a chatter like that of an antbird (Thamnophilidae), and loud "stchep".
Habitat. Inhabits lower levels of dense, humid tropical forest. Recorded from sea-level up to 1700 m in Costa Rica, up to 1400 m in Colombia and up to 1800 m in Venezuela; one record at 3100 m in Panama (Chiriquí).
Food and Feeding. Few published data available on food items consumed; a nesting pair in Panama was seen to carry spiders (Araneae) and orthopterans to its nestlings. Generally solitary. Forages low down in vegetation and on ground, walking in manner of an antpitta (Formicariidae); is occasionally found associated with army ants in Central America, but appears not to follow swarms routinely.
Breeding. Season seems to be quite protracted; adults observed feeding fledged young in mid-Feb in Costa Rica, and nests found in late May and early Jul and female in breeding condition in Nov, all in Panama. Following details from Panama: two nests described (Chiriquí, Canal Zone), made of dead leaves, situated at end of burrows in earthen banks, probably originally excavated by Blue-crowned Motmot (*Momotus momota*) in one case and by Scaly-throated Leaftosser (*Sclerurus guatemalensis*) in the other; respective clutches of 2 and 3 eggs (eggs stated to be white, but without confirmatory detail); at one nest, incubation recorded as 16–17 days and fledging period c. 19–20 days.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Population density usually fairly low, but the species appears to be well distributed in much of its range. Occurs in a number of national parks and similar protected areas, including e.g. Henri Pittier National Park, in Venezuela, Río Palenque Science Centre, in Ecuador, Manu National Park and Biosphere Reserve, in Peru, and Rio Cristalino Forest Reserve, in Brazil.
Bibliography. Allen (1995, 1998), Anon. (1998b), Chapman (1917), Christian & Roberts (2000), Haffer (1975), Hellmayr (1934), Hennessey *et al.* (2003), Hilty (1997, 2003), Hilty & Brown (1986), Meyer de Schauensee (1982), Orejuela *et al.* (1980), Oren & Parker (1997), Perry *et al.* (1997), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Ridgway (1904), Robbins *et al.* (1985), Robinson & Terborgh (1997), Salaman (1994), Schönwetter (1963–1974), Sick (1993, 1997), Slud (1958), Stiles (1984), Stiles & Skutch (1989), Stotz *et al.* (1997), Wetmore *et al.* (1984), Zimmer *et al.* (1997).

79. Northern Nightingale-wren

Microcerculus philomela

French: Troglodyte philomèle **Spanish**: Cucarachero Ruiseñor Norteño
German: Nachtigallzaunkönig
Other common names: Dark-throated Nightingale-wren

Taxonomy. *Cyphorhinus philomela* Salvin, 1861, Alta Vera Paz, Guatemala.
Sometimes treated as conspecific with *M. marginatus*, but differs markedly in vocalizations. Monotypic.
Distribution. Lowlands of S Mexico (N Chiapas), NC Guatemala, S Belize, and Caribbean lowlands of Honduras, Nicaragua and N Costa Rica (S to R Reventazón).



Descriptive notes. 10–11·5 cm; male 17·4–21·5 g, female 16·4–17·4 g. Lores and side of face are dull greyish-brown; crown and upperparts deep chocolate-brown, each feather tipped blackish, giving obscure scaled appearance; primaries, secondaries and extremely short tail dull brownish-black; throat dark grey with blackish-brown mottling; chest and belly dull blackish-brown, speckled paler grey, lower belly and flanks more rufescent, flanks with obscure darker barring; eye dark brown; bill and legs black. Sexes similar. Juvenile is darker and less rufescent than adult, crown and back with obscure black edgings, underparts darker and more dusky with little grey, feather edgings producing scaly appearance. Voice. Song unmistakable and "haunting", a series, up to 30 seconds long, of clearly whistled notes, c. 2 per second, pitch of each note changing either up or down unpredictably (impression of "a slightly tone-deaf person whistling a hymn-tune"), the sequence usually preceded by a softer ascending series of more rapid notes. Call a harsh "thuk"; juvenile begging call a soft, sad "peew".
Habitat. Humid lowland forest, especially undisturbed virgin evergreen forest and contiguous cloudforest; sea-level to 1200 m, sometimes to 1800 m.
Food and Feeding. Little information; in Costa Rica, insects, woodlice (Isopoda), spiders (Araneae) and centipedes (Chilopoda) recorded as food. Typically, feeds on or very near the ground, or on fallen logs, walking with teetering motion.
Breeding. Season from May or Jun until at least Sept in Costa Rica. No other information available.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Uncommon to fairly common in Mexico, uncommon in Guatemala, apparently rare in Belize, uncommon to fairly common in Honduras, and locally common in Costa Rica. Not tolerant of modification of its habitat, and is therefore vulnerable to forest disturbance; large areas of its range have been extensively deforested, a process which continues apace. Some parts of range protected, such as the Selva Lacandona, in Mexico, Boswas and Río Indio, in Nicaragua, and several reserves in N Costa Rica.
Bibliography. Blake (1953), Gillespie (2001), González-García (1993), Griscom (1932b), Hellmayr (1934), Howell & Webb (1995), Land (1970), Lee Jones (2004), Leger *et al.* (2000), Monroe (1968), Paynter (1957), Phillips (1986), Ridgway (1904), Slud (1960, 1964), Stiles (1983, 1984), Stiles & Skutch (1989), Wiley (2000).

80. Flutist Wren

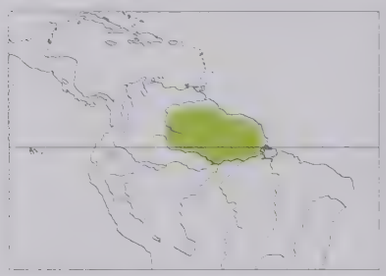
Microcerculus ustulatus

French: Troglodyte flûtiste **German**: Flötenzaunkönig **Spanish**: Cucarachero Flautista

Taxonomy. *Microcerculus ustulatus* Salvin and Godman, 1883, Cerro Roraima, Bolívar, Venezuela.
Four subspecies recognized.
Subspecies and Distribution.
M. u. duidae Chapman, 1929 – cerros of W Bolívar and Amazonas, in S Venezuela.
M. u. lunatipectus J. T. Zimmer & Phelps, Sr, 1946 – cerros of C Bolívar.
M. u. obscurus J. T. Zimmer & Phelps, Sr, 1946 – cerros of E Bolívar (S to Gran Sabana).
M. u. ustulatus Salvin & Godman, 1883 – subtropical zone of W Guyana, SE Venezuela and immediately adjacent N Brazil.

Descriptive notes. 11·5 cm; 22 g. Nominate race has crown medium chocolate-brown, with faint scalloping; upperparts medium chocolate-brown, slightly rufescent on lower back and rump; primaries and secondaries dull blackish-brown, very short tail chocolate-brown; chin pale brown with obscure darker feather edgings; chest more rufescent with more prominent edgings, thighs, lower belly and vent dark chocolate-brown; eye brown; bill black, creamy base of lower mandible; legs black. Sexes similar. Juvenile has obscure dark barring below. Race *obscurus* is darker above and more rufous below than nominate; *lunatipectus* has heavier and more extensive scaling below than other races, extending forwards onto throat; *duidae* is generally paler than nominate, with lighter, less rufous, upperparts, less umber underparts. Voice. Song a superb glissando which, after a couple of introductory notes, gradually and slowly slides up the scale, entire sequence continuing for 10–20 or more seconds; variant song is similar, but with notes more clipped and gradually dropping in pitch.
Habitat. Inhabits dense wet montane subtropical forest, including flat summits of some tepuis, at 860–2100 m.
Food and Feeding. Arthropods; no details. Generally solitary. Picks, gleans and probes for food items on forest floor, occasionally a little above it.
Breeding. No information.

On following pages: 81. Wing-banded Wren (*Microcerculus bambla*); 82. Chestnut-breasted Wren (*Cyphorhinus thoracicus*); 83. Song Wren (*Cyphorhinus phaeocephalus*); 84. Musician Wren (*Cyphorhinus arada*); 85. Donacobius (*Donacobius atricapilla*).



Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in Tepuis EBA. Quite common in some areas. Much of the species' range is almost uninhabited by humans and of very difficult access. Species occurs in various protected areas, such as Canaima National Park (SE Bolívar).
Bibliography. Barnett *et al.* (2002), Blake & Loiselle (1991), Chapman (1931), Cracraft (1985), Hellmayr (1934), Hilty (2003), Mayr & Phelps (1967), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Ridgely & Tudor (1989), Sick (1993, 1997), Snyder (1966), Wheatley (1994), Willard *et al.* (1991).

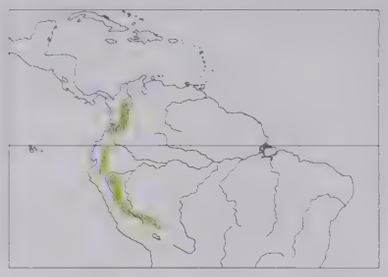
81. **Wing-banded Wren**

Microcerculus bambla

French: Troglodyte bambla **Spanish**: Cucarachero Alifranjeado
German: Weißbinden-Zaunkönig

Taxonomy. *Formicarius bambla* Boddaert, 1783, Cayenne.
Three subspecies recognized.
Subspecies and Distribution.
M. b. bambla (Boddaert, 1783) – extreme E Venezuela (E Bolívar), the Guianas and N Brazil (Roraima E to Amapá).
M. b. caurensis Berlepsch & Hartert, 1902 – S & SE Venezuela (S Bolívar, Amazonas) and extreme E Colombia.
M. b. albigularis (P. L. Sclater, 1858) – E Ecuador (Sucumbíos, Napo, Pastaza), E Peru and NW Brazil (NAmazonas).

Descriptive notes. 11·5 cm; c. 17–19 g. Nominate race has lores and ear-coverts dark brown; crown and upperparts blackish-brown, each feather obscurely tipped darker brown; primaries, secondaries and upperwing-coverts dark chocolate-brown, greater coverts with conspicuous broad white tips (forming complete white bar across closed wing), lesser coverts narrowly tipped whitish; tail very short, rectrices blackish-brown, obscurely barred darker brown; chin dull greyish, throat darker grey, chest grey-brown with obscure darker feather tips, belly and flanks browner than chest, faintly barred; eye brown; bill black above, below yellowish to fleshy pink with dusky-brown tip; legs brownish-grey. Sexes similar. Juvenile lacks conspicuous wingbar, and has underparts more scaly. Race *caurensis* is brighter rufous above than nominate, lacks dusky markings on back, breast and flanks; *albigularis* is similar to previous, but paler throat. Voice. Song is a beautiful series of 3–6 clear, pure high-pitched notes separated by short pauses; sometimes ends after this prologue, or continues in series of accelerating notes which merge into long, sustained glissando of shorter and lower notes. Call is a sharp metallic "click".
Habitat. Lowland rainforest, including forest with dense understorey and somewhat more open types; essential requirement appears to be a wet understorey rich in rotting logs. From sea-level up to 1100 m, in Venezuela sometimes to 1500 m; usually at rather lower levels than those occupied by *M. ustulatus*.
Food and Feeding. Adults in French Guiana seen to carry moths (Lepidoptera), worms, orthopterans, spiders (Araneae) and tiny frogs to nest; no other data on prey items. Feeds on ground or very low down; seems to specialize in exploring rotten logs and the detritus from rotting trees, often disappearing into cavities for a few seconds; appears rarely to explore leaf litter, in contrast to other members of genus.
Breeding. Two nests described (both in Nouragues Natural Reserve), on 21st and 22nd Mar, and individual carrying food on 21st Jan, all in French Guiana. Each nest c. 2 m up in cavity in termite (Isoptera) nest on rotten buttress of fallen dead tree, cavity probably previously excavated by Yellow-billed Jacamar (*Galbula albirostris*); each held one well-grown nestling, which was fed by both of its parents. No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Widely distributed but not particularly common in French Guiana; only recently discovered in Suriname, where is probably rare; apparently commoner in parts of Guyana; local and uncommon in Venezuela; locally distributed in Ecuador, and rare in Peru. Probably requires relatively undisturbed habitat. Some areas of its habitat lie within protected reserves, e.g. at Iwokrama, in Guyana, and Manu, in Peru. This species appears to be at relatively little risk at present, as large parts of its range are very sparsely populated by human beings.
Bibliography. Bangs & Penard (1918), Clements & Shany (2001), Cohn-Haft *et al.* (1997), Cracraft (1985), Dick *et al.* (1984), Friedmann (1948), Gilliard (1941), Haverschmidt & Mees (1994), Hellmayr (1934), Hilty (2003), Huguet & Tostain (1990), Jullien & Cariveau (2001), Mees (1968), Meyer de Schauensee (1982), Novaes (1974), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Servat & Pearson (1991), Snyder (1966), Stiles (1984), Terborgh *et al.* (1984), Tostain *et al.* (1992), Willard *et al.* (1991).



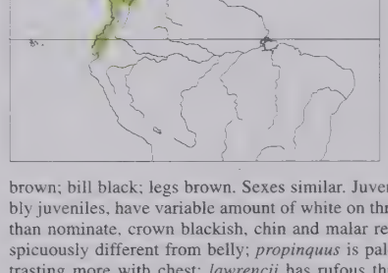
Genus *CYPHORHINUS* Cabanis, 1844

82. **Chestnut-breasted Wren**

Cyphorhinus thoracicus

French: Troglodyte ferrugineux **Spanish**: Cucarachero Pechicastaño
German: Kastanienbrust-Zaunkönig

Taxonomy. *Cyphorhinus thoracicus* Tschudi, 1844, mountains of Uchubamba, near Vitoc, Junín, Peru.
May form a superspecies with *C. phaeocephalus* and *C. arada*. Two subspecies recognized.
Subspecies and Distribution.
C. t. dichrous P. L. Sclater & Salvin, 1879 – W & C Andes of Colombia (S from Antioquia) S to N Peru (San Martín).
C. t. thoracicus Tschudi, 1844 – Peru (Huánuco S to Puno) and W Bolivia.



Descriptive notes. 15 cm; male 30·5–35 g, female 29–29·6 g. Has lores sooty black, ear-coverts and area behind eye deep orange-brown, bare skin around eye blue; crown sooty black, back and rump rich dark brown; shoulders, upperwing-coverts and remiges dark brown, primaries slightly lighter than secondaries; rectrices dark brown; chin brownish-grey, throat and chest deep orange-brown, upper belly buff-orange, flanks and lower underparts dark brown; eye brown; bill and legs black. Sexes similar. Juvenile is very like adult, but lower belly paler. Race *dichrous* is darker on head, wings and abdomen than nominate. Voice. Song a series of usually 3 or 4 ethereal, clear whistled notes in repeated cadence, often one rising note, one at same pitch and one falling, or variations on this theme, repeated continuously; quite different from songs of its two congeners. Call a harsh "churr".
Habitat. Wet montane forest, including epiphytic cloudforest with abundant growth of moss; mostly 1300–2300 m, in Colombia down to 700 m on Pacific slope.
Food and Feeding. No published data on food items. Mostly terrestrial in habits.
Breeding. Season apparently protracted; in Colombia, full-grown juvenile in Apr, birds in breeding condition in Jun, nest-building observed in Sept, and two juveniles attended by adults in Dec. No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Quite common in parts of Colombia; scarce in Ecuador; uncommon to locally common in Peru. Some areas of its range lies within protected reserves. Occurs in e.g. Ucumarí Regional Park, in Colombia, and Cock-of-the-Rock Lodge, in Peru.

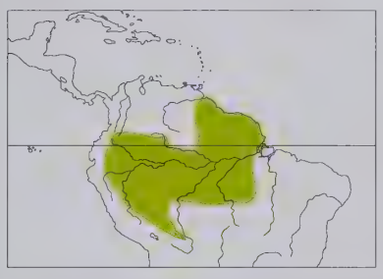
83. **Song Wren**

Cyphorhinus phaeocephalus

French: Troglodyte chanteur **German**: Brillenzaunkönig **Spanish**: Cucarachero Canoro
Other common names: Northern Musician/Northern Musical Wren

Taxonomy. *Cyphorhinus phaeocephalus* P. L. Sclater, 1860, Esmeraldas, Ecuador.
May form a superspecies with *C. thoracicus* and *C. arada*. Sometimes regarded as conspecific with latter, an implausible treatment given the very distinct vocalizations of the two species. Six subspecies recognized.
Subspecies and Distribution.
C. p. richardsoni Salvin, 1893 – Caribbean lowlands of SE Honduras and E Nicaragua.
C. p. infuscatus J. T. Zimmer, 1932 – Caribbean lowlands of Costa Rica and NW Panama (Almirante).
C. p. lawrencii Lawrence, 1863 – Panama (except NW) and extreme NW Colombia (Golfo de Urabá).
C. p. propinquus (Todd, 1919) – tropical lowlands of NW Colombia.
C. p. chocoanus (Meyer de Schauensee, 1946) – W Colombia (from near Panamanian border) S to N Chocó.
C. p. phaeocephalus P. L. Sclater, 1860 – W Colombia (S Chocó) S to S Ecuador (El Oro).

Descriptive notes. 13-15 cm; mean 24·6 g. Has odd-shaped bill compressed laterally, with sharp arched culmen. Nominate race has lores blackish-brown, area behind eye and ear-coverts warm orange-brown; bare skin around eye grey-white or flesh-coloured, some blue at rear of eye; crown blackish-brown, upperparts rich dark brown, upper and middle back with very faint darker bars; outer webs of primaries and secondaries barred orange-brown and dark brown; rectrices dark brown with darker barring; chin, throat and chest warm orange-brown, chest side and belly medium brown, sometimes some white feathers on belly; eye brown; bill black; legs brown. Sexes similar. Juvenile is similar to adult; some individuals, possibly juveniles, have variable amount of white on throat. Race *chocoanus* is darker above and below than nominate, crown blackish, chin and malar region more conspicuously black, chest not conspicuously different from belly; *propinquus* is paler above and below than nominate, throat contrasting more with chest; *lawrencii* has rufous throat contrasting with paler chest; *infuscatus* is similar to previous but generally darker, crown more distinctly black; *richardsoni* has more brightly rufescent rump. Voice. Song a remarkable medley of clear, flute-like whistles, rising and falling, interspersed with harsh "chowk chowk-a-chowk chuck" noises; partners sing antiphonally, each sex contributing its own motif of whistled notes, the combination giving complicated medley, along with harsher "chowk" notes. Calls harsh and croaking, resembling parts of song; alarm a series of harsh churrs.
Habitat. Humid lowland forest and wet second-growth woodland; sea-level to 700 m, more rarely to 1050 m.
Food and Feeding. Apparently only invertebrates, small insects and spiders (Araneae), taken on or near the ground. Generally in family groups during much of year. Sometimes follows ant swarms.
Breeding. Jan–May, rarely Oct, in Costa Rica; in Panama season extends over 7 months, but individuals may breed for period of only 10 weeks; birds in breeding condition Mar–May in Colombia. Mature female may breed with same male for several seasons and then initiate divorce, even when alternative male not immediately available. Nest a bulky, untidy structure of coarse fibrous roots and leaf skeletons, built over thin branch with enclosed nesting chamber on one side, downward-sloping entrance on other, typically c. 0·6–2·5 m above ground; in study in C Panama, 78% of nests found were in acacia trees (*Acacia*) defended by aggressive symbiotic ants, but ant-defended nests no more successful than non-defended ones (in contrast to the situation with some *Campylorhynchus* species). Eggs usually 2, sometimes 3, white with variable amount of brown speckling around blunt end; no information on incubation and fledging periods; male offspring may remain with parents for 4–18 months after fledging, but, unlike some *Campylorhynchus* wrens, they do not provide assistance in rearing younger siblings.



Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Appears to be reasonably common over much of its range. Substantial habitat loss has occurred in several countries; whether this has caused any declines in this species' numbers is not known.
Bibliography. Best *et al.* (1997), Butler (1979), Chapman (1917), Cracraft (1985), Haffer (1975), Hellmayr (1934), Hilty & Brown (1986), Howell (1957), Loiselle (1988), Monroe (1968), Poulin & Lefebvre (1996), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Robinson (1998a, 1998b), Robinson *et al.* (2000), Skutch (1940, 1960, 1985b), Slud (1960, 1964), Stiles & Skutch (1989), Wikelski *et al.* (2003).

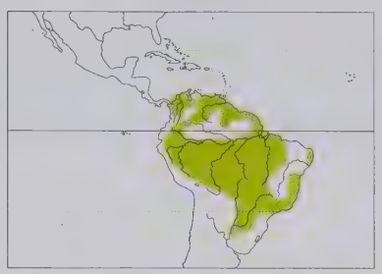
84. **Musician Wren**

Cyphorhinus arada

French: Troglodyte arada **German**: Orpheuszaunkönig **Spanish**: Cucarachero Musical
Other common names: Musical/Southern Musical Wren, Quadrille Wren, Carillon Wren, Organ Wren (some races), Necklaced Jungle Wren (some races)

Taxonomy. *Myrm[ornis] arada* Hermann, 1783, Cayenne.
May form a superspecies with *C. thoracicus* and *C. phaeocephalus*. Sometimes regarded as conspecific with latter, an implausible treatment given the very distinct vocalizations of the two. It has been suggested that NE races possibly represent a separate species from W & S races. Species name often erroneously emended to *aradus*; the name is not of Latin origin but from a local native language, and as such must remain invariable. Eight subspecies recognized.
Subspecies and Distribution.
C. a. arada (Hermann, 1783) – E Venezuela, the Guianas and NE Brazil (E from lower R Negro, S to Amazon).
C. a. urbanoi (J. T. Zimmer & Phelps, Sr, 1946) – Gran Sabana (SE Bolívar), in SE Venezuela.
C. a. faroensis (J. T. Zimmer & Phelps, Sr, 1946) – region of Faro and Óbidos (probably also W to mouth of R Negro), on lower Amazon (Brazil).
C. a. transfluvialis (Todd, 1932) – base of E Andes in S Colombia (Caquetá) E to NW Brazil (E to R Negro).
C. a. salvini Sharpe, 1882 – S Colombia (Putumayo), E Ecuador and NE Peru (Loreto).
C. a. modulator (d'Orbigny, 1838) – lowlands of E Peru, W Brazil (E, S of Amazon, to R Madeira) and N Bolivia.
C. a. interpositus (Todd, 1932) – NC Brazil from R Madeira E to R Tapajós, S to N Mato Grosso.
C. a. griseolateralis Ridgway, 1888 – S bank of lower Amazon E of R Tapajós, S to R Jamanxim (Brazil).

Descriptive notes. 12·5 cm; 18–24 g. Nominate race has forehead and forecrown rufous, becoming chestnut-brown on rear crown; postocular supercilium pale buff narrowly bordered blackish; postocular stripe chestnut-brown, ear-coverts orange-brown, broad brownish-black collar with conspicuous longitudinal white streaks across shoulders and upper back; lower back and rump colder, less reddish-brown, than head; primaries and secondaries medium brown with narrow darker brown bars; rectrices medium brown with narrow darker brown bars; chin, throat and upper chest bright orange-brown, sharply separated from pale buff lower chest and belly; flanks and lower belly medium ochraceous-brown; eye brown; bill greyish-black above, greyish with whitish base below; legs brown or greyish-black. Sexes similar. Juvenile is similar to adult, may have indistinct barring on lower belly. Race *urbanoi* has collar, but is paler above and below than nominate; *faroensis* has very conspicuous white streaks on shoulders; *transfluvialis* is smaller and paler than nominate; *salvini* very dark, lacks streaked collar, has uniform brown auriculars and cheeks; *modulator* is closest to previous, but with more extensive supercilium, lighter upperparts; *interpositus* also lacks collar, has brownish-grey (not rufous) auriculars; *griseolateralis* has collar reduced in extent compared with nominate, is greyer below. Voice. Song, produced antiphonally by both sexes, is a series of clear, haunting whistles, varying greatly in pitch, the same phrase repeated many times with minor variation before switching to different motif, often interspersed with lower gurgling sounds. Call a harsh "churk".
Habitat. Lower levels of humid forest; in *várzea* in Brazil. Mostly sea-level to 500 m; occasionally to 1000 m, rarely to 1400 m, in Venezuela.
Food and Feeding. Mostly invertebrates; recorded prey items include caterpillars, beetles (Coleoptera), spiders (Araneae), millipedes (Diplopoda) and Crustacea. Berries also eaten. Usually found in pairs or family parties; does not usually associate with other species in mixed flocks, but occasionally follows ant swarms. Forages mostly on or near the ground, among debris and in leaf litter.
Breeding. Season quite protracted; eggs in Jul in Guyana, and fledged young in late Jul and nest with small young in Sept in Suriname. Nest roughly spherical, funnel-shaped neck with large entrance hole, made of leaf skeletons and coarse grass, lined with a few large feathers, usually supported across branch. Eggs 2, pure matt white. No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Generally uncommon to fairly common over its sizeable range. Although much of its habitat has been destroyed or rendered unsuitable, large areas remain over much of its range. Occurs in a number of protected areas, including Manu National Park and Biosphere Reserve, in Peru.
Bibliography. Allen (1995), Bangs & Penard (1918), Beebe *et al.* (1917), Best *et al.* (1997), Butler (1979), Chapman (1917), Chubb (1921), Clements & Shany (2001), Cracraft (1985), David & Gosselin (2002a), Gyldenstolpe (1950), Haverschmidt (1968), Haverschmidt & Mees (1994), Hellmayr (1934), Hilty (2003), Hilty & Brown (1986), Meyer de Schauensee (1982), Novaes (1974), Oren & Parker (1997), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Robinson & Terborgh (1997), Sick (1993, 1997), Snyder (1966), Terborgh *et al.* (1984), Tostain *et al.* (1992).



Genus *DONACOBIUS* Swainson, 1832

85. **Donacobius**

Donacobius atricapilla

French: Donacobe à miroir **German**: Rohrspottdrossel **Spanish**: Angú
Other common names: Black-capped Donacobius, Black-capped Mockingthrush

Taxonomy. [*Turdus*] *atricapilla* Linnaeus, 1766, Cape of Good Hope, South Africa; error = Brazil. Taxonomy long disputed: has frequently been thought to belong in family Mimidae, arguments for which treatment include large size, morphology (long tail, short rounded wings, heavy feet and legs), open cup-nest, and rambunctious and extroverted behaviour; in contrast, its well-developed social structure (with duetting vocalizations and mutual display) is very reminiscent of some troglodytids, notably in genus *Campylorhynchus*, in addition to which anatomical studies argue in favour of placement in present family; recent DNA studies, however, strongly suggest that this species is neither a mimid nor a troglodytid, but an aberrant "sylvioid", a group that includes the babblers (Timaliidae) and the Old World warblers (Sylviidae). Species name often erroneously emended to *atricapillus*, but *atricapilla* is a Latin noun and is thus invariable. Four subspecies recognized.
Subspecies and Distribution.
D. a. brachypterus Madarász, 1913 – Panama (E Darién) and NW Colombia (E to Santa Marta region, S to N Tolima).
D. a. atricapilla (Linnaeus, 1766) – N Venezuela, the Guianas, most of Brazil, Paraguay and extreme NE Argentina.
D. a. nigrodorsalis Traylor, 1948 – S & SE Colombia, E Ecuador and E Peru (S to Madre de Dios).
D. a. albovittatus d'Orbigny & Lafresnaye, 1837 – SW Brazil (Acre) S to N & E Bolivia (Beni, E Cochabamba, Santa Cruz).

Descriptive notes. 21·5–22 cm; 31–42 g. Nominate race has most of head and upperparts glossy jet-black, back suffused dark brown, rump warm olive-brown; primaries and secondaries dusky black, white base of primaries (conspicuous white patch visible on both open and closed wing); rectrices black, tipped white, amount of white increasing laterally, outer rectrix two-thirds white; chin buffy white, bare patch of deep yellow on each side of throat (not normally visible except during display); throat and chest warm buffy yellow, belly deep buff-yellow, upper flanks variably barred finely black; eye bright staring yellow; bill black; legs greenish-dusky. Sexes similar. Juvenile is dusky brown, rather than black, above, with pale line behind eye, the back medium brown, edged with rufous-brown, underparts unbarred and duller than adult's. Race *brachypterus* is smaller than nominate, lighter below, and with paler rump; *nigrodorsalis* is blacker on back; *albovittatus* differs from others in having prominent white supercilium. Voice. Sexes sing antiphonally, male a series of loud, ringing upward-slurred liquid whistles, "who-it, who-it, who-it", female a lower, sizzling or grating sound; other members of co-operative group may also sing, with sex-specific song. Calls are grating scolds.
Habitat. Brushy areas along riversides, especially in successional vegetation in oxbow lakes; also overgrown edges of artificial water impoundments. May forage away from riversides, but breeds only in marshy areas. Sea-level to 600 m; occasionally as high as 1400 m in Ecuador.
Food and Feeding. Food almost exclusively invertebrates; recorded items (Suriname) include hymenopterans, beetles (Coleoptera), orthopterans, neuropterans and arachnoids. Forages in pairs and in groups. Items usually taken from leaf surfaces, but occasionally caught in flight.
Breeding. Season very protracted in N of range, Jan–Aug, peak in May–Jul; in Peru mainly in rainy season, from Oct onwards, with majority fledging in Nov–Jan. Often breeds co-operatively, pair may have up to two helpers, offspring from previous year or the year before that, which help in nest defence and in brood-feeding; unassisted pairs less successful than assisted ones. Partners display by perching close to one another while singing, bobbing the head and waving the partly spread tail sideways rhythmically; other members of a co-operative group may also sing. Nest-building apparently mainly by female, which may pilfer material from nests of other species; deep bulky cup made of vegetable fibres, snakeskins, etc., c. 10–15 cm in diameter, cup 7·5–8 cm across and 6 cm deep, situated 0·25–1 m up, occasionally to 2 m, in vegetation, frequently over water; tends to be higher up when over dry ground; territories in good habitat can be very small, often only a few metres wide and up to 100 m long. Clutch usually 2 eggs in N South America, quite commonly 3 in SE Brazil (São Paulo), eggs purplish-white, thickly covered with purplish and reddish spots and blotches; incubation by female alone, period 16–18 days; hatchling naked, with conspicuous pattern of three black spots on pink base inside mouth (almost unique among Neotropical passerines); chicks fed by both parents, also by helpers if present, adults cool them by wetting own feathers prior to brooding; fledging period 17–18 days. Success apparently dependent on presence of helpers; unassisted pairs usually fledged only one young, whereas all observed cases in which two young were reared involved pairs with helpers.
Movements. Sedentary; in study of individually marked birds in Peru, no evidence of movement noted between suitable areas of habitat only 2 km apart.
Status and Conservation. Not globally threatened. Generally common throughout much of extensive range; abundant in suitable habitat in some areas. May in some cases benefit from human activity, as where water impoundments are allowed to become overgrown at edges.
Bibliography. Aguilar (1995), Anon. (1998b), Barker *et al.* (2002), Bloch *et al.* (1991), Clench *et al.* (1982), David & Gosselin (2000, 2002a), Griscom (1923), Hilty (2003), Hilty & Brown (1986), Kiltie & Fitzpatrick (1984), Lowen *et al.* (1996), Parker & Goerck (1997), Pozza & Pires (2003), Ragusa-Netto (1996, 1997, 1998), Ridgely & Greenfield (2001), Ridgely & Gwynne (1989), Ridgely & Tudor (1989), Robinson (1997), do Rosário (1996), Schäfer & Phelps (1954), Sick (1993, 1997), Skutch (1968, 1985b), Tostain *et al.* (1992), Young (1925).

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family MIMIDAE (MOCKINGBIRDS and THRASHERS)

- Medium-sized thrush-like birds, with short wings, long legs and long tail; generally dull-plumaged, mostly grey or brown, some with white or rufous.
- 19–32 cm.

- New World.
- Second growth, open woodland, scrub and desert habitats.
- 11 genera, 34 species, 85 taxa.
- 5 species threatened; none extinct since 1600.

Systematics

The family Mimidae is a relatively compact group of some three dozen species of ten-primaried oscine songbirds that extends broadly throughout the New World, from southern Canada south to the southern extremities of South America. Its species occupy mainly scrub and arid habitats, with a centre of diversity and radiation in south-western North America, but reaching, and radiating on, islands on both the Pacific and the Atlantic sides of the continents.

Mimids bear a superficial resemblance to other largely ground-foraging birds in both the Western Hemisphere and other parts of the world. Such superficially similar species are found particularly among the thrushes (Turdidae), a resemblance that accounts for the early classification of mimids with thrushes; it is reflected also in their early common names, such as "Curve-billed Thrush" and "Rufous Thrush" for, respectively, the California Thrasher (*Toxostoma redivivum*) and the Brown Thrasher (*Toxostoma rufum*). The term "thrasher" itself, in common use for species in the genera *Toxostoma*, *Oreoscoptes*, *Margarops* and *Ramphocinclus*, constituting 14 of the family's members, is likely derived from "thrusher" or "thresher", words of old English dialect and meaning "thrush" or "thrush-like". In fact, there are unrelated birds in other biogeographical regions that are ecologically equivalent and more similar to mimids, in terms of superficial morphology, than are thrushes. Good examples are found among the Old World babblers (Timaliidae), including African *Turdoides* species and, especially, Australian *Pomatostomus* species, among some African larks (Alaudidae) of the genera *Alaemon*, *Mirafra*, *Chersophilus* and *Chersomanes*, and especially in the South American earthcreepers (*Upucerthia*) of the family Furnariidae. All of these birds share with *Toxostoma* and related thrashers the habit of foraging on the ground in scrub or semi-desert, aided by long legs, a long tail and a long, decurved bill, and are excellent examples of convergent evolution.

The systematic disentangling of the mockingbirds and thrashers from the thrushes began in the middle of the nineteenth century, when C. L. Bonaparte erected the family name in current usage. This name, Mimidae, incidentally, takes precedence over the name "Toxostomidae", suggested by C. J. Sundevall in 1872. By the final decade of that century the family was a well-established entity. It took somewhat longer, however, for the generic names with which ornithologists are now familiar to become stabilized. Initially, North American mimids, mockingbirds and thrashers alike, were classified as species of *Mimus*, but J. Cassin, writing in 1853–1855, used the name *Toxostoma* for the western thrashers. Later, and well into the mid-1900s, thrasher species were widely referred to the genus *Harporhynchus*, but *Toxostoma*, by dint of the usual rules of nomenclatorial precedence, has carried the day.

In traditional taxonomic sequences over the last century or so, the mockingbirds and thrashers have remained in close prox-

By virtue of their conspicuous behaviour, and their distribution from southern Canada to Tierra del Fuego, the most familiar mimids are mockingbirds in the genus Mimus. *They have long tails, strong legs, slightly decurved bills and boldly patterned wings. Although two species are extremely familiar suburban birds across much of North America and the northern Neotropics, the main radiation is found in austral climes: six of the nine species of* Mimus *have ranges centred on Peru, Brazil, or countries further south. One of these, the* ***Long-tailed Mockingbird****, occurs in the semi-arid coastal lowlands of Ecuador and Peru.*

[*Mimus longicaudatus longicaudatus*, Cerro Chaparri, Lambayeque, Peru. Photo: Tui de Roy/ The Roving Tortoise]

The most diverse genus in the family is Toxostoma, *with ten species. This group of thrashers differs from* Mimus *mockingbirds chiefly in having more retiring habits, plainer wings and tail, and a longer, more dramatically decurved bill. The thrashers use the bill for sweeping aside sand and debris when foraging on the ground, a sideways swiping motion that necessitates a specialized cranial structure and associated jaw and neck musculature. The main radiation occurs in the arid scrublands and deserts of the south-western USA and north-western Mexico, where the ranges of six* Toxostoma *species, including the* ***Crissal Thrasher****, are centred.*

[*Toxostoma crissale*, Riverside County, California, USA. Photo: Brian E. Small]

imity to the thrushes, and adjacent to the wrens (Troglodytidae), to which they were thought to be most closely related. Recent evidence, however, supports a quite different affiliation, namely of mimids to starlings (Sturnidae). C. G. Sibley and J. E. Ahlquist used electrophoresis of egg-white proteins and DNA–DNA hybridization as means of examining the broader relationships among avian families, publishing their findings in 1984 and 1990. Their radically new taxonomy subdivided the oscine passerines, which include about one half of all avian species, into two "parvorders", which they called Corvida and Passerida. They further subdivided the latter into three superfamilies, Muscicapoidea, Sylvioidea and Passeroidea. The first of these encompasses the waxwings (Bombycillidae), the dippers (Cinclidae), the thrushes and the Old World flycatchers (Muscicapidae), as well as the family Sturnidae. In this arrangement, the traditional links between mimids and wrens, and between starlings and crows (Corvidae), were abolished. Sibley and Ahlquist concluded, in particular, that the Old World "Sturnini" and the New World "Mimini" were sister-tribes in the Sturnidae, and represented each other's closest relatives. This link is further strengthened by similarities in morphological attributes, namely jaw musculature and cranial structure, and also by serological studies. The Sturnini are Old World endemics and the Mimini New World endemics; the split between the two groups is thought to have occurred about 28–23 million years ago, when North America was last linked to Eurasia across the north Atlantic and climates were benign.

Nearly two-thirds of the species in this family are presently placed in two genera, *Mimus* and *Toxostoma*. The first of these includes the Northern Mockingbird (*Mimus polyglottos*), very widely distributed over most of North America, and the Tropical Mockingbird (*Mimus gilvus*), which extends from southern Mexico and the Caribbean southwards to north and east South America. The main radiation of this genus, however, is in temperate and subtropical South America, where *Mimus* is the only representative of the family, and where six other species occur. Two of these, the Long-tailed (*Mimus longicaudatus*) and Chilean Mockingbirds (*Mimus thenca*), are grouped together on account of their larger size and the possession of blackish "whiskers"; they occupy non-overlapping ranges west of the Andes. Four non-whiskered species occur east of the Andes, ranging from Surinam and Brazil south to southern Argentina and, marginally, southern Chile, with some degree of sympatry. Although all are typically found in open, scrub or desert habitats, one species, the Chalk-browed Mockingbird (*Mimus saturninus*), with an extensive range in eastern South America, has isolated populations in savannas and non-forested areas of lower Amazonia.

The second large mimid genus, with one more species than *Mimus*, is *Toxostoma*. This has a radiation centred in the arid scrublands and deserts of the south-western USA and north-western Mexico. Six of the ten *Toxostoma* thrashers have ranges that either include or are restricted to this region. Some attempt has been made to determine species relationships within the genus. For example, the California Thrasher, the Crissal Thrasher (*Toxostoma crissale*) and Le Conte's Thrasher (*Toxostoma lecontei*) form a rather distinct group of plain-breasted and long-billed, basically allopatric species that are considered to be each other's nearest relatives. Le Conte's Thrasher has a population isolate in the Central Valley of southern California, and another in Baja California has been proposed as a distinct species, "*Toxostoma arenicola*". These species are distinct from congenerics that have a spotted breast and a somewhat less curved bill. With regard to the latter, close relationships are recognized among three species of eastern North America, these being the Brown Thrasher, the Long-billed Thrasher (*Toxostoma longirostre*) and the Cozumel Thrasher (*Toxostoma guttatum*), the last confined to the island of Cozumel, off Mexico's Yucatán Peninsula. The term "superspecies" has been used for these various species groups. Two other members of this genus, Bendire's Thrasher (*Toxostoma bendirei*) and the Grey Thrasher (*Toxostoma cinereum*), are allopatric and thought to be sister-species, but the affiliations of two largely Mexican species, the Curve-billed (*Toxostoma curvirostre*) and Ocellated Thrashers (*Toxostoma ocellatum*), are less clear.

Three other mimid genera, all monotypic, are of mainland distribution, apart from a few populations on near-shore islands. One contains the Sage Thrasher (*Oreoscoptes montanus*) of the Great Basin desert of the western USA, which is regarded as closer to *Mimus* than to the *Toxostoma* thrashers. The two catbird genera, *Dumetella* and *Melanoptila*, comprise species of northern and eastern temperate distribution, one ranging widely over the eastern and central parts of the USA and spending the non-breeding season south of the Mexican border, and the other restricted to the Yucatán Peninsula. The two are phylogenetically close, and the Black Catbird (*Melanoptila glabrirostris*) is sometimes placed together with its more widespread northern relative in *Dumetella*. In contrast, the two species of *Melanotis* are typical of tropical and subtropical scrub and edge habitats in Mexico.

The Blue Mockingbird (*Melanotis caerulescens*) occurs north of the Isthmus of Tehuantepec and the Blue-and-white Mockingbird (*Melanotis hypoleucus*) is found on the other side of it.

The remaining genera in the family, representing a good percentage of its diversity, consist of island taxa, presumably derivatives of mainland ancestors that successfully reached and persisted on the islands. Perhaps as a result of the propensity of mimids for living in open, edge or disturbed habitats in general, the family has demonstrated a truly remarkable ability for island colonization, and thence divergence into distinct island taxa. As a consequence, there is a notable variety of endemic genera, 45% of the family total, on islands off both the eastern and the western mainland coasts. Five genera, containing ten of the family's 34 species and 26 of its 85 accepted taxa at subspecies (or monotypic species) level, are restricted to various of these islands. If two insular species in other genera, the Bahama Mockingbird (*Mimus gundlachi*) and the Cozumel Thrasher, are taken into account, then the figures rise to twelve species and 29 subspecies, or 35% and 34% of the respective totals.

Caribbean islands are the setting for the most spectacular evolution of insular endemic mimids. A substantial radiation has resulted in a traditional taxonomy that distinguishes three genera, *Cinclocerthia*, *Margarops* and *Ramphocinclus*, containing two, two and one species, respectively. *Margarops* has a wide range in the Caribbean, extending from the Bahamas southwards through the Greater Antilles to the Lesser Antilles, and including South American islands off the north coast of Venezuela, but the other two genera are restricted to the Lesser Antilles. In contrast to the traditional taxonomy, recent molecular evidence supports recognition of the three distinct clades of *Cinclocerthia* at the species level; it also indicates that *Margarops* should be divided into two genera, with the widely distributed Pearly-eyed Thrasher (*Margarops fuscatus*) retained in that genus and the resurrection of *Allenia* for the Scaly-breasted Thrasher (*Margarops fuscus*) of the Lesser Antilles. All these genera are considered likely, again on the basis of molecular evidence, to be monophyletic with the catbird genus *Dumetella* of the North American mainland, although *Ramphocinclus* may be the product of an earlier invasion. The island forms diverged around 4 million years ago, and commonly three or four of these Caribbean endemic species co-occur on larger islands in the central Lesser Antilles.

There are two mimid genera found only on Pacific islands. These are the monotypic *Mimodes*, restricted to Socorro Island, off the west coast of Mexico, and, most notably, a radiation of species in the genus *Nesomimus* on the Galapagos Islands, west of Ecuador. Both are likely derivatives of mainland *Mimus* species. Species boundaries among the mockingbirds of the Galapagos are not well understood, but most authorities recognize four distinct species, no two of which occur on the same island, and three of which were collected by Charles Darwin. They are undoubtedly the products of a single, ancestral colonization event, perhaps by the mainland Long-tailed Mockingbird. One of the island taxa, the Galapagos Mockingbird (*Nesomimus parvulus*), is widespread. Two others, the San Cristobal Mockingbird (*Nesomimus melanotis*) and the Espanola Mockingbird (*Nesomimus macdonaldi*), are restricted to the single islands of those respective names. The fourth, the Floreana Mockingbird (*Nesomimus trifasciatus*), is confined to a few islets adjacent to Floreana, on which larger island it is now extinct, although it was common there in Darwin's time. The Galapagos mockingbirds are remarkable chiefly for their co-operative breeding habits (see Breeding). This behaviour is not known to occur among other members of the family, with the possible exception of one or two mainland *Mimus* species and the White-breasted Thrasher (*Ramphocinclus brachyurus*) on the Caribbean island of St Lucia, although it is commonly practised by mimid counterparts elsewhere, such as the Old World babblers.

Several systematic questions concerning the Mimidae remain unresolved, which leaves ambiguities in the number of acceptable genera and species. Depending on various taxonomic ideas, nine to twelve genera and 28–37 species could be recognized. Among the interesting and debatable questions in the classification involving island taxa are the following. Should the Scaly-breasted Thrasher be separated from the Pearly-eyed Thrasher and be placed in its own genus *Allenia*? Should the Tropical Mockingbird derivative on San Andrés be raised to full species status, as *Mimus magnirostris*? Does the Cozumel Thrasher deserve its current full species status or should it be merged with the mainland Long-billed Thrasher? There are similar questions relating to mainland taxa. For example, should the Black Catbird be moved to *Dumetella*, rather than being retained in a monotypic genus? Should the two *Melanotis* mockingbirds on each respective side of the Isthmus of Tehuantepec be con-

The propensity of mimids to cross large stretches of open sea has allowed them to colonize an array of oceanic islands in the Caribbean and western Pacific, where they have speciated. Indeed, within the family as a whole, as many as twelve of the 34 species are confined to islands. One of the best known radiations is found in the Galapagos, where the genus Nesomimus *has evolved and diversified from a single mainland ancestor. Of four resultant species, the* ***Galapagos Mockingbird*** *is the most widespread, occurring on dozens of large islands and associated islets.*

[*Nesomimus parvulus parvulus*, Fernandina, Galapagos. Photo: Günter Ziesler]

sidered conspecific, despite their dramatic differences in appearance? On the other hand, should the taxonomic status of the isolated population of Le Conte's Thrasher in Baja California be raised to that of a full species, under the name of *Toxostoma arenicola*?

In some of these instances, the case for enhanced nomenclatorial distinctions, or "splitting", is supported by DNA evidence that suggests only distant common ancestry and considerable differences at the genetic level. Often, however, this is offset by a lack of divergence between taxa at the morphological, ecological or behavioural levels. Where arguments for taxonomic distinction rest largely on size or bill differences, as is the case with the San Andrés mockingbird, they are tempered by consideration of the ubiquity of such morphological changes, especially in island populations, and especially in bill dimensions. Thus, there seems no compunction to regard such changes as anything other than the products of local selective regimes comprising different habitats and different suites of competitors, and not necessarily indicative of wholesale or species-level adaptations.

As discussed by E. A. Sgariglia and K. J. Burns, distributions of genealogical lineages within a given species are probably the result of complex series of ecological and historical events. These authors investigated the evolutionary history of populations of the California Thrasher by undertaking a nested-clade analysis of the variation in mitochondrial DNA among samples from different parts of the species' range. The results, in combination with other phylogeographical factors examined, suggested that the species had a southern ancestry and that an early division between northern and southern populations took place; this was followed by a northward range expansion, and a later expansion back into southern regions already inhabited by the species. In addition, the authors' identified isolation by distance, particularly in southern California, so that gene flow between different localities, although it occurs, would seem to be restricted.

Pending resolution of the uncertainties, and in some cases the probable formal recognition of the newer taxa that the molecular evidence supports, it is considered better at present to follow more traditional lines with regard to the treatment of genera and species. This somewhat conservative stance is also that taken recently by the compilers of the American Ornithologists' Union 1998 *Check-list of North American birds*. Future research is likely to shed much additional light on these complex matters.

Morphological Aspects

Mimidae is made up of relatively close-knit genera and the species are morphologically rather homogeneous, with few significant departures from the familial norms. This generalization is somewhat more compelling if one includes in it only *Mimus*, *Oreoscoptes* and *Toxostoma* and their derivatives, some 26 of the total of 34 mimid species. It is less precise if the Middle American *Melanotis* mockingbirds, and the *Dumetella* and *Melanoptila* catbirds and their Caribbean island derivatives, are included, as these are rather more divergent in habits and habitat, and therefore in morphology. Species in the former group, for example, share the characteristic of a single scute at the base of the outer toes, whereas in species of the latter group the foot scutes are divided. A further distinction is that the members of the first grouping are larger, more plainly coloured and more terrestrial species, whereas the species in the second group are smaller, more arboreal and, in tropical latitudes, rather more brightly patterned and coloured.

In size, the mimids span a modest range of some 20–30 cm in total length and about 40–120 g in weight, with the two catbirds being the smallest, and several species of *Toxostoma* and *Margarops* thrashers collectively the largest of the family. Most species exhibit little, if any, sexual dimorphism in either coloration or size. The sexes of many thrasher species are scarcely distinguishable in terms of weight, but males are on average 9% heavier than females in the case of the Curve-billed Thrasher and 8% heavier in the Northern Mockingbird. Males of the Socorro Mockingbird (*Mimodes graysoni*) weigh on average 6% more than females, but the genders are more easily separated by a combination of wing and tarsus lengths, which are longer in males. Sexual dimorphism is similarly modest in three of the four *Nesomimus* mockingbirds, males of which are about 10% heavier than females, but in the fourth, the Espanola Mockingbird, the males are 17% heavier than the females. In contrast, the weight of the female Sage Thrasher exceeds that of the male range-wide by about 10%, and the same applies also in the case of breeding Grey Catbirds (*Dumetella carolinensis*).

Catbirds are anomalous mimids with relatively plain plumage and short, straight bills. The Grey Catbird (Dumetella carolinensis) *is distributed across eastern and central parts of the USA, migrating to Central America in the non-breeding season. The* ***Black Catbird****, meanwhile, is restricted to the Yucatán Peninsula. Both species are placed in monotypic genera, though the southern form perhaps represents a sort of melanistic version of its better-known counterpart. Future research may uncover a close evolutionary relationship between the two, supporting a merger of* Melanoptila *and* Dumetella*; in such a case, the latter takes priority as the genus name.*

[*Melanoptila glabrirostris*, Cozumel Island, Mexico. Photo: Johannes Ferdinand]

A noteworthy morphological feature of several of the endemic Caribbean mimids is that females not only are larger in size than males but also, especially, have a longer bill. This situation, known as "reversed" sexual dimorphism, occurs in the Pearly-eyed Thrasher, but it is particularly striking in the Brown Trembler (*Cinclocerthia ruficauda*). In the case of the latter, the extent of the gender-related dimorphism varies among island populations, and weight dimorphism is substantially less than is that of bill length. Similar reversed sexual dimorphism is apparent in other avian groups, notably raptors such as accipitrine hawks, and owls (Strigiformes), and among factors cited as responsible for it are the female's role in egg-production and nest defence, both presumably enhanced by larger body size, and the wider range of prey available to smaller males, which are primarily responsible for early nest-provisioning to the female and chicks. It is possible that parallel arguments could be advanced to account for the phenomenon among some island mimids, along with the influences of varying food resources and variation in the incidences of other birds that compete for them. This would be an interesting topic for detailed studies, which are presently lacking.

For a majority of the Mimidae, those with the "typical" family attributes of largely terrestrial habits (see General Habits), the most conspicuous morphological features are long legs, a long tail, and often a long, robust and curved bill. The first two features are characteristic of many, unrelated birds that forage largely on the ground. As an adaptation to feeding among the accumulated plant detritus within and below shrubs, long legs elevate the bearer above the substrate, and provide some leverage and stability for "thrashing" and digging. Further, in typical mimid species, locomotion over short distances, and even much longer ones, is customarily achieved by running, rather than by flying (see General Habits). Clearly, long, strong legs are an asset to such behaviour, perhaps more from predator-evasion considerations than from foraging ones. Nestling thrashers are very noticeably "leggy" creatures, and when out of the nest they can run well before they can fly.

Long tails are traditionally thought to be an adaptation for terrestrial locomotion among ground-foraging birds, essentially providing balance. A tail held lowered when the bird is running is often elevated abruptly, as a braking aid, when it stops. The Brown and Grey Tremblers (*Cinclocerthia gutturalis*) of the Lesser Antilles are rather short-tailed, and both are arboreal; the catbirds and the tropical Blue and Blue-and-white Mockingbirds also forage largely above the ground, and likewise are not conspicuously long-tailed.

A long, strong and decurved bill is a notable feature of most of the *Toxostoma* thrashers. It is also possessed by other mimids in areas where these thrashers are absent, as demonstrated by the two tremblers and the White-breasted Thrasher on Caribbean islands, *Mimodes* on Socorro Island, and *Nesomimus* on the

The genus Melanotis *contains two mockingbird species, both of which are unusual in their bluish plumage. The* ***Blue Mockingbird*** *is endemic to Mexico, occurring north of the Isthmus of Tehuantepec, while its close relative the Blue-and-white Mockingbird* (M. hypoleucus) *occurs southward to Honduras and El Salvador. The northern form is essentially dark blue, streaked paler blue on the crown throat and chest, while the southern form is similar apart from its strikingly white underparts, from throat to belly. Both species have a diagnostic blackish mask extending from the lores to the auriculars.*

[*Melanotis caerulescens caerulescens*, Mexico. Photo: Patricio Robles Gil]

In the traditional taxonomic sequence the genus Cinclocerthia *contains two species of mimid, but recent genetic analysis suggests there may be three. The genus itself, however it is subdivided, comprises a fairly well-defined insular radiation restricted to the Lesser Antilles. Each of these Caribbean islands is occupied by a single representative, St Lucia and Martinique being home to the* ***Grey Trembler****. This species typifies the genus in its long, straight bill, its relatively short tail and its unpatterned upperparts. Likewise, it is more a bird of humid forests than most other mimids, and its lifestyle is more notably arboreal.*

[*Cinclocerthia gutturalis macrorhyncha*, Edmund Forest Reserve, St Lucia, Photo: Doug Wechsler/ VIREO]

*The **Pearly-eyed Thrasher** is another specialized inhabitant of Caribbean islands, amongst which it is quite widespread from the Bahamas to Bonaire. A large, brash, conspicuous species of dense thickets and dry forests, it currently shares the genus* Margarops *with the Scaly-breasted Thrasher* (M. fuscus), *although previous morphological analysis, backed up by recent genetic work, hints that the latter should be removed to* Allenia. *Both these species are allied to the tremblers, but, aside from the fact that they do not tremble, they differ markedly in habitat choice and bill morphology.*

[*Margarops fuscatus densirostris*, Morne Diablotin, Dominica. Photo: Roland Seitre]

Galapagos. On the small south-western Caribbean island of San Andrés, the resident subspecies of the Tropical Mockingbird, sometimes recognized as a separate species (see Systematics), is distinguished from other races by its distinctly larger and longer bill. The chief uses to which the long, curved bill is put are in foraging tactics (see Food and Feeding).

These impressive curved bills, while widespread among several mimid taxa, are absent in Bendire's Thrasher and in mainland *Mimus* mockingbirds. Characteristically, these shorter-billed species co-exist with one or another of the long-billed *Toxostoma* thrashers in the same vegetation. In a similar fashion, the two *Margarops* thrashers are sympatric on several Lesser Antillean islands, with one being conspicuously longer-billed than its congener. The Northern Mockingbird co-exists with the larger and longer-billed Pearly-eyed Thrasher, one of these *Margarops*, on Puerto Rico. In the 1970s, it also colonized Socorro Island, which it shares with the endemic Socorro Mockingbird. The two are similar in size and both are basically short-billed, but they occur in different habitats, the recent invader being found only in the disturbed and more open vegetation.

The evolution of long bills and the attendant side-swiping foraging tactics of several *Toxostoma* species has been accompanied by specialized development of the cranial structure and the jaw and neck musculature, as was described by W. Engels in 1940. Comparable structures might be looked for in other mimids that share similar bills and habits, and are expected to be present in the ecologically equivalent birds of other continents, such as some of the Old World timaliids.

In appearance, the great majority of the Mimidae are rather bland, being variously greyish or brownish in coloration above, and paler below. This modest, if not drab, mien is alleviated in a number of cases by the presence of a spotted or streaked breast, and nearly all species that are otherwise plainly coloured have black or white head, wing or tail markings that add considerable distinction. Among the *Toxostoma* species, those of the more humid regions of the eastern USA and Mexico, the Brown Thrasher and its relatives the Long-billed and Cozumel Thrashers, are brown-backed, in contrast to their basically grey-backed congeners of the south-western arid regions. The California Thrasher, a denizen of Mediterranean-climate chaparral, is markedly darker and browner-backed than its desert relatives. The *Mimus* mockingbirds are generally greyish above, but several Neotropical species, including the Chilean, Brown-backed (*Mimus dorsalis*) and White-banded Mockingbirds (*Mimus triurus*), are somewhat browner dorsally. A spotted, scaly or streaked breast is a characteristic of some thrasher groups, of some mainland and island *Mimus* and *Mimus* derivatives, and of the Caribbean *Margarops* thrashers. In the case of some mockingbirds with plain-breasted adults, such as the Socorro and Chilean Mockingbirds, the juveniles are distinguished by their breast streaking, which is lost when adult plumage is gained.

*As well as being the smallest members of the family, the catbirds are amongst the least terrestrial, as a result of which their bills and tails are unusually short for the family. At a glance they resemble diminutive, slender thrushes (Turdidae), rather than mockingbirds or thrashers. The plumage of the **Grey Catbird** is a soft slaty grey, offset by a black cap and a chestnut-brown crissum, the latter feature reappearing elsewhere in the family, most notably in the genus* Toxostoma. *One of its calls bears an uncanny resemblance to the mewling of a cat, a fact duly noted by the European settlers who gave this bird its English name.*

[*Dumetella carolinensis*, Long Island, New York, USA. Photo: Tom Vezo]

The majority of mimids live in semi-arid habitats, as illustrated biogeographically by the genus Mimus *in South America. The dry Pacific coastal zone from Ecuador to Chile accounts for two endemic species, with a third in the arid Andes of Bolivia and north Argentina. The similar dry zones of Brazil and Argentina are partitioned amongst three more species: the Patagonian Mockingbird* (M. patagonicus) *occupies the stunted shrublands of the far south; the* **White-banded Mockingbird** *occupies taller* monte *scrub and low Chaco woodland; and the Chalk-browed Mockingbird* (M. saturninus) *occupies savanna-like* cerrado, *invading Amazonia wherever large-scale deforestation occurs.*

[*Mimus triurus*, Argentina. Photo: Günter Ziesler]

Among well-studied members of the family, downy nestlings begin their very first moult in the nest, and complete it to acquire juvenile plumage, in most cases only subtly different from that of the adult, outside the nest. In general, mimids undergo an annual moult in late summer to early autumn, most North American species moulting during July–September.

The most radical departures from the usual grey-brown upperparts and paler but sometimes spotted underparts are found in the catbirds. Both are aptly named. The northern species, the Grey Catbird, is all grey with a black cap and a dark chestnut-brown crissum, and the Yucatán species, the Black Catbird, is entirely black. The two *Melanotis* mockingbirds are blue above and either blue or white below, with a black ear patch, and the White-breasted Thrasher, also black-eared, is dark above and white below.

Even in the dullest-coloured mimids, the plumage is embellished with white markings that, besides their function in intraspecific displays (see General Habits), serve as convenient field markings for the observer. The incidence of white wing patches and/or white tail markings is widespread among the species of several genera. Wing patches are a common feature of *Mimus* mockingbirds, and they may be very large and conspicuous, or smaller and fairly obscure, but they are lacking in some members of this genus. Sympatric species seem to be dissimilar in this respect, conspicuous patches being present in one species and absent in the other; examples are the Northern and Tropical Mockingbirds, sympatric in southern Mexico, and the White-banded and Chalk-browed Mockingbirds, sympatric in northern Argentina, the former in each case having the large wing patches. In addition, white tail tips and/or white outer tail feathers are common among the *Mimus* species, and are exhibited also by the Sage Thrasher and the Caribbean *Margarops* thrashers.

Dull coloration is further countered in most mimids by various facial markings. The black ear patches of the *Melanotis* mockingbirds, mentioned above, are shared with the *Nesomimus* mockingbirds in the Galapagos and the *Cinclocerthia* tremblers in the Caribbean, and white lines above the eyes, often in conjunction with adjacent black stripes, are also common. Many *Mimus* species have a white "eyebrow", or supercilium, above a dark or black eyeline. The Sage Thrasher has a white eyebrow, as does the Ocellated Thrasher, and several other thrashers have white or black malar or submalar lines below the cheek and above a paler throat.

Iris colours are often distinctive, and can add flair to an otherwise plain appearance. Among the Mimidae, the iris colour ranges from black and brown to reddish, orange, yellow and white. In some cases, the most closely related species often differ with regard to eye colour, as illustrated within the genera *Margarops* and *Toxostoma*, and this character seems therefore not to be a conservative taxonomic parameter.

The final feature of some distinction in the appearance of certain mimids is the coloration of the undertail-coverts, or crissum. This area is conspicuously coloured, in contrast to both the upperparts and the belly, in the Grey Catbird, and among the *Toxostoma* species its colour ranges from bright cinnamon-rufous to tawny-brown and to pale buff.

Habitat

All of the mainland mimids, north and south of the equator, typically live in low and rather open scrubby habitats, and less usually in the undergrowth of low woodland or in savanna. The majority of species inhabit the more arid parts of the two continents, where they occupy various sorts of desert and semi-desert vegetation. Away from the desert regions, woodland edge or scrubby second growth, or riparian vegetation in more open country, are the preferred habitats of the three common mimids of the eastern half of the USA, namely the Grey Catbird, the Northern Mockingbird and the Brown Thrasher. The same applies to the South American Chalk-browed Mockingbird at its lower tropical latitudes, which include the Amazon Basin. This species occupies open savannas and also cleared, deforested areas within the rainforest region, so long as a few bushes and low trees remain. At tropical latitudes in Mexico, the Black Catbird inhabits scrubby edge and low woodland on the Yucatán Peninsula, but it drops out to the south when the woodland becomes taller and evergreen. Found in similar habitats on the Pacific coast is the Blue Mockingbird, which follows the dense, bushy understorey of low tropical deciduous woodland well north into the north-western state of Sonora. Its allopatric congener, the Blue-and-white Mockingbird, is found in scrub, edge and second-growth habitats far-

ther south, to Honduras and El Salvador. The Tropical Mockingbird has a range entirely within tropical latitudes, but it also eschews forest and is typical of the driest, open or disturbed sites, essentially the same habitats as those exploited by its northern congener, the Northern Mockingbird, from the Isthmus of Tehuantepec all the way north to Canada.

The most significant departures from this association with open and more arid habitats are exhibited by the endemic Caribbean genera, and in particular by the *Cinclocerthia* tremblers, both of which may be found in evergreen tropical forest at higher elevations. This pattern is repeated to some extent in the Galapagos Islands, where the *Nesomimus* mockingbirds occupy not only the arid scrub of the lowlands, but also upland mesic forest on some of islands' volcanoes.

Outside desert and semi-desert habitats, with their naturally low, sparse and open vegetation, several mimids have clearly benefited, probably in terms of both geographical range and breeding density, from the clearing and opening-up of woodland and forest habitats by humans. Several non-desert species thus occupy edge and second-growth habitats where the natural vegetation cover would have precluded their presence. This is true for species equally of tropical and of temperate latitudes. Suburban parks and gardens, fitting the prerequisites for open but bushy or sparsely treed sites, provide appropriate habitat for several mimid species, which are therefore very familiar birds even to townsfolk. Indeed, the Northern Mockingbird must be one of the most widely recognized birds in the USA (see Relationship with Man). The Tropical Mockingbird is similarly ubiquitous in cities and towns of the northern Neotropics, and several other mimids of the South American temperate regions, including the Chalk-browed, White-banded and Chilean Mockingbirds, are familiar birds of agricultural landscapes and populated areas.

The number of species of any higher taxon co-occupying a habitat at a given site is known as the "α-diversity" of that taxon. For the Mimidae, the α-diversity is usually a single species, or perhaps two, with short-billed and long-billed species co-existing together, as discussed above (see Morphological Aspects). A general rule for this family is that related species either occupy different habitat types, being then termed "β-replacements" and contributing to a β-diversity component in the family's overall diversity, or occupy the same habitat but have different ranges within that of the habitat ("γ-replacements", contributing to a γ-diversity component). The northern deserts each have characteristic thrasher species that are β-replacements: the Sage Thrasher in the steppe-deserts of the Great Basin, Le Conte's Thrasher in the Mojave Desert, and the Curve-billed Thrasher in the Sonoran and Chihuahuan Deserts, often with the addition of the Northern Mockingbird or Bendire's Thrasher in taller desert scrub.

From California south to central Mexico, a dense scrub vegetation occurs between oak (*Quercus*) woodlands and lower, more open scrub of the sagebrush (*Artemisia*) type, at intermediate position on precipitation gradients. This vegetation, variously termed chaparral, *encinal* or *matorral*, is occupied by the California Thrasher in Alta and northern Baja California, by the Crissal Thrasher inland at the desert edge and in mountain foothills south to central Mexico, and by the Ocellated Thrasher in the highlands of Oaxaca adjacent to the local oak woodland there. The three species occupy similar habitat, are allopatric, and would classify as γ-replacements within chaparral vegetation, broadly construed. Similarly, the Curve-billed Thrasher occupies dry thorn-scrub, as well as deserts, throughout northern Mexico, but in the thorn-scrub of the Cape Region of southern Baja California the Grey Thrasher is the family's representative.

In central to northern Argentina, three *Mimus* species have partly overlapping ranges, but they differ with regard to the typical habitats in which they are found. In one pair of extensively sympatric species, the White-banded Mockingbird is typical of low Chaco woodland and *monte* scrub, whereas the Patagonian Mockingbird (*Mimus patagonicus*) prefers lower desert scrub and steppe. The White-banded Mockingbird is extensively sympatric also with the Chalk-browed Mockingbird to the north-east, but the latter is typical of more open, savanna-like country. A fourth species that occurs east of the Andes, the Brown-backed Mockingbird, prefers arid foothill scrub not unlike that occupied by the Patagonian and White-banded Mockingbirds farther south, but its more northerly range, extending from Bolivia south to Tucumán, in north-west Argentina, precludes much contact between it and its more southerly congeners.

General Habits

In their general comportment, the majority of typical mimids are conspicuous by dint of their striking vocalizations and frequent

*The **California Thrasher** is one of several mimids specializing on low-stature vegetation in the Californian Floral Kingdom. In Alta and northern Baja California it frequents the dense scrub formation, variously termed chaparral,* encinal *or* matorral*, that is typical of intermediate points on the precipitation gradient, between well-watered oak* (Quercus) *woodland and low-lying, dry scrub of the sagebrush* (Artemisia) *type. It also occurs, but usually at lower densities, in oak woodland with scrubby understorey, in well developed sagebrush saltbush* (Atriplex)*, in juniper scrub, and in stunted woodland of piñon pines and Joshua trees.*

[*Toxostoma redivivum*, California, USA. Photo: Dave Maslowski/ Maslowski Productions]

The association between mimids and arid or semi-arid landscapes only breaks down on a few Caribbean islands, where some members of the family tolerate, or even prefer, more humid habitats. This is especially true of the tremblers, both of which may be found in taller forests at higher elevations. The only mimid that qualifies as a true rainforest bird in most of its range is the ***Brown Trembler****, a species that usually eschews drier formations and restricts itself to humid forest. On Dominica, for example, it is common in windward evergreen forest and rainforest, but scarce in leeward dry forest, plantations and montane thickets.*

[*Cinclocerthia ruficauda tremula*, Guadeloupe. Photo: Regis Cavignaux/ Bios]

use of exposed song perches at bushtops in low, scrubby vegetation. On the other hand, many of them, owing to their unobtrusive coloration and terrestrial foraging, are difficult to observe when they are not singing. When engaged in foraging or nesting activities, many mimids are quite inconspicuous, remain in the densest cover, and are, indeed, frequently difficult to detect. This is not only because they conduct these activities often in dense vegetation on or near the ground, but also because they are in general rather retiring birds, and some of them are exceedingly elusive. The Crissal Thrasher epitomizes this description; it is notoriously difficult to observe at close quarters, and extremely effective at retreating to the far reaches of its territory without offering sight or sound of itself. California and Ocellated Thrashers are very much like the Crissal Thrasher in this respect. All three are easy enough to locate and identify when singing 50–100 m away, but it is extremely difficult to approach them or even to find them at closer distances.

Further, locomotion over short distances, and even much longer ones, is customarily achieved by running, rather than by flying. Indeed, many mimid species appear markedly reluctant to fly from a source of disturbance, and their escape to cover is readily accomplished by running. The desert thrashers of the south-western USA are noted for their abilities to streak away from the observer, running across open ground and quickly disappearing into the sparse vegetation. Some, such as the Crissal, Curve-billed and Le Conte's Thrashers, will even leave exposed song perches by slipping down through the brush to the ground, to make their escape on foot rather than by flying. Although these and other members of the family nest above the ground and sing from high points in the vegetation, access to both is often gained by climbing through the bushes, and not by flight. Such behaviour is recorded for many North American mimids, and also for South American *Mimus* species.

This combination of characteristics, involving noisy, persistent and even exuberant vocalists on strongly defended territories, but with a propensity to avoid approach and intolerant of close observation, well describes most of the better-known mimid species. In this respect, they are quite the opposite of most small and medium-sized birds, which are difficult to locate from afar but, once located, are easily approached and observed. Perhaps like many other larger passerines that spend most of their time low in dense vegetation, these catbirds, mockingbirds and thrashers seem to find ample time for quiet loafing and preening when not engaged in nesting or territorial activities. Such are the benefits of a private and retiring lifestyle.

The use of exposed songposts at the top of the vegetation is not universal among the family's members. Species that inhabit dense shrubbery and woodland-edge vegetation customarily sing from within the vegetation; the Grey Catbird of the eastern USA and the Central American *Melanotis* mockingbirds are examples of species that are rarely seen to sing from exposed positions. In low and scrubby woodlands in Argentina, Patagonian and White-banded Mockingbirds sing from perches 3–5 m above the ground, but still a half-metre or so below the treetops.

The more apparent aspects of thrasher and mockingbird behaviour are attributable to their being highly territorial species.

The ***Brown Trembler****, as its name suggests, has a diagnostic display in which its wings are drooped a couple of centimetres, then quivered for about one second, and then returned to the original position. Both sexes display regularly, usually every few seconds, but the rate increases in the presence of conspecifics. The fact that trembling is more frequent in social contexts suggests that it is an important intraspecific signal, perhaps to maintain contact between pair members. Interestingly, this species lacks a contact call.*

[*Cinclocerthia ruficauda ruficauda*, Dominica. Photo: John F. Cooper]

Some mockingbirds in the genus Mimus *often hold their wings open for anything from a split second to a few seconds. It seems clear that "wing-lifting", or "wing-flashing", has evolved to show off their gleaming white underwings, or strikingly patterned upperwings, but, in contrast to the situation in tremblers, the context is not always social. The* ***Chalk-browed Mockingbird*** *opens its wings during squabbles over food and when posturing in front of rivals or potential mates, but it also uses this display in non-social contexts. Thus an individual may flash its wings when alighting on bushtops, singing, foraging, or when challenging predators near the nest, when conspecifics are not in view. Likewise, a solitary* ***Patagonian Mockingbird*** *will use this display at seemingly random intervals when foraging on the ground. This curious behaviour is easily observed at tourist spots and coastal car-parks, where tame individuals have learnt to take scraps from picnickers. The function of wing-flashing in solitary foragers is not clear, but it probably relates to territoriality or predation, or both. It may be directed at distant conspecifics, as a signal of presence and ownership, or it may be directed at predators as a sign of vigilance, alertness and liability to escape, as is suspected of tail-flicking in Common Moorhens* (Gallinula chloropus), *and stotting in Thomson's gazelles* (Gazella thomsoni).

[Above: *Mimus saturninus frater*, Governador Valadares, Minas Gerais, Brazil. Photo: Edson Endrigo

Below: *Mimus patagonicus*, Península Valdés, Argentina. Photo: Francisco Erize]

Although there is very little on record about bathing and preening in mimids, they are popular pastimes amongst the thrashers at least, as illustrated by these fine portraits. The first shows a ***Long-billed Thrasher*** *and the second a* ***Brown Thrasher****, two very similar species in the genus* Toxostoma. *It is likely that all members of the family devote a fair proportion of time to preening, but some species live in habitats virtually devoid of fresh water, and thus must very rarely drink or bathe. Some of the Galapagos Islands, for instance, lack a permanent supply of fresh water, and the resident* Nesomimus *mockingbirds are presumably adapted to survive for long periods without access to this luxury.*

[Above: *Toxostoma longirostre sennetti*, Rio Grande Valley, Texas, USA. Photo: Tom Vezo.

Below: *Toxostoma rufum*, High Island, Texas, USA. Photo: Rob Curtis/ The Early Birder]

Most mimids are permanently territorial, pair-living, socially monogamous birds, but the situation is turned on its head in the Galapagos Islands, where three of the four species of Nesomimus *mockingbirds live in groups of up to ten individuals, all of whom co-operate to defend large territories and raise broods. Groups of* ***Espanola Mockingbirds****, for example, usually contain 7-10 adults, often comprising a single monogamous pair with helpers, and at other times containing two or more active pairs. As with all co-operative group-living species, sexual conflict is often intense, and social interactions are relatively complex.*

[*Nesomimus macdonaldi*, Española Island, Galapagos. Photo: Sam Fried/VIREO]

Since seasonal movements are limited to a minority of species living at higher latitudes and in more seasonal environments (see Movements), most mimids occupy and defend territories almost throughout the year. Such aspects of behaviour as song and visual displays are therefore prominent, and advertise the presence of the territory-holder and broadcast its residency to conspecifics and others, as well as to human observers. Furthermore, in many species, pair-members remain mated and jointly resident on territories for periods longer than a single breeding season, in some cases for many years. Conspicuous calls announce the whereabouts of one or the other partner within the territory, and as territories are often large, following from a combination of fairly large birds living in low vegetation, the calls and the songs are loud and far-carrying. Thus, even outside the breeding season, these mimids are usually quite vocal and readily identified.

On the whole, mockingbirds, thrashers and tremblers are vocal birds, often disclosing their whereabouts with a volley of calling, or a bout of song. In part because of the strength and quality of sound they produce, as well as the open landscapes they prefer, mimids are usually audible from long range. Further, many species are territorial all year round, and thus their songs are heard at all seasons, often becoming a signature for their respective habitats. The song of the ***Sage Thrasher****, an exuberant torrent of random notes and phrases, sometimes given for many minutes without pause, immediately evokes the sagebrush plains of North America.*

[*Oreoscoptes montanus*, Mono Lake, California, USA. Photo: Marie Read]

Territories are occupied in most instances by monogamously mated pairs, and, given the lack of sexual dimorphism in appearance and size (see Morphological Aspects), the sexes may yet be separable by differences in their behaviour. This, however, is not always the case, as the females of some species sing and actively join the males in territory defence, while the males assist in nest-building and in the feeding of the young. Thus, differences in gender roles may be poorly defined, as is so with, for example, the California Thrasher and several of its desert relatives. Exceptions to the rule of breeding territories being occupied and defended by breeding pairs, with young raised solely by the parents, occur most notably in the co-operatively breeding Galapagos mockingbirds *Nesomimus* and in some of the South American *Mimus* species (see Breeding).

Strong territoriality is the norm for Mimidae, and a considerable amount of information on territory choice, defence, size and function has accumulated. Territory sizes vary both with the size of the bird and with the vegetation, as is usual. In knee-high steppe vegetation of the Great Basin deserts, the Sage Thrasher occupies territories in the range of 0·4–1·7 ha, and territories of the Northern Mockingbird are similar in size. Three of the four Galapagos mockingbirds also have territories of about 1 ha on average, but those of the fourth species, the San Cristobal Mockingbird, are significantly larger, around 4 ha. Territory sizes of species such as the Brown Thrasher and the Grey Catbird, living in more mesic and productive habitat, are towards the low end of the mimid range, generally smaller than 1 ha, whereas those of the desert-dwelling thrashers are often much larger, extending to many hectares. California Thrasher territories in the chaparral of southern California cover approximately 2·5 ha, and those of the closely related and similarly sized Crissal Thrasher, which inhabits more arid scrub, are on average about twice this size.

The defence of territories is accomplished primarily by song, for the characteristics of which, such as range, quality, duration and "pyrotechnics", the family is justly famous (see Voice). Aerial

*The **Northern Mockingbird** is one of the most widely recognized and universally admired birds in Canada and the USA, a fact that derives in large part to its famously varied and uplifting song. As its scientific name suggests, this is one of nature's polyglots. The original "mockingbird", it learns the sounds produced by other species, as well as a whole range of artificial or mechanical noises, and mimics them faithfully in its own disjointed outpourings. Thus, by imitation, the repertoire of motifs and phrases that it amasses is so broad that it cannot be exhausted during a single bout of song, no matter how prolonged. Moreover, new sounds are learnt and old sounds discarded throughout the life of a territorial bird. This type of mimetic behaviour is widespread in the family, though by no means ubiquitous. More broadly, and with the conspicuous exception of parrots (Psittacidae), it is a skill confined to the oscine passerines, that large and varied group of families, the members of which possess the syringeal apparatus for producing complex notes, and the neural faculties for learning sounds.*

[*Mimus polyglottos*, Texas, USA. Photo: Tom Vezo]

The diet of mimids contains a wide variety of items, usually including a range of insects, seeds and fruits, such that they are best described as omnivores. The ***Tropical Mockingbird****, for example, eats a lot of insects and berries, but supplements this intake with larger fruits, such as ripe mangoes, as well as the eggs of birds and lizards, and whatever scraps it can find at feeders. There is virtually nothing on record about mimids eating flowers, but this individual is blatantly guzzling the petals of an ornamental bloom.*

[*Mimus gilvus tobagensis*, Tobago. Photo: Konrad Wothe]

displays may accompany song, and are particularly well developed in the *Mimus* mockingbirds. Individuals in full song will rise several metres above the perch in a leisurely and looping display-flight, singing continuously, before returning to the original perch or to another nearby. During these displays, the white wing and tail markings are shown to full advantage. The wings and tail of several *Mimus* species are mostly black or blackish in colour, and their white highlights are therefore all the more dramatic. In this genus, cocking, spreading or folding of the tail, both in flight and while perched, appear evocative of mood and intent, and reveal or conceal the lateral white flashes or terminal markings. Mockingbirds feeding on the ground will also engage in "wing-lifting", a type of behaviour that reveals the conspicuous wing markings and presumably signals the individual's presence and site-possession to other birds. Wing-flashing and tail-flashing are employed also in courtship displays, and wing-fluttering displays are well known for Sage Thrashers. The purpose of the "wing-trembling" that gives the Brown Trembler its name remains largely unknown, but it does appear to be far more frequent in social contexts than among solitary birds. It involves a perched individual repeatedly drooping its wings rapidly.

Such displays are presumably designed for conspecific receivers, but interspecific interactions with potential competitors are widely recorded. Some of these occur between confamilials, such as between the California Thrasher and the Northern Mockingbird in California, the Brown Thrasher and the Northern Mockingbird in eastern and central North America, and the Long-billed Thrasher and the Northern Mockingbird in Texas, while in the Mojave Desert Northern Mockingbirds are distinctly wary and silent around active Crissal Thrashers. In the Sonoran Desert, aggressive interactions between the Curve-billed Thrasher and the Cactus Wren (*Campylorhynchus brunneicapillus*) are commonplace, and may involve competition for both nesting and foraging sites. Many of the larger thrashers will routinely attack and displace other birds such as thrushes, shrikes (Laniidae) and large finches (Fringillidae), and show a general intolerance of other ground-foraging birds in close proximity to their foraging sites. Among those species that relocate seasonally, interspecific aggression extends also to the defence of winter territories. In South America, Chalk-browed and Tropical Mockingbirds are known to be interspecifically territorial, and Patagonian and White banded Mockingbirds show a significantly low co-occupancy of habitats that appear equally acceptable to both species.

Mimids in general have a well-deserved reputation for being noisy and aggressive, and their aggression extends beyond potential competitors and is directed also at potential nest predators (see Breeding).

Voice

Many species, certainly a majority, in the family Mimidae are generally accorded recognition as superlative singers. Somewhat whimsically, a dozen of them have gained entry to a list of "the world's most acclaimed avian songsters", even though, by other accounts, the more accomplished of the mimid species are omitted.

Throughout the family, the songs are loud and penetrating, the delivery is forceful and persistent, and the content is wonderfully varied both among and within species. Moreover, a single individual can have an extensive repertoire of individual notes and phrases, only a small portion of which may be revealed in any given song bout. Repertoire size and content are individually variable, in addition to which the content of any one Northern Mockingbird's repertoire is known to change continuously over time, as new components are added and others that were previously used are dropped. The Brown Thrasher, too, is an excellent example of this family's vocal talents. In studies of its "vocal virtuosity", the Brown Thrasher was found to have over 2000 song types.

Repertoire size is generally regarded as an index of fitness under sexual selection, and some evidence suggests that males with larger repertoires rank higher, secure better territories, and are more attractive to females. Many species are notable for their abilities to imitate the songs and calls of other bird species, and to incorporate these imitations into their own territorial song. In some cases, other noises are picked up by the vocalist and deployed to enhance its repertoire; these include, among others, dog barks, frog calls, bells, the postman's whistle, and even a

Fruit consumption is widespread amongst mockingbirds. It is perhaps especially prevalent in those species that live in the tropics, but the ***Northern Mockingbird****, a bird of temperate latitudes, is an avid frugivore nonetheless. Adults will leave their territories, sometimes flying high over those of their neighbours, to reach a fruiting tree, while juveniles, like the one pictured here, often harvest the late-summer berry crops. In both cases, small fruits are the usual target, but in the tropics the choice is broader. The lower photograph shows a* ***Chalk-browed Mockingbird*** *pecking, in thrush-like manner, at a ripe fruit far too wide to swallow whole. When even larger fruits, such as mangoes, papayas and bananas, are particularly ripe, or when their skins are opened by birds with hefty bills, the mimids take advantage of the feast.*

convincing imitation of the coyote's (*Canis latrans*) howl. The felicity of this vocal mimicry has received a good deal of attention and reportage. The name "mockingbird" is owed to these imitative abilities, but they are characteristic of mimids other than mockingbirds, being at least as well developed among thrashers and other members of the Mimidae.

Mimid songs are quite different from the short, discrete and relatively unvarying songs of many passerines, such as finches and parulid warblers, that are immediate and unequivocal signals of species identity. Mimid songs consist of a succession of phrases, each given once or, more usually, repeated several times. Successive phrases show a bewildering variety of forms, and follow each other rapidly, in a seamless or near-continuous string, or at a slower and more deliberate pace with measured pauses between them. The collection of phrases that comprises the song may continue for minutes on end without abating, and at the appropriate time of year and day a group of neighbouring thrashers or mockingbirds will almost completely dominate the airwaves for long periods of time. Rather unusually among songbirds, both males and females of several mimids are known to sing the typical song of the species; this has been recorded for the California and Le Conte's Thrashers and for Northern Mockingbirds.

Although the song, with its varied and unpredictable sequence of phrases and notes, is seemingly haphazard in its details, each species is nevertheless readily recognizable and distinguished by the attuned ear. In certain desert-edge sites in the south-western USA, where four or five mimids breed and sing within hearing distance of each other and the human listener, one has no problem in distinguishing one species from another, despite overall similarities in the song structures and even in some of their components. The pace of the song, its continuity or otherwise, and the nature of component phrases, whether mellow and flutier or harsher and more staccato, are the most obvious clues. The songs of locally co-existing thrushes in Europe, such as the Common Blackbird (*Turdus merula*), Song Thrush (*Turdus philomelos*) and Mistle Thrush (*Turdus viscivorus*), would be distinguished by similar interspecific differences in the quality and repetition of phrases. The spritely but rather harsh and colourless phraseology of the Northern Mockingbird's song would comprise one extreme, with the unbroken continuity of the sweeter and fast-paced Sage Thrasher song the other. In between, Crissal Thrasher phrases are slower, deeper and more deliberate, compared with which those of Le Conte's Thrasher are somewhat faster and less guttural, while Bendire's Thrasher sings flutier phrases with more continuity than the aforegoing two but, with distinct pauses, its song is slower and less interconnected than that of the Sage Thrasher. The fact that the songs of the desert thrashers are audible over many hundreds of metres is a great aid in locating and identifying these birds.

Early western naturalists vied with each other in their lyrical descriptions of the different thrasher and mockingbird songs, debated their comparative attributes, and varied in their advocacy of one or the other species as the superior vocalist. In North America, perhaps Bendire's Thrasher would win the ballot, and in South America the White-banded Mockingbird, by virtue of its superlative mimicry, would seem to be the front-runner. As the songs of all species are well represented on tapes and CDs, each listener can make his or her own judgement on their relative merits.

As many mimids are resident on their territories throughout the year (see General Habits), they correspondingly sing in all months. California, Le Conte's and Crissal Thrashers are examples of this. Nevertheless, these and other mimid species do exhibit seasonal peaks in singing activity, and also a relative cessation at other times, often during the post-breeding period. Although the California Thrasher can be heard singing throughout the year, it is rather quiet in late summer and early autumn. Singing becomes more than sporadic after the onset of winter rainfall in October and November, and builds in intensity throughout the winter months until nesting commences, in February. The Northern Mockingbird's song output is related to the stage of the breeding cycle over successive broods, reaching a peak during nest-building, slowing throughout the incubation and early nes-

As might be deduced by a comparison of their bills, the thrashers are more insectivorous than the mockingbirds. The proportion of plant material ingested is relatively small, usually around 10%, chiefly comprising small seeds found on or near the ground. Meanwhile, around 90% of food items are arthropods. These are usually captured while foraging on the ground under dense shrubs, and at this the thrashers excel. The long-billed species, such as ***Le Conte's Thrasher****, sweep their bills from side to side, vigorously displacing debris, digging small pits, and flicking fallen plant material aside. In this way they uncover hidden arthropods, including large numbers of beetles, grasshoppers, spiders and scorpions.*

[*Toxostoma lecontei lecontei*, Kern County, California, USA. Photo: Brian E. Small]

Out in the deserts of the south-western USA a few plants produce copious quantities of juicy nectar, investing much of their hard-earned supply of sugars and moisture to create an irresistible lure. Perhaps predictably, thrashers have developed a taste for the syrupy feast, and frequently ascend from their usual haunts to visit flowers. In the Sonoran Desert, the ***Curve-billed Thrasher*** *attends the flowering stalks of* Agave *plants, as well as the apical inflorescence of saguaros* (Carnegiea gigantea). *In all cases, the nectar is accessed directly, such that pale patches of pollen are daubed onto the forehead and chin, as can be seen in the accompanying photograph.*

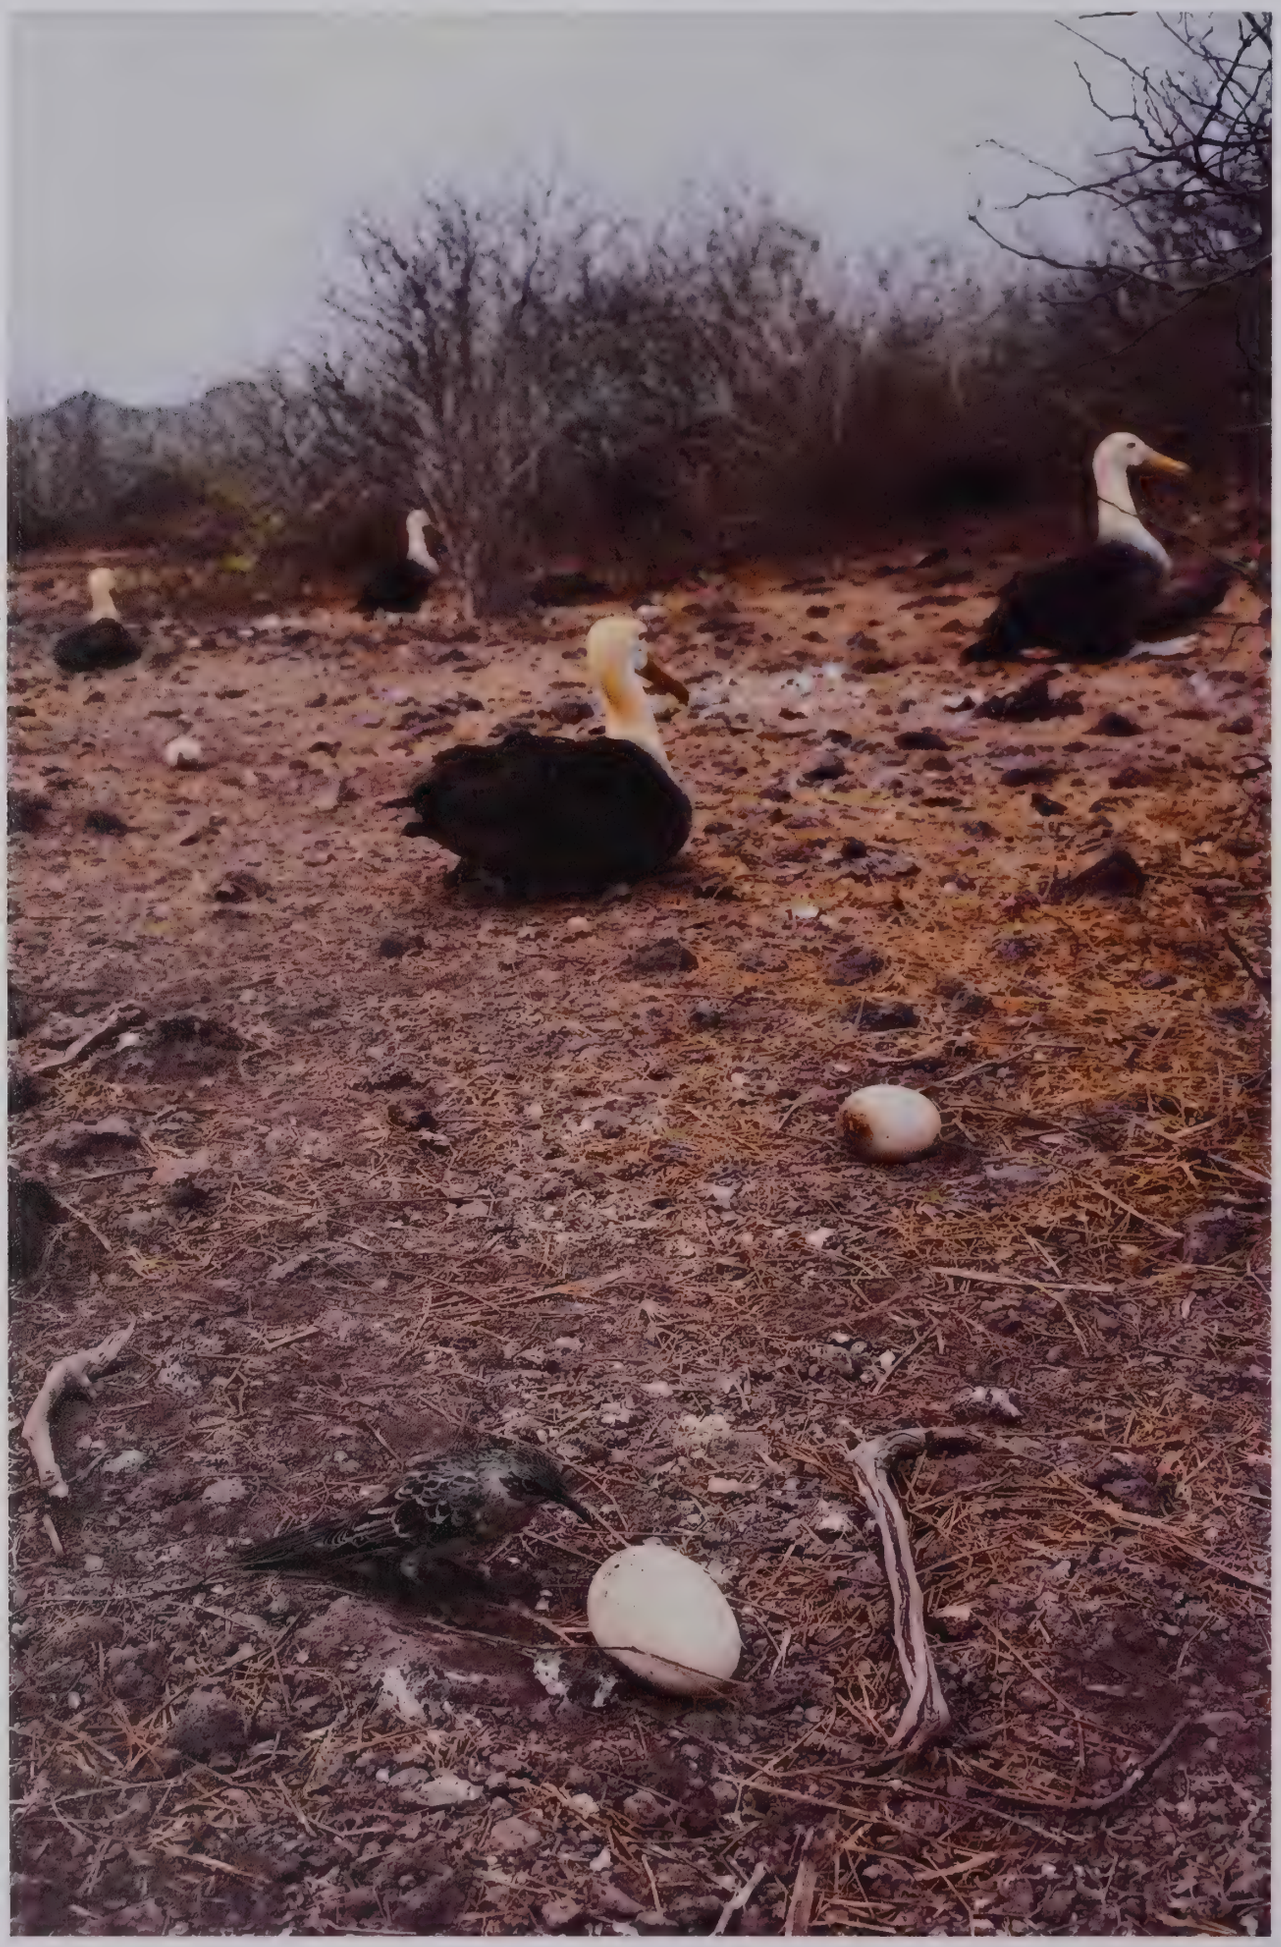
[*Toxostoma curvirostre*, Pima County, Arizona, USA. Photo: Brian E. Small]

tling stages, then resuming as the nestlings grow and peaking again as another nest is built for the next clutch.

Vocal mimicry is widespread, although not ubiquitous, in the family. Usually it is the songs or calls of other birds, especially those of species that occur commonly in the mimic's territory, that are imitated and repeated in territorial songs. This propensity for mimicry provides for a popular ornithological diversion, that of identifying the number of calls or phrases in a mockingbird's song that are clearly derived from other birds. Occasionally, other natural sounds, including a wide variety of anthropogenic noises, are mimicked. In some species, such as the Chalk-browed Mockingbird, the song is said to be composed mostly of imitations of other birds. Other *Mimus* species, such as the Northern, Tropical, Chilean and Patagonian Mockingbirds, are accomplished mimics, and the White-banded Mockingbird is considered to be particularly outstanding in this respect. The Bahama Mockingbird, however, is not known to mimic other species. Among other *Mimus* derivatives on islands, the Socorro Mockingbird is a mimic but the Galapagos *Nesomimus* species are not. Mimicry is unknown also in some other mimids, such as the Long-billed and Crissal Thrashers, and it is occasional or weak in some of those species' close relatives, including the Brown and Le Conte's Thrashers, but well developed in others, as illustrated by the California Thrasher. The California Thrasher retains the songs of summer visitors to its habitat and mimics them in winter, long after the model has departed; it also imitates in the summertime the notes of departed wintering migrants. The same facility is reported for White-banded Mockingbirds in Argentina, which deliver in the breeding season songs learned on their northern non-breeding grounds. The Grey Catbird is a good mimic, but its Mexican relative and species in the Caribbean endemic genera apparently do not engage in vocal mimicry.

Besides their territorial songs, many mimids are equally distinguished, and distinguishable, by their calls. Loud and conspicuous calls presumably serve to maintain contact between paired individuals on territories within thick vegetation, and when the birds are not singing they can often be located by this calling behaviour. Variations on a basic call may signal sociable contact at one extreme and, at the other, high alarm. It is perhaps not inconsequential that, among related species with similar songs, the call notes are quite different. In one superspecies group that can serve as an example, the disyllabic low-intensity contact call of the California Thrasher, "churrit", becomes "pitchreee" in the Crissal Thrasher and "suweeep" in Le Conte's Thrasher, while these species' high-intensity and more monosyllabic alarm calls are correspondingly rendered as, respectively, "tschak", "choit" and "brrrrrt". The strident "chat" or "chert" calls of *Mimus* species are widely recognized, and the double "whit-whit" of the Curve-billed Thrasher, one of the pervasive sounds of the Sonoran Desert, is similarly diagnostic. Other mimids elsewhere have comparable and distinct calls.

Food and Feeding



The mimids are most accurately described as omnivores, since they consume not only a variety of insect and other invertebrate prey but also many seeds and, especially, fruits. The diets of many North American members of the family are well studied, and there are extensive similarities among these. The degree of omnivory, measured as the ratio of animal matter to plant matter in the diet, varies interspecifically and intraspecifically. Thus, within a given species, it varies seasonally and also from one locality to another, as sites differ widely in terms of fruit availability. In general, the proportion of insects and other invertebrates in the diet is highest in the breeding season and lowest in the autumn and winter. The Grey Catbird, for example, consumes insects and plants in the ratio 4:1 while breeding, but the ratio is 1:4 in the autumn.

While foraging on the ground and searching in leaf litter beneath shrubs, many mimid species encounter and consume similar sorts of insects. Among the taxa well represented in their diets are, in approximate order of importance, beetles (Coleoptera), grasshoppers and crickets (Orthoptera), ants, bees and wasps (Hymenoptera) and lepidopteran larvae. The larger thrashers, such as the California and Brown Thrashers, probably take the largest invertebrates available in their habitats, and they handle with ease tough insects of 20 mm or more in length. Other invertebrates, such as spiders (Araneae), are also seasonally conspicuous in diets. Northern Mockingbirds and Brown Thrashers, in the more

In the North American deserts the fruits of a variety of cactus species, such as prickly-pears (Opuntia) *and saguaros* (Carnegiea gigantea), *provide a vital supply of nutrients and moisture for any creature capable of reaching them. Perched atop a towering spiny column, the saguaro fruit is only accessible to bats and birds, and thrashers figure prominently among the avian contingent. Both the California Thrasher* (Toxostoma redivivum) *and Bendire's Thrasher* (T. bendirei) *reap the benefits of desert fruits, as does the* ***Curve-billed Thrasher****, each of these species consuming both pulp and pips. Having played a role in pollinating cactus flowers, the thrashers now distribute the seeds, and thus their contribution to the life-cycle of these stately desert plants is quite significant.*

[*Toxostoma curvirostre celsum*, south-east Arizona, USA. Photo: Dave Maslowski/ Maslowski Productions]

Several members of the family are known to eat eggs opportunistically. Usually this involves robbing the clutches of passerines, sometimes even those of conspecifics, without any apparent systematic effort to locate active nests. Life on the Galapagos Islands, however, is a little different. The four species of Nesomimus *mockingbird live in a harsh environment, where water, fruit and insects are relatively scarce. In some cases this has given rise to extreme forms of opportunism, verging on vandalism. The mockingbirds have learnt to take advantage of serendipitous windfalls, such as that supplied by broken seabird eggs. In booby (Sulidae) colonies, egg breakages are relatively common due to the clumsiness of incubating adults, and their reckless altercations with neighbouring birds. It is possible that all* Nesomimus *species consume the contents of eggs broken in this way, but at least two, including the* ***Espanola Mockingbird****, have taken the next step: they break the egg themselves. Any egg, even that of the Waved Albatross* (Diomedea irrorata)*, can be cracked open by the sharp beaks of mockingbirds. At oceanic islands in general, and the Galapagos in particular, nesting seabirds are trusting and docile animals, allowing hungry mimids to invade their colonies with impunity.*

[*Nesomimus macdonaldi*, Punta Cevallos, Española Island, Galapagos. Photo: Tui de Roy/ The Roving Tortoise]

mesic habitats of the eastern USA, are known to dig up and eat worms, and in southern Texas the Long-billed Thrasher depends on a large helping of snails in its diet. Marine arthropods are routinely taken from the shorelines of the Galapagos islands by the *Nesomimus* mockingbirds living there. Other animal food taken includes small vertebrates such as lizards, frogs and snakes, which are probably seized in a purely opportunistic fashion, and for no species do they constitute a large component of the diet.

Several members of the family are known to eat the eggs of other bird species, even those of conspecifics, but this behaviour does not appear to be regular for any of them. By far the most bizarre feeding habits observed relate to the Galapagos Mockingbird, one individual of which was seen to steal food from a 20-cm centipede (Chilopoda) that was foraging for crickets in cracks in the lava; the mockingbird successively took two large crickets from the centipede and ate these. Even more startling is the blood-drinking behaviour of Galapagos Mockingbirds. Such behaviour was reported earlier from the islands and involved Sharp-beaked Ground-finches (*Geospiza difficilis*), but its occurrence among the mockingbirds was documented more recently. It is apparently not unusual there, as Espanola Mockingbirds were seen to drink blood from beached and wounded bull sea-lions (*Zalopus californianus*), and from placentas on sea-lion nursery beaches. This same mimid drinks blood from small wounds in the tails of marine iguanas (*Amblyrhynchus subcristatus*), perhaps a by-product of its practice of gleaning ticks (Acarina) from the skin of these large lizards. These mockingbirds are also egg predators, in addition to which they seize fish brought to booby (*Sula*) chicks by the parents, and even kill and eat the newly hatched boobies. More usually, and as with the ground-finch, mockingbirds drink blood from the neck and head wounds of Masked Booby (*Sula dactylatra*) chicks that have been attacked by neighbouring adult boobies in the nesting colonies. These mockingbirds were even interested in the blood running down scratched human legs. Such bold behaviour is apparently not without risk, as the presence of several dead mockingbirds in the booby colony attested.

Commonly, one third to one half of the diet of a wide variety of mimids consists of fruit or other plant material, and even higher percentages are typical in the non-breeding season. In Caribbean woodlands, the Scaly-breasted Thrasher is thought to be predominantly frugivorous, and fruit consumption is likely more prevalent among the mimids of tropical latitudes. Northern Mockingbirds, too, are avid frugivores, and will leave their territories, flying high over those of neighbours, in order to visit fruiting trees.

In general terms, small, soft berries are the usual fruit consumed, and, as an extremely wide range of plant species provides this element of the diet, there are few other generalities other than berry size. Nevertheless, a few items do recur in the diets of different mimids in several different habitats; these include elderberries (*Sambucus*), both wild and domestic grapes (*Vitis*), huckleberries (*Vaccinium*), figs (*Ficus*) and berries of poison oak and poison ivy (*Toxicodendron*). In the south-western USA, the succulent fruits of several cactus species are eaten, both for the pulp, a handy moisture source in the desert habitats, and for the seeds. Prickly-pears (*Opuntia*) and saguaro (*Carnegiea gigantea*) supply such foods, and the Curve-billed, Bendire's and California Thrashers are known to make use of them. Galapagos mockingbirds also depend heavily on cactus fruits. In the Sonoran Desert, the Curve-billed Thrasher often visits the flowering stalks of *Agave* plants, presumably making use of the copious supplies of nectar that they produce, and another source of water in an otherwise arid habitat. Dry fruits are also widely consumed by mockingbirds and thrashers, and their stomachs often contain various grains, some taken from birdfeeders and some from the field. Larger and tougher fruits are not ignored. Acorns are eaten by both California and Brown Thrashers, and the birds will lodge the item in a crevice on the ground while hammering away at the shell. Walnuts (*Juglans*) are handled in a similar way. Some mimids consume large, soft fruits, and regurgitate the large and inedible seeds.

When foraging for arthropods, rather than berries, mockingbirds and thrashers do the majority of their feeding on the ground, as is clearly indicated by their general morphology (see Morphological Aspects). Typically, the search for terrestrial arthropods is conducted in dense cover in the litter and accumulated plant material beneath shrubs. In this situation, the long-billed species employ a technique known as "bill-sweeping", in which the bill is flicked from side to side in order to displace the litter and uncover the food items. These birds rarely, if ever, use their feet and legs to scratch in litter but, rather, the bill is deployed to pick

Once an egg has been successfully broken, an ***Espanola Mockingbird*** *consumes the contents much as it would glean nectar from a flower. It inserts its bill into the aperture, and drinks the liquid yolk and albumen. The amount of nutritious food contained within a seabird egg is considerable, enough to provide a meal for an entire co-operative group of mockingbirds. Several birds often gather round the egg, taking turns to gorge themselves, the precedence of one individual over another governed by dominance hierarchies established within the group.*

[*Nesomimus macdonaldi*, Punta Cevallos, Española Island, Galapagos. Photo: Tui de Roy/ The Roving Tortoise]

The avifauna of the Galapagos Islands is depauperate, allowing the few successful colonists to expand their ecological niches. In this environment, species such as the ***Espanola Mockingbird*** *find themselves rather high up the food chain. A reduction in competition, and an increase in prey, has led them to adopt a more predatory lifestyle than their mainland counterparts. They routinely harvest marine arthropods, and capture lizards, frogs and snakes if the opportunity presents itself. It is possible that they kill turtle hatchlings from time to time, but the individual pictured here was probably attracted to carrion.*

[*Nesomimus macdonaldi*, Galapagos. Photo: Pete Oxford/ Nature Picture Library]

through the leaves and twigs, to probe and to expand the cracks and crannies, and often to dig small pits. These activities are often undertaken with considerable vigour, and a foraging thrasher, for example, will energetically displace rocks and fallen branches of a considerable size.

The catbirds, and their relatives and derivatives, are less terrestrial, and forage largely above the ground, gleaning insects from the vegetation. The most arboreal of the mimids seem to be the Caribbean tremblers and thrashers in the genera *Cinclocerthia* and *Margarops*, which are omnivores and search for insects in leaf clusters, vine tangles and epiphytes. The third endemic genus in these tropical woodlands, *Ramphocinclus*, is, however, largely terrestrial. It shares the Lesser Antillean islands of Martinique and St Lucia with four other mimid species, comprising three in the above-mentioned two genera and the Tropical Mockingbird. It is perhaps not surprising that some of the co-existing species have evolved arboreal foraging habits.

Breeding

Typical mimids are monogamous, territorial birds, this basic breeding system being common to the majority of temperate landbird species. Further, in most members of the family, the sexes

One of the more bizarre foraging adaptations in Nesomimus *species is "vampirism". This macabre habit seems to be restricted to the* ***Espanola Mockingbird****, which drinks blood from beached and wounded bull sea-lions* (Zalophus californianus)*, as well as from placentas on sea-lion nursery beaches. Opportunistic individuals are also regularly seen sipping at the head-wounds of nestling boobies (Sulidae), those perennial victims of neighbourhood hostility, and they even attempt to glean blood from humans whose calves have been scratched in the unforgiving scrubland.*

[*Nesomimus macdonaldi*, Española Island, Galapagos. Photo: D. Parer & E. Parer-Cook/Auscape]

seem to take a nearly equal role in the tasks associated with reproduction, including territorial defence, nest-building, incubation of the eggs and feeding of the young.

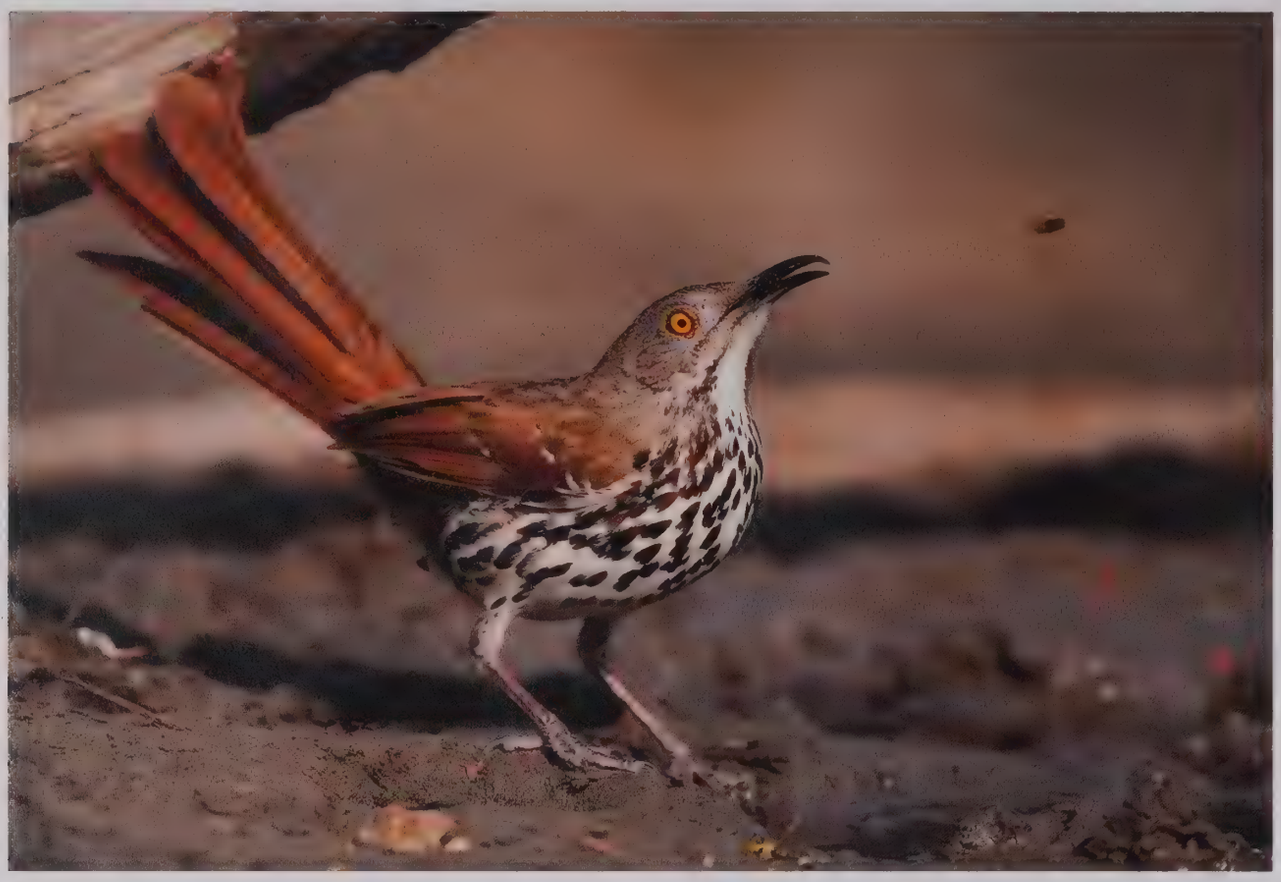
The breeding season is generally long, and often indicative of multiple broods. Several temperate-zone mimids are known for their early start to breeding, as early as late winter in some coastal species such as the California Thrasher, which then extends through the summer. Several of the mimids living in drier habitats initiate breeding after the onset of the rainy season, and species such as the Galapagos Mockingbird make use of high-rainfall "El Niño years" for greatly extended breeding opportunities. Some tropical members of the family, of which the Tropical Mockingbird is a good example, have been found breeding in virtually all months of the year.

Mimids have a variety of displays, many of these used throughout the year (see General Habits). It is worth mentioning here that wing-flashing and tail-flashing, in particular, are widely employed also in courtship displays.

For the most part, these are open-nest species, constructing a rough and large twiggy nest low down in dense vegetation. Desert thrashers customarily choose the spiniest of shrubs for their nests, which they often place in cacti. Nests are usually built by both members of the pair, although apparently only by females in the case of the Grey Catbird, and are variously lined with finer materials, such as grass and rootlets, fur, feathers, moss and other fibrous matter. As exceptions to the general rule, the Sage and Brown Thrashers occasionally nest on the ground, and the arboreal Caribbean tremblers construct a domed nest with a side entrance, often in a cavity or niche in a tree trunk. Also in the Caribbean, the Pearly-eyed Thrasher is commonly a cavity-nester, and on Mona Island, near Puerto Rico, it is known to nest in caves.

Clutch sizes of mimids are generally around 3–4 eggs at intermediate latitudes in the deserts, chaparral and other arid scrublands, but they follow the usual trend for higher clutch size at higher latitudes, both within and among species, and lower clutch size in the tropics. Breeding at the highest latitudes, the Sage Thrasher lays up to seven eggs and the Patagonian Mockingbird up to six eggs. Clutches of two eggs are typical of the Central American mockingbirds and the Black Catbird, and two or three eggs are the norm for the Caribbean endemics. The cooperatively breeding Galapagos mockingbirds, however, despite living at equatorial latitudes, lay four or five eggs per clutch. It is likely that strong seasonality on the Galapagos Islands, coupled with dramatic variation in conditions from one year to another, will select for higher clutch sizes.

The eggs of mockingbirds and their relatives are rather heavily blotched, those of the *Toxostoma* thrashers more lightly so, but the catbirds and their Caribbean derivatives have clear and unspotted blue to greenish-blue eggs. An interesting exception is the unspotted eggs of the Crissal Thrasher. This is apparently unrelated to exposure to brood parasites such as cowbirds (*Molothrus*), as both this and the related Le Conte's Thrasher reject cowbird eggs and, moreover, Le Conte's Thrasher's own eggs are spotted. Incubation, generally lasting for 12–14 days, is typically undertaken by both males and females, again with the exception of the Grey Catbird, in which only the female sits; the males of some mimid species develop a passable brood patch. Both parents feed the young.



The number of broods raised per year varies among species. While a single brood is usual at higher latitudes, two or more are typical elsewhere. Following wet "El Niño years" in the Galapagos, up to eight broods are reared by the Galapagos mockingbirds in a breeding season that can last for up to eight months.

Nest predation is a major source of mortality for many mimid species, the open nests of which are vulnerable to a wide range of predators. Snakes, corvids, tree squirrels and ground squirrels figure prominently among these. For example, Brown Thrashers lose many nestlings to American Crows (*Corvus brachyrhynchos*), and California Thrashers lose many of theirs to Western Scrub-jays (*Aphelocoma californica*). On Socorro Island, the local subspecies of the Red-tailed Hawk (*Buteo jamaicensis*) is a major nest predator, as are introduced feral cats, and in mainland areas these and other mammals, such as foxes (*Vulpes*) and raccoons (*Procyon*), take a similar toll of the young birds. Thrashers, mockingbirds and catbirds will variously attack animals perceived as threats, including snakes, rats (*Rattus*), squirrels, dogs and cats, and not infrequently human beings. The California Thrasher is extremely pugnacious in defending its nest against the Western Scrub-jay, an inveterate nest-robber, and these encounters have been known to result in the death of the jay. Both Le Conte's and Curve-billed Thrashers are known to defend their nests vigorously against nest-robbing Greater Roadrunners (*Geococcyx californianus*). Such anti-predator behaviour is frequently accompanied by alarm calls, wing-raising and tail-flashing, which sometimes attract to the defenders' aid birds of other species, as in the mobbing of owls or hawks perched within a territory.

One of the most famous inhabitants of the Galapagos archipelago is the marine iguana (Amblyrhynchus subcristatus). *Mockingbirds on a variety of islands do these placid and pokerfaced lizards a considerable favour by gleaning the ticks (Acarina) with which they are often infested. Perhaps as a by-product of this activity, the* ***Galapagos Mockingbird*** *has learnt to pull sections of loose skin away from the body of basking iguanas. Judging by the amount of time it spends perched on these reptiles, lizard lice and sheets of lizard skin are its favourite snacks.*

[*Nesomimus parvulus*, Fernandina Island, Galapagos. Photo: Tui de Roy/ The Roving Tortoise]

*There is scarcely anything written about drinking in mimids, but it may be reasonable to predict that the highest rate of drinking will be in the insectivorous species of hot and relatively dry environments. The **Long-billed Thrasher** fits this bill quite neatly, and is seen here visiting a pool of water in the Rio Grande Valley of southern Texas. Like other passerines, drinking mimids dip their bills into standing water, then raise their heads to let the liquid trickle back down their throats. This portrait aptly captures the long, strong legs and ample tail of thrashers, classic adaptations to a cursorial lifestyle.*

[*Toxostoma longirostre sennetti*, Rio Grande Valley, Texas, USA. Photo: Tom Vezo]

Probably in response to the heavy level of nest predation, mimids have evolved the characteristic of rapid chick growth and early fledging. The young leave the nest generally after 12–14 days, many days before they can fly, and at well below adult weight. In some instances, they are no more than two-thirds the weight of the adults.

A marked divergence from the typical breeding system, in which young are raised by a mated pair working alone, is that in which the pair has "helpers at the nest". In such co-operative breeding systems, the young are fed also by conspecifics, these helpers often being the young of previous broods of the parents that they assist, although that is apparently not always the case. The adaptive advantages of helping to raise younger siblings are clearly a product of kin selection, but, when their genetic relatedness is more distant, the advantages to the helpers are less obvious. There are numerous examples of such systems, which recur predominantly in tropical latitudes, in low-productivity regions such as Australia, and among certain taxonomic groups, such as the Old World babblers and starlings and the New World jays (Corvidae), among many others. In the Mimidae, however, they are exceptional. Indications of co-operative breeding have been noticed in the case of several *Mimus* mockingbirds and, recently, the White-breasted Thrasher, but the behaviour has been most elaborately developed by the Galapagos *Nesomimus* mockingbirds, to which most studies relate. In those *Mimus* species for which helpers have been reported, they are apparently the exception rather than the rule. In one long-term study of Chalk-browed Mockingbirds in Argentina, helpers were seen to feed nestlings in two separate years, and, in the one case in which the parentage of the helper was known, it was assisting birds other than its own parents. There is suggestive evidence of helpers at the nests of Long-tailed Mockingbirds in Ecuador and of Tropical Mockingbirds in Venezuela. With the latter species, the young of previous broods remain in their parents' territory while subsequent broods are reared, and they may assist in the process.

The Galapagos mockingbirds are also strictly territorial, but in three of the four species the territory is occupied by social groups of up to ten or more individuals, rather than by pairs, that collectively defend fixed areas and participate in co-operative breeding. Studies have revealed that each group consists of a dominant male and female, which are generally monogamous, but on the larger group territories up to four breeding females are present. Usually each female lays eggs in her own nest, but sometimes eggs are jointly contributed to a single nest. The nestlings are fed by their parents and by helpers in the group, although not all members of the group assist in feeding the brood. Most helpers are adults, and males are significantly more likely than females to help at the nest; both sexes are more likely to assist if the brood's parents are also their own parents. Nevertheless, un-

*In most mimids studied to date both sexes contribute to nest construction, and this is the case in the **Sage Thrasher**. In common with* Toxostoma *species of semi-arid landscapes, breeding pairs build a bulky, cup-shaped structure of twigs, usually placing it out of reach in the thorniest location available. Unlike other mimids, they sometimes nest on the ground, but always well concealed under dense vegetation. The coarse outer structure is always lined inside with softer materials, such as grass, rootlets, feathers and moss. This individual is carrying what looks like animal fur precisely for this purpose.*

[*Oreoscoptes montanus*, Mono County, California, USA. Photo: John Gerlach/DRK]

The mockingbirds are typical of the family in building large, open-topped nests low down in dense vegetation. Compared to the tightly woven or firmly mud-moulded nests of thrushes (Turdidae), mockingbird nests tend to look hastily cobbled together. The structure is made up of chunky twigs, loosely assembled, and the lining is often rudimentary. One outcome of this open nest-design is that it renders mimids vulnerable to brood parasites. Indeed, the ***Chalk-browed Mockingbird*** *is one of the main hosts of the Shiny Cowbird* (Molothrus bonariensis)*, with up to 80% of its nests parasitized.*

[*Mimus saturninus frater*, Minas Gerais, Brazil. Photo: Anita Studer]

related helpers are not uncommon. Helpers have not been recorded at nests of the San Cristobal Mockingbird, the population density of which is much lower than that of mockingbirds on other islands, and the territories much larger and occupied by mated pairs only. Elsewhere, larger groups occupy larger territories, and nests with three helpers produce more than twice as many young as do nests with no helpers.

Movements

A large majority of the Mimidae are residents. They either are sedentary, remaining on fixed territories throughout the year, or engage in very local post-breeding movements as new recruits are incorporated into the population and territories subsequently re-established.

In North America, four species have breeding distributions that reach north to Canada. Two of these, the Northern Mockingbird and the Grey Catbird, range from the Pacific coast east to the Atlantic seaboard, while the Brown Thrasher breeds in the eastern and central states and the Sage Thrasher in the west. The first-mentioned is largely sedentary, although some individuals that breed at higher latitudes may shift to different territories in winter or partially vacate the northern extremities of the breeding range. It does, however, retain a presence at its northern outposts throughout the winter months. The Brown Thrasher is a summer visitor to the northern two-thirds of its breeding range, a year-round resident in the south-eastern states of the USA, and a winter visitor to central Texas, south-west of and beyond the breeding range. It also occurs as an occasional winter vagrant farther west, from New Mexico to California, and southwards in states in the northern third of Mexico, as well as in the Caribbean from the Bahamas south to Cuba.

The remaining two northern species migrate to winter ranges wholly or largely separate from the breeding ranges. The Sage Thrasher moves south from the Great Basin Desert to spend the winter months in the more southerly Mojave, Sonoran and Chihuahuan Deserts, while the Grey Catbird vacates all of its broad range except for strictly coastal areas of the USA from Massachusetts south to Florida. Grey Catbirds winter around the Gulf of Mexico and in Central America south to Panama, as well as on islands in the Greater Antilles; they have been recorded as vagrants in Colombia. This species, which has the longest migration of any mimid, appears to display "leapfrog" migration: individuals in the extreme south-west of the wintering range, in Panama, had been ringed in the extreme north-east of the breeding range, in Nova Scotia. Grey Catbirds in Altimira, in Panama, exhibited site-fidelity over several successive winters.

One other North American mimid is a partial migrant. Bendire's Thrasher lives in desert-scrub habitats from south-eastern California, southern Nevada, Utah and Colorado south to southern Sonora, in Mexico. It leaves the northern half of this range after breeding, and the northern birds apparently join southern conspecific residents to spend the non-breeding season in the region from southern Arizona and southern New Mexico southwards to the extreme of the breeding range.

A similar picture of seasonal movements is found among the Neotropical members of the genus *Mimus*. The two species with more southerly ranges east of the Andes, the Patagonian and White-banded Mockingbirds, spend the non-breeding season to the north and partially outside their breeding ranges. The former occupies much of northern Argentina in the austral winter, while the latter moves over longer distances from its central Argentine breeding range to encompass much of Bolivia, Paraguay, Uruguay and parts of southern Brazil. The extent to which the breeding ranges of these two species remain occupied in the winter period is uncertain, but it appears that many individuals remain at or near local breeding sites.

Several members of the family have been recorded as vagrants on the eastern side of the Atlantic Ocean. Not surprisingly, these involve the three migratory species with breeding ranges that include the eastern parts of North America. The Grey Catbird has reached Europe on at least five occasions, the most recent in October 2001, when an individual was found on Anglesey, off north Wales; in addition, one was discovered on Tenerife, in the Canary Islands, in November 1999. Northern Mockingbirds have crossed the Atlantic three or four times, and there are two European records of the Brown Thrasher.

In this connection, there are a number of instances of mimids landing on ocean-going vessels while at sea. One of the most

Breeding in mimids is an egalitarian enterprise. In most species both sexes share the tasks in equal measure at all stages of the nesting cycle, and thus males invest roughly the same amount of effort in territorial defence, nest-building, incubation of eggs and feeding of young as do females. This is certainly the case in the ***Brown Thrasher****, the simultaneous arrival of this pair to feed a brood providing a fitting symbol of their close collaboration. The allocation of duties in the* ***Curve-billed Thrasher*** *is slightly less democratic, with females contributing rather more than males in terms of incubation and provisioning. The upper image shows a thrasher nest placed on the ground, a rare sight in most* Toxostoma *species, while the lower image shows one cradled deep in the unwelcoming arms of a cholla cactus* (Opuntia)*, a much more typical placement. By making use of the plant's defensive armoury, Curve-billed Thrashers, and other desert-dwelling mimids, virtually assure their brood of a safe passage through the incubation and nestling phases. In both these species the young are fed a diet of insects, with a small amount of fruit, and take anything between 11 and 16 days to leave the nest.*

[Above: *Toxostoma rufum*, Presque Isle County, Michigan, USA. Photo: John Gerlach/DRK.

Below: *Toxostoma curvirostre*, Green Valley, Arizona, USA. Photo: Tom Vezo]

*As if to accentuate the thrush-like impression it conveys, this **Grey Catbird** is carrying an earthworm (Oligochaeta) to its brood. This particular prey item is rare in the diet of most mimids, chiefly because they live in drier habitats where worms are scarce, or difficult to dig for. This generalization does not apply to the Grey Catbird, which tends to nest in damp undergrowth, as this photograph attests. This species is also unusual for a mimid in that the male contributes little to nest construction, and never, or rarely, incubates. He does feed the nestlings, however, which helps them to develop quickly: they fledge after about 12 days.*

[*Dumetella carolinensis*, Sirdar, British Columbia, Canada. Photo: S. Roberts/Ardea]

interesting cases concerned a Grey Catbird that, in October 1998, joined a Europe-bound cruise liner sailing from New York. When the ship called in at the port of Southampton, on the south coast of England, the catbird remained on board, having presumably learnt to enjoy an easy life on the handouts provided by the passengers and crew.

Relationship with Man

A number of mimids have a rather close relationship with humans, to the extent that they find acceptable living conditions in suburban gardens, city parks and plazas, and in the disturbed, open vegetation associated with habitat clearance and agriculture. Several North American members of the family are among the perhaps half-dozen bird species familiar to the more observant urban dweller. Indeed, the Northern Mockingbird must be one of the most widely recognized birds in the USA, especially with its propensity for nocturnal singing, and it is the "official bird" of no fewer than five states; the Brown Thrasher serves in that capacity for the state of Georgia. This contact with the bulk of the populace, together with an appreciation of these birds' conspicuous and often quirky behaviour, renders them akin to suburban icons. Tropical Mockingbirds extend this familiarity through the lower latitudes, while the various South American *Mimus* species are equally effective ambassadors, between their taxa and ours, from Brazil and Ecuador south through most of Chile and Argentina.

A few of the species are locally regarded as mild pests for their habit of feeding on agricultural grains and on orchard fruit and nut crops. In the Caribbean, for example, the omnivorous Pearly-eyed Thrasher is sometimes considered a very unwelcome visitor, as it consumes commercial crop fruits such as papaya and bananas. Generally, however, mimids are not persecuted to an excessive degree by humans.

In the early part of the twentieth century, some Northern Mockingbird populations were decimated by the cagebird trade in a bid to satisfy customers eager to possess these talented songsters. Fortunately, however, these negative effects were short-lived. Indeed, it was the release by disgruntled shippers of caged birds destined for domestic markets that enabled Tropical Mockingbirds to colonize Panama in the 1930s; this species was thereby able to fill in a natural hiatus in its range, between Costa Rica and Colombia. The colonists have thrived, and are still expanding their range in that country. Members of this family are still kept as cagebirds throughout Central and South America, but trapping for this purpose is not thought to be having any significant effect on their wild populations.

It is perhaps of interest to add here an anecdote, relating to the describer of the genus *Dumetella*, as an example of ornithological detection. S. L. Olson's detailed investigation of this matter, published in 1989, is summarized below.

*Intensive provisioning by both parents, accelerated growth of chicks, and truncated fledging periods are features common to most mimids. A young **Bendire's Thrasher** spends roughly 12 days in the nest, an incredibly brief period for a bird of its size. In effect, thrasher chicks leave the nest prematurely, when they are only two-thirds of adult weight, and many days before they can fly. This unusual strategy has probably arisen in response to high rates of predation. Flightless fledglings are vulnerable, but at least they are scattered in dense undergrowth, raising the likelihood that some individuals will survive to adulthood.*

[*Toxostoma bendirei*, Mexico. Photo: Patricio Robles Gil]

Ever since Darwin's day, Galapagos wildlife has been famous for its fearlessness. The endemic Nesomimus *radiation is no exception, as illustrated by this cameo of the* ***Espanola Mockingbird*** *in its natural habitat. The energetic curiosity of these birds sets them apart from most local fauna, and endears them to many visitors. In reality, their fascination with human beings stems from the discovery that most large reptiles and mammals, not least the modern-day tourist, are a reliable source of tasty treats.*

[*Nesomimus macdonaldi*, Española Island, Galapagos. Photo: Andy & Gill Swash]

The "Cat Bird" referred to by M. Catesby in the first half of the eighteenth century served as the type of Linnaeus's "*Muscicapa carolinensis*". Over a century later, when the species was first placed in its own monotypic genus, separate from *Mimus*, it was given the name *Galeoscoptes*, proposed by J. Cabanis in 1850. For several decades thereafter, the Grey Catbird was widely referred to under the name *Galeoscoptes carolinensis*. In the early years of the twentieth century, however, C. W. Richmond advised that a certain "S.D.W." had applied the name *Dumetella* to this species in a journal entitled *The Analyst*, and in 1907 W. Stone proposed that this generic name be substituted for *Galeoscoptes*. Three years later, the American Ornithologists' Union, in the third edition of its *Check-list of North American Birds*, adopted this suggestion, since when the Grey Catbird has borne the scientific name of *Dumetella carolinensis*. It seems, however, that nobody had ever attempted to identify the full name of "S.D.W.", the original author of the new generic name.

The Analyst was a London-based English publication, described as a "journal of science, literature, natural history, and the fine arts". It survived for only a short period, from 1834 to 1840. Many of its contributors gave only their initials or pseudonyms, or pseudonymous initials, as was the general practice in those days. The original description of the genus *Dumetella* appears in the preamble to an 1837 article entitled "The fishes (Pisces) of Britain, systematically arranged"; previous issues of the journal contain similar lists of British birds and mammals, and several discourses on ornithological nomenclature, by the same author. "S.D.W." appears as a vigorous proponent of a highly idiosyncratic system of nomenclature and orthography. One of his basic beliefs was that the genus should be reflected not only in the scientific name of an organism but also in its English name, a proposal that had already been advanced by N. Wood in the same journal, and he made extensive arbitrary changes to both. In 1908, Richmond listed all the proposed new generic names of birds, and attributed them all to "S.D.W.". About 20 years earlier, at least one of S.D.W.'s names, "*Densirostra*", was listed in an index of avian genera by F. H. Waterhouse, who gave the author's name as "Wood". This provides the first clue to the identity of "S.D.W.". Neville Wood was the fourth son of Charles Thorold Wood, both of whom published books on ornithology in the years 1835–1836. C. T. Wood, in *The Ornithological Guide*, repeated one of S.D.W.'s papers in *The Analyst* almost in its entirety, stating that it accorded with his own views of nomenclature, and N. Wood, in *The Ornithologist's Text Book*, was extremely favourable in his reviews of some of S.D.W.'s contributions. Both express a very high opinion of *The Analyst* as a journal. From the character and tone of their writing, and from the inference in Waterhouse's 1889 index, there is no doubt that S.D.W. is either C. T. Wood or his son.

From the circumstantial evidence, the former is immediately the more likely. His son, Neville, put his own name to his contributions in *The Analyst* and, furthermore, referred to articles by "S.D.W." in such a way as to indicate that they were penned by somebody other than himself. Moreover, C. T. Wood, writing in *Magazine of Natural History*, stated that he had "altered the name" of a species listed in two articles in *The Analyst* that are signed "S.D.W.". Further corroboration that "S.D.W." is a pseudonym of C. T. Wood is found in his son's book *British Song Birds*. In this, the names of several birds are attributed directly to C. T. Wood, in each case with the reference cited as either "*Analyst* 13" or "*Analyst* 14"; in these issues of the journal, the names in question appear only in the lists signed "S.D.W". It is quite clear from this evidence, there-

Although it occupies a restricted range entirely within the borders of Chile, the ***Chilean Mockingbird*** *is common, and its long-term future appears to be secure. It occupies a wide range of semi-arid habitats from sea-level to 2000 m, but reaches peak abundance in maquis or matorral-type habitat on the lower slopes of coastal ranges. Elsewhere it occurs, but at lesser densities, in semi-desert, succulent coastal scrub, and disturbed habitats such as successional vegetation in the vicinity of settlements. Most of these habitats seem very unlikely to be at risk within the foreseeable future.*

[*Mimus thenca*, Yelo-Dam, Región 5, Chile. Photo: Johannes Ferdinand]

*The total global population of the **Espanola Mockingbird** currently stands at 1000-2500 individuals, all of which reside on the Galapagos island of Española, and the tiny adjacent islet of Gardner. Because its range is permanently limited, and because its numbers could at any point be smashed by a single disaster, natural or otherwise, this species is listed as Vulnerable. For the moment, however, it appears to be thriving in the arid littoral scrub and thorny woodland of its island home. The most crucial conservation measure is to ensure that Española remains free of introduced mammalian predators, especially rats.*

[*Nesomimus macdonaldi*, Española Island, Galapagos. Photo: Josep del Hoyo/ Lynx Edicions]

fore, that the identity of S.D.W., the describer of the genus *Dumetella*, is C. T. Wood.

Status and Conservation

As the majority of mimid species live in arid and scrubby vegetation unsuitable for intensive agriculture, and others thrive in disturbed areas at the edges of woodland or in even closer proximity to man and his activities, these birds have, by and large, escaped the wholesale and often devastating negative effects of habitat clearance and fragmentation. In *Threatened Birds of the World*, published in 2000, BirdLife International nevertheless listed five of the 34 species in the family as globally threatened and one as Near-threatened.

Among the North American mainland species, the Crissal, Le Conte's and Bendire's Thrashers, three desert-dwelling mimids, are designated as "species of special concern" by the State of California. This perhaps signifies that these thrashers, with their naturally rather discontinuous ranges, may be sensitive to disturbances such as off-road vehicle traffic, habitat degradation, and sprawl around desert urban centres. Similarly, a fourth species, the Sage Thrasher, is of concern in the State of Washington, where its preferred sagebrush habitat has been reduced by one third to three-quarters of its pre-settlement levels in some regions of the state. Its status at the extreme northern edge of its range, in British Columbia, is more precarious. Here, only a few hundred hectares of suitable terrain remain in the several southern valleys of the province that provide breeding habitat, and the species is under consideration for "Endangered" status.

While the Black Catbird is reasonably common in some parts of its range in the Yucatán Peninsula, it is often regarded as rare and local. Over much of the upper portion of the peninsula it is uncommon to rare, and possibly only seasonal in its occurrence. It is similarly rare in the south of its range, in north Guatemala. In the core area of its distribution on the eastern side of the peninsula, including Cozumel Island and the Belize cays, much habitat loss and fragmentation has resulted from tourism-related developments and the conversion of scrubby woodland and forest to coconut plantations. In Belize, the Siwa Ban Reserve was established in 1998, with the express purpose of protecting the Black Catbird population on Caye Caulker. Whether this initiative has been effective is, however, uncertain. Because of the continuing loss of habitat to which this species is subjected, it is currently placed in the conservation category of Near-threatened.

In a family that shows extraordinary capabilities for colonizing islands, it is not surprising that the major conservation challenges are found among several of its island populations. Perhaps the one at greatest risk of extinction is the Cozumel Thrasher, confined to the island of that name off the north-east coast of the Yucatán Peninsula. This species was reasonably common until, in September 1988, a major hurricane hit the island. This clearly had a massive effect on the species' numbers, for this thrasher suddenly became very rare; indeed, only three individuals were found during the ensuing seven years, all mist-netted during the course of survey work. In 1995, the island was lashed by another big hurricane, after which, and despite annual surveys, the thrasher was not seen again and was feared by some to be extinct. It was a great surprise, therefore, when a single Cozumel Thrasher was discovered in June 2004, the first for almost nine years. Although it has been assumed that the two hurricanes were

*The **White-breasted Thrasher** is restricted taxonomically to a monospecific genus, and geographically to two Lesser Antillean islands. Once common, its population crashed in the twentieth century, and now comprises some 150 pairs, 40 on Martinique and the rest on St Lucia. These last pairs suffer the usual litany of threats to island fauna: habitat loss; introduced predators; and alien competitors. Given its precarious situation, it is classified as Endangered.*

[*Ramphocinclus brachyurus sanctaeluciae*, Anse la Sourciere, St Lucia. Photo: Doug Wechsler/ VIREO]

By far the rarest species of Nesomimus, *the* ***Floreana Mockingbird****, is now extinct on Floreana itself, perhaps as a result of nest predation by introduced rats. It survives on two tiny satellite islets, one of 0·8 km² and the other just 0·1 km². Its combined population lies in the region of 150–250 individuals. With so few individuals surviving in such a minute range, this species is vulnerable to an array of critical factors, including meteorological fluctuation, accidental mammalian introductions, inbreeding and disease. It is listed as Endangered.*

[*Nesomimus trifasciatus*, Campeón Island, Galapagos. Photo: Tui de Roy/ The Roving Tortoise]

responsible for the demise of this mimid, it is worth pointing out that Cozumel, because of its geographical location, must have suffered from these devastating meteorological events at relatively frequent intervals over an extremely long period of time prior to 1988. One would have expected the thrasher to have become adapted to this situation and to have evolved the means of surviving the huge damage wrought by such events. This species is currently listed as Critical, but it should be borne in mind that, not many decades ago, as many as 10,000 Cozumel Thrashers lived on the 480-km² island. Although this mimid was earlier reported to inhabit scrubby woodland and dense undergrowth, and the edges of tropical forest, the three individuals found in 1994 and 1995 were well away from scrub, two in deciduous forest and the third in semi-deciduous forest. A thorough investigation of its ecology may help to provide some further explanation for its exceedingly rapid decline.

A second species resident on a Mexican island is also classed as Critical. This is the Socorro Mockingbird, the sole representative of its genus, which is restricted to a single island of 132 km² in the Revillagigedo Archipelago, some 600 km off Mexico's north-western coast. At least one endemic landbird, the Socorro Dove (*Zenaida graysoni*), and possibly a second, the local subspecies of the Elf Owl (*Micrathene whitneyi*), are already extinct there. The total population of the Socorro Mockingbird numbered about 350 individuals in 1994, a drastic decline from the levels found a half-century earlier. Three primary causes are suggested as being responsible for this: predation by feral cats, habitat alteration caused by sheep grazing, and competition from a new colonist, the Northern Mockingbird, which arrived on Socorro between 1971 and 1978. Various studies have revealed little evidence that predation is a serious problem, and the Northern Mockingbird is thought unlikely to be an important competitor, as it is smaller than the Socorro Mockingbird and differs from it ecologically. The most probable reason for the latter's decline is intensive grazing by sheep, which has already destroyed a great deal of the species' habitat. A conservation programme aimed at removing both sheep and cats from the island has already started.

Similar concerns surround the status of the White-breasted Thrasher, another species in a monotypic genus. This globally threatened Caribbean mimid has a narrow range, restricted to the two Lesser Antillean islands of Martinique and St Lucia, where it was formerly common and widely distributed. By the middle of the twentieth century, however, it was thought to have become extinct, but subsequent fieldwork revealed that the thrasher was still present, although in greatly reduced numbers. Its current population is thought to total approximately 150 pairs. The nominate race, on Martinique, consists of 40 or more pairs, while the St Lucia population, *sanctaeluciae*, estimated at 46 pairs in 1992, was believed to number about 120 pairs in a survey carried out three years later. More recently, a global population of no more than 250 individuals has been suggested. The decline in this species was brought about initially by habitat clearance, subsequently accelerated by predation by rats and mongooses (*Herpestes*) and further degradation of low woodland and scrub-forest. Although Martinique and St Lucia are comparatively large islands, with respective surface areas of 1080 km² and 600 km², the White-breasted Thrasher is found in just two areas totalling little more

The ***Soccoro Mockingbird****, sole representative of the genus* Mimodes, *lives on a single island in the Revillagigedo Archipelago, some 600 km off Mexico's north-western coast. By 1994, its population had declined to around 350 individuals, probably as a result of predation by feral cats and overgrazing by introduced sheep. The rate and scale of decline suggests that this species is in a precarious situation, and thus it is listed as Critical. A programme aimed at removing both sheep and cats from the island (now a biosphere reserve) has begun.*

[*Mimodes graysoni*, Monte Evermann, Socorro Island, Mexico. Photo: Juan Cornejo]

Another island endemic listed as Critical, the ***Cozumel Thrasher****, is perhaps the mimid closest to extinction. Its population numbered around 10,000 birds until, in 1988, a hurricane hit the Mexican island of Cozumel. This wreaked havoc with native habitat, and the thrasher almost vanished. Only three were found in the next seven years, and none at all after 1995, when a second storm devastated the island. It was rumoured to be extinct, and news of another sighting, in June 2004, was greeted with surprise and relief. As it happens, this enigmatic mimid is possibly safer than history suggests, as large areas of habitat remain very poorly surveyed.*

[*Toxostoma guttatum*, Mexico. Photo: John S. Dunning/ VIREO]

than about 20 km². Its nests, eggs and juveniles are preyed on by mongooses, rats and snakes, and also by Pearly-eyed Thrashers. On St Lucia, competition from the the Spectacled Thrush (*Turdus nudigenis*), a recent colonist, is an additional factor cited as responsible for the decline. The White-breasted Thrasher is "officially" placed in the conservation category of Endangered, but it is hoped that efforts to control its predators will lead to some recovery in its numbers. A conservation initiative has been started on St Lucia, with the aim of determining the species' true population size, its precise distribution and ecological requirements, and the impact of predation and human disturbance on its breeding success. Of particular interest is the fact that this species has recently been found to breed co-operatively.

The remaining two globally threatened species are found in the Galapagos Islands. The Floreana Mockingbird was once common on the large island of that name, previously known as Charles Island, and it was observed there by Charles Darwin in 1835, but it had disappeared some 50 years later. It now survives on two small satellite islets off Floreana, where its combined population is probably of the order of 150–250 individuals. The species is listed as Endangered. Introduced black rats (*Rattus rattus*) have been implicated in this mimid's extinction on the main island; whereas other islands of the Galapagos had, or have, native rats, Floreana had no rats whatever until the introduction of this nest predator to a naive mockingbird population. The survival of the two extant populations is not assured, either. Some scientists are concerned that, in the absence of immigration from Floreana itself, the birds on these tiny islets, one of which is 0·8 km² in size and the other just 0·1 km², may have already lost a significant amount of genetic diversity, rendering them more vulnerable to fatal diseases. Furthermore, this species is greatly influenced by weather events, extreme conditions causing substantial fluctuations in its numbers.

Although listed as globally threatened, and placed in the conservation category of Vulnerable, the Espanola Mockingbird appears to be still common. It inhabits arid littoral scrub, low thorny mesquite (*Prosopis*) scrub and scrubby woodland with scattered trees. Its current population, estimated to be between 1000 and 2500 individuals, lives on Española, formerly called Hood Island, and on one tiny adjacent islet. There is no evidence that either has been populated by rats. The primary conservation concern over this species stems from the fact that it is confined to two small islands on which its population trends are not known. It seems quite possible that extreme weather events in the Galapagos could have effects on this species similar to those known to be suffered by the Floreana Mockingbird. In addition, any accidental introduction of alien predators to Española or Gardner-near-Española would almost certainly have major adverse consequences for these islands' only mimid inhabitants.

Several other island mimid populations give cause for concern or, in some cases, are beyond recovery. For example, the Pearly-eyed Thrasher is known to have disappeared from the small Venezuelan island of Horquilla, at the southern edge of its extensive east Caribbean range southwards from the Bahamas, although it persists not far away to the west, on Bonaire. Its congener, the Scaly-breasted Thrasher, is thought to be lost from several islands that it previously occupied within its more limited Lesser Antillean range.

While the extinction of any unique island taxon is irreparable, and rightly perceived as a conservation failure with moral overtones, a biogeographical view of the colonization and extinction dynamics of island populations regards both components as inexorable parts of the evolutionary process. The term "taxon cycle" was coined by E. O. Wilson to describe, originally in respect of Melanesian ants, the cycle of broad-ranging and generalized species that colonize depauperate islands, evolve there through stages of increasing taxonomic distinction from their ancestors, and eventually succumb to extinction as the pressure of newly arriving colonists drives the cycle. Thus, the loss of island endemics is inevitable over the longer term; average lifespans in the Lesser Antillean avifauna are estimated at about 2 million years. Notwithstanding this, in virtually every historical instance of island extinction witnessed over the last century or so, human actions, both direct and indirect, have clearly accelerated the taxon cycle and pushed older, endemic species closer to the brink.

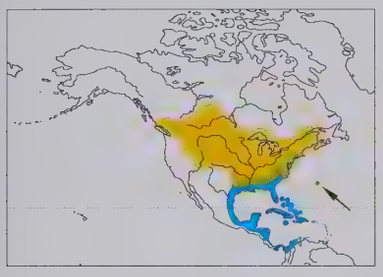
PLATE 45

inches 4
cm 10



Genus *DUMETELLA* C. T. Wood, 1837

1. **Grey Catbird**

Dumetella carolinensis

French: Moqueur chat **German**: Katzenvogel **Spanish**: Pájaro-gato Gris
Other common names: Common/Northern Catbird

Taxonomy. [*Muscicapa*] *carolinensis* Linnaeus, 1766, Virginia, USA.
Closely related to *Melanoptila glabrirostris*, and these two species are sometimes considered closely enough related to be lumped in the same genus; in such an arrangement, present genus has priority. In past, present species was commonly isolated in genus *Galeoscoptes*, but *Dumetella* subsequently shown to be the older name (see page 474). Proposed races *ruficrissa* (W parts of range), *meridiana* (C & S) and *bermudiana* (Bermuda) appear to be too weakly defined to be reliably distinguishable. Monotypic.
Distribution. Breeds S Canada (British Columbia E to Nova Scotia) and C, E & SE USA (E Washington and E Oregon SE to Utah and Texas, E to Atlantic coast, also on Bermuda; non-breeding extreme S & SE USA, N Caribbean islands, and Atlantic coastal areas of Central America S to Panama and Colombia.

Descriptive notes. 21–24 cm; 23–56 g. This and related *Melanoptila* are the smallest mimids; has wings short and rounded, tail rather long. Plumage is uniform dark grey, with black forehead, crown and tail; under-tail-coverts chestnut (usually not conspicuous); iris dark brown; bill black, legs dull fleshy brown to dusky or blackish-brown. Sexes alike. Juvenile is brownish-grey, mottled below, iris grey. VOICE. Long series of varied, deliberate repeated phrases, variously harsh, squeaky, or more musical and mellow, typically with less repetition than other mimids; male and female known to duet. Typical calls distinctive, including harsh and rapid "chek-chek-chek", soft and low-pitched "whirt", and cat-like mewing; mimics other bird species to varying degrees, also mechanical sounds and frog calls.
Habitat. Inhabits dense shrubbery and second growth, hedgerows and windbreaks, and well-vegetated residential areas; uncommon in forest and in conifers. Utilizes low, often successional habitats during migration. Winters in similar edge habitat and scrub in tropical zones, generally below 1000 m.
Food and Feeding. Generalized omnivore, feeds on insects and fruits; predominantly frugivorous in late summer, on migration, and in wintering sites in tropics. Known to destroy eggs of other species. Nestling diet almost exclusively small insects. Gleans insects from foliage, usually within 2–3 m of ground, occasionally higher; often feeds on ground, where searches for insects by flicking aside litter with the bill. Sexes defend separate territories in winter.
Breeding. Season varies with latitude; egg-laying begins late Apr in SE USA, Jun in S Canada; two broods typical, possibly three in SE of range. Nest, built mostly by female, a bulky open cup made of grasses, bark, small twigs and rootlets, lined with finer material, placed typically 1–2 m above ground in dense cover of shrub; strongly territorial around nest, territory c. 0·2–0·4 ha, sometimes excludes other species, including nest-parasitic Brown-headed Cowbird (*Molothrus ater*), from territory. Clutch 3–4 eggs, occasionally up to 6, clutch size larger towards NW extremity of range, smaller in later part of season, eggs unspotted turquoise-green; incubation by female, period 12–15 days, mostly 13 days; chicks fed by both parents, nestling period up to 12 days.
Movements. Migratory. Winters in SE USA, N Mexico, on islands in Caribbean and along Caribbean coast of Central America as far S as Colombia. Present in C part of breeding range early May to late Aug; non-breeders in Central America early Oct to mid-Apr. Site-fidelity in successive years noted on both breeding and wintering territories. Vagrants recorded in Venezuela, also in E Atlantic (Tenerife, in Canary Is) and several times in Europe.
Status and Conservation. Not globally threatened. Common throughout most of breeding range; sporadic at edge of range, e.g. NE Wyoming (EC USA). Mid-term variation in population density apparent, e.g. overall 3–5% decrease in SE USA during 1966–1991, but increased density in same area 1966–1979, and strong declines (1–10%) 1982–1991. Probably benefits from forest clearance, planting, shelterbelts, and other human activities that have modified pre-settlement landscapes in North America. As non-breeding migrants in Caribbean and Central America use largely scrub and second-growth habitats, likely not so sensitive to habitat clearance in those areas as are other Neotropical migrants.
Bibliography. Amos (1991), Andrews (1987), Anon. (1998b), Baicich & Harrison (1997), Bancroft (1981), Barlow (1960), Batts (1962), Belles-Isles & Picman (1986c), Bent (1948), Berger (1951, 1954), Binford (1989), Campbell *et al.* (1997), Castrale & Donaldson (1986), Charles (1954), Cimprich & Moore (1995), Craves (2003), Crowell (1962), Cyr & Larivée (1995), Darley *et al.* (1971, 1977), Davis (1942), DeGraaf & Rappole (1995), Dwyer (1998), Eddins (1989), Eddins & Rogers (1992), Fletcher & Smith (1978), Gabrielson (1913), Garvin *et al.* (2003), Gill (1934, 1935, 1936), Greenberg (1992), Greenberg *et al.* (1997), Gross (1948), Harcus (1973), Hauber (1998), Hazelton *et al.* (1984), Heise & Moore (2003), Heise & Rimmer (2000), Hellmayr (1934), Holcomb (1966), Johnsgard (1979), Johnson & Best (1980, 1982), Kaufman (1996a), Keith *et al.* (1999), Kroodsma (1996), Latham (1936), Lent (1990, 1992), Leonard & Freifeld (2001), Lowther (1980), Lynch (1992), Marsh (1977, 1979, 1981, 1983, 1984), Marshall *et al.* (2001), McGeen & McGeen (1962), Michael (1970), Monroe (1968), Murphy & Fleischer (1986), Nickell (1958, 1965, 1969), Oelke & Klopfer (1970), Paynter (1995), Peck & James (1987), Pence & Casto (1975), Pérez-Rivera & Soto (1991), Piergallini & Yahner (2001), Prescott (1982), Preston (1989), Price *et al.* (1995), Rand & Traylor (1949), Rappole & Warner (1980), Rappole *et al.* (1992), Raynor (1979), Ridgely & Gwynne (1989), Rivers & Sandercock (2004), Root (1988), Scott (1977, 1993), Scott, Darley & Newsome (1988), Scott, Lemon & Darley (1987), Sheppard *et al.* (1968), Slack (1973, 1976), Slud (1964), Small (1994), Spooner *et al.* (1996), Stevenson & Menk (1978), Stiles (1985), Stiles & Skutch (1989), Suthers & Suthers (1990), Suthers *et al.* (2000), Thompson & Jane (1969), Waide *et al.* (1980), Wetmore & Swales (1931), Wiedenfeld *et al.* (1992), Woodward (1976), Worthington (1985), Young (1968), Yunick (2000), Zimmermann (1963).

Genus *MELANOPTILA* P. L. Sclater, 1858

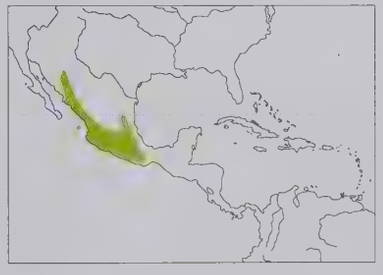
2. **Black Catbird**

Melanoptila glabrirostris

French: Moqueur noir **German**: Glanzkatzenvogel **Spanish**: Pájaro-gato Negro

Taxonomy. *M[elanoptila] glabrirostris* P. L. Sclater, 1858, Omoa, Honduras.
Sometimes placed in genus *Dumetella*, to which present species certainly appears to be closely related. Separation of populations on Cozumel I (off NE Yucatán Peninsula) as race *cozumelana* appears unwarranted. Monotypic.
Distribution. Yucatán Peninsula S to S Campeche (Mexico), N Guatemala and N Belize, including Cozumel I and other nearby Caribbean reefs.

Descriptive notes. 19–20·5 cm; 31·6–42 g, average 36·3 g. This and *Dumetella* are the smallest mimids; has wings short and rounded, tail somewhat long. Plumage is uniform glossy blue-black; iris dark reddish; bill and legs black. Sexes alike, female slightly less heavy than male. Juvenile is brownish-grey, mottled below, iris grey. VOICE. Repeated phrases of harsh, scratchy to warbled, fluty notes. Call notes a nasal "chrrh", harsh "rriah", and grating "tcheeu;" not known to mimic other species.
Habitat. Scrub, deciduous thorn-scrub, woodland edges and low deciduous woodland with dense shrub understorey; on Yucatán Peninsula, drops out to S when woodland becomes taller, more open beneath canopy. Abundant in thickets and low woodland edge on Cozumel I. Habitat generally similar to that occupied by *Dumetella carolinensis* in SE USA. At low elevations.
Food and Feeding. No detailed studies. Forages low down; gleans insects in dense, shrubby vegetation. Superficially similar to *Dumetella carolinensis* in foraging habits.
Breeding. Nest building starts in early May, in Belize; small young in nest in mid-Aug, at Cancún. Nest an open cup of twigs, lined with finer material, placed low in dense shrub. Clutch 2 eggs, uniform greenish-blue. No other information.
Movements. Largely resident; may move S seasonally from drier N parts of Yucatán Peninsula in late summer to early winter.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Relatively common in some parts of mainland range, but often regarded as rare and local; common on Cozumel I; common to uncommon on other offshore reefs in Mexico and Belize. Uncommon to rare over much of upper Yucatán Peninsula; rare in Petén area of N Guatemala. Not recorded in Honduras since the type specimen was collected there, at Omoa, in 1850s; was apparently rare at Omoa when first discovered. In E parts of range, has suffered much loss and fragmentation of habitat through tourism-related developments and the conversion of scrubby woodland and forest to coconut plantations. In Belize, the Siwa-Ban Reserve was established in 1998, with the express purpose of protecting the population on Caye Caulker; it is uncertain whether this initiative has been effective. Continuing loss of habitat gives cause for concern over this species' prospects.
Bibliography. Anon. (1998b), Brewer (2001), England (2000), Hellmayr (1934), Howell (1999), Howell & Webb (1995), Klaas (1968), Lee Jones (2004), Miller, B. & Miller (1991), Miller, C.M. (1995), Monroe (1968), Morgenthales (2003), Paynter (1955), Stotz *et al.* (1996), Van Tyne (1935).



Genus *MELANOTIS* Bonaparte, 1850

3. **Blue Mockingbird**

Melanotis caerulescens

French: Moqueur bleu **German**: Blauspottdrossel **Spanish**: Mulato Azul

Taxonomy. *Orpheus caerulescens* Swainson, 1827, Mexico.
Probably forms a superspecies with *M. hypoleucus*; was in the past sometimes considered conspecific, but this view based on aberrant specimens of race *longirostris*. Proposed race *effuticus* (from W Mexico) generally regarded as indistinguishable from nominate. Two subspecies recognized.
Subspecies and Distribution.
M. c. caerulescens (Swainson, 1827) – W, E & S Mexico (Sonora and SE Chihuahua S to Oaxaca, and SW Tamaulipas S to Puebla and W Veracruz).
M. c. longirostris Nelson, 1898 – Tres Marías Is, off W Mexico.

Descriptive notes. 24–26·5 cm; 50–69 g. Medium-sized mimid with short, rounded wings and long tail. Plumage is overall deep blue, streaked paler blue on crown, throat and chest; contrasting black mask from bill back to ear-coverts; iris red; bill and legs black. Differs from *M. hypoleucus* in having blue, not white, underparts. Sexes alike, female slightly smaller. Juvenile overall dull grey, bluish tints in wings and tail, iris dull. Race *longirostris* is somewhat paler than nominate by dint of few silvery-edged feathers, also wing and tail shorter, bill longer. VOICE. Unmistakable song, usually from dense cover, an extended string

On following pages: 4. Blue-and-white Mockingbird (*Melanotis hypoleucus*); 5. Brown Trembler (*Cinclocerthia ruficauda*); 6. Grey Trembler (*Cinclocerthia gutturalis*); 7. White-breasted Thrasher (*Ramphocinclus brachyurus*); 8. Pearly-eyed Thrasher (*Margarops fuscatus*); 9. Scaly-breasted Thrasher (*Margarops fuscus*).

of repeated phrases of richly varied notes, mellow to harsh and guttural; distinct from that of other mimids in its slow, deliberate note repetition. Calls varied, including harsh, mewing "meearrh", loud, mellow "cheeoo" notes, and many others.
Habitat. Brushy riparian areas in arid Pacific-coast lowlands; tall, variously dense thorn-scrub, low tropical deciduous woodland and forest edge, especially in SW of range; edge and thick understorey of taller oak (*Quercus*) woodland, humid pine–oak–fir (*Pinus–Quercus–Abies*) forest in highlands. Common in heavy forest on Tres Marías Is (race *longirostris*). Generally to 3000 m in highlands, but to coastal plain, and foothills (Oaxaca); down to sea-level on Pacific slope in Nayarit.
Food and Feeding. Omnivorous, though probably largely insectivorous in breeding season. Feeds low in vegetation or on ground; forages energetically in leaf litter, flipping aside leaves with the bill.
Breeding. Apr–Jul on mainland and Jun–Aug on Tres Marías Is; no information on number of broods per season. Nest an open cup of coarse, loose twigs, lined with rootlets and other fine material, placed 1–2·5 m above ground in dense shrub or leafy tree. Clutch 2 eggs, unspotted deep turquoise-blue. No other information.
Movements. Resident; no routine seasonal movements documented, although vagrants recorded in SW USA, several hundred km outside known breeding range.
Status and Conservation. Not globally threatened. Common to fairly common. Routinely encountered in preferred habitat from Sonora S to Oaxaca; common in Nayarit, Jalisco and Colima. Race *longirostris* common in forest on Tres Marías Is, but has become more restricted there with logging of forest, and with habitat degradation following browsing by introduced deer and goats.
Bibliography. Anon. (1998b), Binford (1989), Brewer (2001), Corcuera & Butterfield (1999), Forcey (2002), González-García *et al.* (2004), Hellmayr (1934), Howell & Webb (1995), Hunn *et al.* (2001), Kaufman (1996a), van Rossem (1945), Rowley (1966, 1984), Schaldach (1963), Selander & Giller (1959), Stager (1957), Stotz *et al.* (1996).

4. **Blue-and-white Mockingbird**

Melanotis hypoleucus

French: Moqueur bleu et blanc **German**: Lasurspottdrossel **Spanish**: Mulato Pechiblanco

Taxonomy. *Melanotis hypoleucus* Hartlaub, 1852, Guatemala.
Probably forms a superspecies with *M. caerulescens*; was in the past sometimes considered conspecific, but this view based on aberrant specimens of race *longirostris* of latter. Monotypic.
Distribution. SE Mexico (Chiapas) E to Honduras and N El Salvador.

Descriptive notes. 24–28 cm; 60–64 g. Medium-sized mimid with short, rounded wings and long tail. Plumage is deep blue with silvery sheen above, streaked paler blue on crown; contrasting black mask from bill back to ear-coverts; entirely white below, except for dark blue-grey flanks and vent; iris red; bill and legs black. Sexes similar, female slightly smaller than male. Juvenile is overall dark grey, bluish on wings and tail, bill light grey, iris dull, underparts mottled; moult to first-year plumage completed by end of Aug. Voice. Striking and distinctive song, given intensely Mar–May, a string of repeated phrases of richly varied, often alternately high and low, notes, and trills, similar to that of *M. caerulescens*. Calls are many and various, including loud, mellow "cheeoo" notes as well as abrupt, harsher scolding, clucking or growling calls, e.g. "ahrrr-took-took-took-took". Sometimes imitates other species.
Habitat. Humid highlands to semi-arid vegetation at lower elevations. Thorny scrub and second growth, low scrubby woodland, and forest edge, thick undergrowth in pine–oak (*Pinus–Quercus*) woodland. At 900–3000 m; mainly 2000–2500 m in NE Guatemala, mainly 1000–2000 m in Mexico (Chiapas).
Food and Feeding. Largely insectivorous; also small fruits, within and outside breeding season. Forages chiefly on ground, also low in vegetation; secretive, shy, wary of intruders. Feeds in ground litter; rarely uses feet, displaces fallen leaves by making side swipes with bill. Adults and immatures may consort in loose groups or be found singly outside breeding season.
Breeding. Breeds late Apr to mid-Jul at higher elevations, and May–Sept at lower elevations in Guatemala; incubation from mid-May. Territorial. Nest, built by female, a shallow cup lined with rootlets, supported by platform of coarse, long twigs, placed 1–4·5 m above ground in dense shrubbery. Clutch 2–3 eggs, the larger number reported at lower elevations, eggs unspotted glossy light blue; incubation by female alone, period unknown; chicks fed by both parents, nestling period 14–15 days.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in the North Central American Highlands EBA. Common in interior and highlands of Chiapas (S Mexico) and Guatemala. No known threats. May benefit from forest clearance and degradation, which create wider availability of edge and brush habitats.
Bibliography. Álvarez del Toro (1954), Anon. (1998b), Brewer (2001), Dickey & van Rossem (1938), González-García (1993), Hellmayr (1934), Howell & Webb (1995), Komar (2002), Komar & Domínguez (2001), Komar & Thurber (2003), Land (1970), Monroe (1968), Salvin & Godwin (1879), Skutch (1950), Stotz *et al.* (1996).

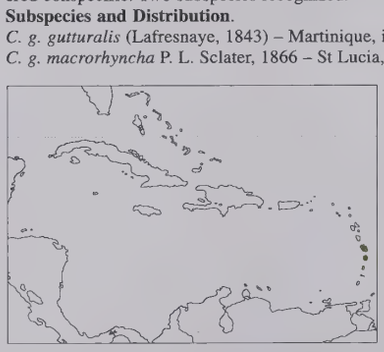
Genus *CINCLOCERTHIA* G. R. Gray, 1840

5. **Brown Trembler**

Cinclocerthia ruficauda

French: Trembleur brun **German**: Braunzitterdrossel **Spanish**: Cocobino Pardo

Taxonomy. *Stenorhynchus ruficauda* Gould, 1836, locality unknown = Dominica.
Genus may be most closely related to *Margarops*; contrary to earlier opinion, appears not to be close to *Ramphocinclus*. Probably forms a superspecies with *C. gutturalis*, and previously considered conspecific. Race *tremula* possibly merits treatment as a separate species; proposed races *pavida* (St Kitts) and *sola* (Montserrat) considered indistinguishable from that race. Three subspecies recognized.
Subspecies and Distribution.
C. r. tremula (Lafresnaye, 1843) – N Lesser Antilles (Saba, Barbuda, St Kitts, Nevis, Montserrat, Guadeloupe).
C. r. ruficauda (Gould, 1836) – Dominica, in C Lesser Antilles.
C. r. tenebrosa Ridgway, 1904 – St Vincent and Grenada, in S Lesser Antilles.



Descriptive notes. 23–26 cm; 43–71 g. Large forest mimid with very long, slightly downcurved bill, relatively short tail often cocked over back; wings often drooped and jerkily shaken. Nominate race is rufous-brown above, more reddish-brown towards rump and on tail and wings; throat pale greyish-buff, becoming greyish-brown on chest; lower underparts buffy brown; iris yellow; bill black; legs brownish-black. Distinguished from *C. gutturalis* by more rufous coloration above, darker underparts. Sexes similar, female somewhat smaller than male but with noticeably longer bill. Juvenile has faint dusky-grey spotting on chest. Race *tremula* is like nominate but longer-billed and c. 10% larger, also sexual dimorphism more marked (female weighs up to 20% less than male, but has exposed culmen up to 20% longer); *tenebrosa* is intermediate in overall size, darker above, chest more strongly and extensively suffused greyish, and shows less sexual dimorphism in bill length (9% longer in female) and weight (male on average 3% heavier). Voice. Full song, from mid-Mar, a series of loud and varied notes and phrases, harsh to melodious, at measured intervals of c. 2 seconds; also a quiet "subsong" 5 seconds long, and a rapid and jumbled "excitement" song during territorial disputes. Rasping "yeeak" call.
Habitat. Humid forest (from rainforest to montane forest), occasionally plantations, on most islands within range. On Dominica, rather more common in windward evergreen forest in lowlands and in rainforest than in leeward dry forest in lowlands and montane thickets, but generally distributed throughout island.
Food and Feeding. Diet includes variety of large arthropods, among them scorpions (Scorpiones), spiders (Araneae) and various insects, e.g. beetles (Coleoptera), cockroaches (Blattodea) and orthopterans; also seed, pulp and capsules of various fruits. Small vertebrates (such as tree-frogs) and snails also taken. Smaller fruits, e.g. melastomes, swallowed whole and undigestible parts regurgitated. Chiefly arboreal in foraging habitats (unlike most mimids); forages throughout vegetation, up to forest canopy (c. 40 m above ground). Searches vegetation tangles, especially epiphytes such as bromeliads orchids and ferns, also trunks, branches, crotches and hollows of trees, for invertebrate prey; long bill presumably an adaptation for epiphyte-searching. Also seen to forage terrestrially; hops between foraging spots, pecks and probes at leaf litter and into ground.
Breeding. Breeds Mar–Apr. Thoughht to be a territorial breeder; loose groups of up to six individuals consort in single tree before breeding season. Nest an open cup of small twigs and roots, lined with fibre material and dead leaves, placed in tree cavity, hollow in tree-fern, palm, or crotch of tree, also reported as domed with side entrance; nestbox sometimes used. Clutch 2–3 eggs, greenish-blue and unspotted; no information on incubation and fledging periods, nor on roles of sexes.
Movements. Generally sedentary. Occasional records of vagrants on several of Virgin Is (e.g. St Eustacius, St Thomas) and Antigua, near N edge of Lesser Antilles.
Status and Conservation. Not globally threatened. Restricted-range species: present in the Lesser Antilles EBA. Status varies among the different islands, ranging from common to rare; this variation may be a function of competition with other mimids, or availability of its preferred wet-forest habitats.
Bibliography. Anon. (1998b), Arendt *et al.* (2004), Bond (1985), Brewer (2001), Diamond (1973), Faaborg (1985), Hellmayr (1934), Hunt *et al.* (2001), Keith (1997), Lack (1976), Markowsky *et al.* (1994), Raffaele *et al.* (1998, 2003), Ricklefs & Bermingham (1997), Steadman *et al.* (1980), Storer (1989), Stotz *et al.* (1996), Zusi (1969).

6. **Grey Trembler**

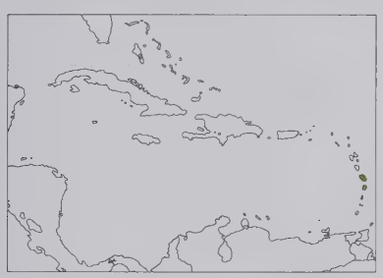
Cinclocerthia gutturalis

French: Trembleur gris **German**: Grauzitterdrossel **Spanish**: Cocobino Gris

Taxonomy. *R[amphocinclus] gutturalis* Lafresnaye, 1843, Martinique, Lesser Antilles.
Genus may be most closely related to *Margarops*; contrary to earlier opinion, appears not to be close to *Ramphocinclus*. Probably forms a superspecies with *C. ruficauda*, and previously considered conspecific. Two subspecies recognized.
Subspecies and Distribution.
C. g. gutturalis (Lafresnaye, 1843) – Martinique, in C Lesser Antilles.
C. g. macrorhyncha P. L. Sclater, 1866 – St Lucia, in SC Lesser Antilles

Descriptive notes. 23–26 cm; 65–76·2 g. Large forest mimid with very long, slightly downcurved bill, relatively short tail often cocked over back; wings often drooped, and tail jerkily shaken. Nominate race is warm grey-brown above, lores and ear-coverts darker, wings more dusky-coloured; dull to buffy white on throat and median portions of breast and abdomen; sides of breast, flanks and thighs plain brownish-grey to greyish-brown, flanks more markedly brown or olivaceous; undertail-coverts greyish-brown more or less margined with whitish; iris pale yellow; bill blackish; legs dark. Differs from *C. ruficauda* mainly in greyer, less rufous, coloration, paler underparts. Sexes alike in plumage, but female c. 3% smaller than male in most linear dimensions but with bill 18% longer. Juvenile is browner, with mottled chest. Race *macrorhyncha* has underparts dull buffy whitish to pale greyish-buff, undertail-coverts and flanks pale cinnamon to wood-brown, sides tinged olive-greyish, female bill averages 16% longer than male's. Voice. Repeated notes and phrases, harsh to melodic, quavering whistles; distinct from voice of *C. ruficauda*.

Habitat. Mature wet forest, less so in drier scrub and open woodland, mostly on leeward sides of islands. Less restricted to rainforest habitats than is *C. ruficauda*. Some evidence for segregation of tremblers into wetter, more closed forest habitats than drier, more open vegetation typical of *Ramphocinclus brachyurus*.
Food and Feeding. No detailed studies of diet; various invertebrates, especially insects, also fruits in season. Mainly arboreal, but feeds at all heights in vegetation, and also on ground. Long bill used to tear open vegetation tangles, and to probe into epiphyte clusters. Foraging habitats apparently like those of *C. ruficauda*.
Breeding. Breeds Mar–Apr. Nest apparently domed, of grassy materials, placed in palm, or in crotch or hollow of tree. Clutch 2–3 eggs, unspotted greenish-blue. No other information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in the Lesser Antilles EBA. Fairly common throughout Martinique and St Lucia. Occurs at all elevations in wide variety of habitats. Some qualitative evidence that race *macrorhyncha* is more restricted to rainforest habitats on St Lucia than it was a century ago, this possibly related to presence of *Ramphocinclus brachyurus* in lower, drier habitat. No threats to populations known, other than those implicit in its very restricted geographical range.
Bibliography. Anon. (1998b), Arendt *et al.* (2004), Benito-Espinal & Hautcastel (1988), Bond (1985), Brewer (2001), Danforth (1935), Diamond (1973), Faaborg (1985), Hellmayr (1934), Hunt *et al.* (2001), Keith (1997), King (1978/79), Lack (1976), Markowsky *et al.* (1994), Raffaele *et al.* (1998, 2003), Ricklefs & Bermingham (1997), Steadman *et al.* (1980), Storer (1989), Zusi (1969).



Genus *RAMPHOCINCLUS* Lafresnaye, 1843

7. White-breasted Thrasher

Ramphocinclus brachyurus

French: Moqueur gorge-blanche **Spanish**: Cuitlacoche Pechiblanco
German: Weißbrust-Spottdrossel

Taxonomy. *Turdus brachyurus* Vieillot, 1818, Martinique, Lesser Antilles.
Was in the past sometimes placed in genus *Cinclocerthia*, but the two genera may not be closely related. Race *sanctaeluciae* considered a separate species by some authors. Two subspecies recognized.
Subspecies and Distribution.
R. b. brachyurus (Vieillot, 1818) – Martinique, in C Lesser Antilles.
R. b. sanctaeluciae (Cory, 1887) – St Lucia, in SC Lesser Antilles.

Descriptive notes. 20–23 cm; nominate averages 48·2 g, *sanctaeluciae* 59·9 g. Medium-sized mimid of distinctive appearance, with rather long, slightly decurved bill; droops and flicks wings. Nominate plumage is dark brown above, faint white supercilium, whitish scalloping on head, lores to ear-coverts blackish, greyish-white edging on scapulars; throat and underparts plain white, vent brown; iris red; bill blackish; legs dark. Sexes alike in plumage, female very slightly smaller in all linear dimensions, including bill. Juvenile is brown below, becoming white-breasted with age. Race *sanctaeluciae* is darker and more uniform, c. 10% larger in linear dimensions than nominate, sexual size dimorphism also greater, male c. 3% larger than female (sexes of nominate nearly equal in size). Voice. Repeated short, mellow and varied phrases, each of several syllables. Call notes, on Martinique "chek-chek-chek", on St Lucia "tschhhhhhh".
Habitat. Dry woodland, coastal thickets, wooded stream valleys, scrub-forest on windward coast at lower elevations, with little or no ground cover but abundant leaf litter. Present in transitional zone between dry coastal woodland and interior rainforest, but absent from true rainforest; may be excluded by *Cinclocerthia gutturalis*.
Food and Feeding. Terrestrial arthropods; also small fruits, berries; small vertebrates, such as lizards (*Gymnopthalmus pleei*, *Anolis luciae*) and frogs (*Eleuthrodactylus johnstonei*), sometimes taken. Forages mainly on ground, searching leaf litter for prey; also ascends to several metres in vegetation. Relatively longer legs and shorter bill than *Cinclocerthia*, thus more adapted to terrestrial foraging than to arboreal probing.
Breeding. Breeds Apr–Aug. Co-operative breeding recently discovered on both St Lucia and Martinique; on St Lucia, roughly a third of nests have helpers, which are mainly or exclusively retained offspring. Nest a rough, bulky cup of twigs and leaves, lined with grass and rootlets; on Martinique, placed 2–8 m above ground, on St Lucia 0·5–3 m (averages 1·5 m), in shrub or sapling. Clutch 2 eggs, unmarked greenish-blue; incubation 14 days; nestling period 12 days; fledged young dependent on parents, spend most of their time on ground. Two or more successful broods may be raised in a year. Nesting success on St Lucia 44% in 1997, 29% in 2001, and 38% in 2002–2004; predators of nests and juveniles include mongooses (*Herpestes*), opossums (*Didelphis*), rats (*Rattus*), snakes and *Margarops fuscatus*.
Movements. Sedentary.
Status and Conservation. ENDANGERED. Restricted-range species: present in the Lesser Antilles EBA. Current global population thought to total c. 1300–2600 breeding adults, of which 200–400 on Martinique (nominate race) and 1100–2200 on St Lucia (*sanctaeluciae*) in 2004; latter population estimated at only 46 pairs in early 1990s, but since then a major new site for the species has been discovered further S on E coast of St Lucia. Although Martinique and St Lucia are large islands (1080 km² and 600 km², respectively), this species is found in only two narrowly confined areas, the Caravelle Peninsula (519 ha) on Martinique and a limited stretch of E coast of St Lucia, totalling little more than c. 20 km². Was common and widespread in 19th century; by first half of 20th century was believed extinct, but subsequent fieldwork revealed that it was still present, in greatly reduced numbers. The most important factor responsible for its decline is habitat loss; other possible factors include predation of nests, eggs and juveniles by mongooses, opossums rats and snakes, as well as by *Margarops fuscatus*, and perhaps competition from a recent colonist, the Spectacled Thrush (*Turdus nudigenis*). On St Lucia, a tourist resort currently under development threatens up to 23% of the overall population. There are no protected areas for the species on St Lucia; on Martinique, most of the remaining habitat is protected, either within the Caravelle Nature Reserve or under other forms of designation.
Bibliography. Anon. Genus *MARGAROPS* P. L. Sclater, 1859

8. Pearly-eyed Thrasher

Margarops fuscatus

French: Moqueur corossol **German**: Perlaugen-Spottdrossel **Spanish**: Cuitlacoche Chucho

Taxonomy. *Turdus fuscatus* Vieillot, 1808, Puerto Rico.
Four subspecies recognized.
Subspecies and Distribution.
M. f. fuscatus (Vieillot, 1808) – Bahamas (S from Eleuthera I), Turks and Caicos Is, Beata I (off S Hispaniola), Mona I, Puerto Rico, Virgin Is and N Lesser Antilles (Antigua).
M. f. densirostris (Vieillot, 1818) – Lesser Antilles (Montserrat and Guadeloupe S to Martinique).
M. f. klinikowskii Garrido & Remsen, 1996 – St Lucia, in SC Lesser Antilles.
M. f. bonairensis Phelps, Sr & Phelps, Jr, 1948 – Bonaire I, in Netherlands Antilles.

Descriptive notes. 28–30 cm; 75–142 g, average 102·6 g. The largest mimid, with streaky-brown appearance, robust bill; noisy and conspicuous. Nominate race has crown and upperparts brown with darker feather centres, sides of head and face mottled darker, uppertail-coverts with small whitish centres and tips; wings and tail blackish-brown, outer webs of secondaries edges rufous, tertials tipped whitish, outer rectrices with broad whitish tips; throat and underparts whitish, streaked brown, belly less marked; iris pale grey-white; bill yellowish; legs brown to pinkish or greyish-flesh. Distinguished from *M. fuscus* by larger size, longer and yellow bill, somewhat paler coloration, especially on wings and tail, less scaly-looking breast, no wingbar. Sexes similar in appearance, female generally somewhat larger and heavier than male. Juvenile resembles adult. Race *densirostris* is larger than nominate, darker above and more broadly streaked below; *klinikowskii* is largest race, has breast markings more contrastingly dark brown and white, more extensive white tips on wings and tail; *bonairensis* is more greyish-olive than brownish. Voice. Song, often from elevated perch, heard day and night, a slow series of whistled phrases, 1–3 syllables, lengthy pauses between segments, rambling; harsh, raucous call notes, e.g. "craw-craw", "chook-chook".
Habitat. Dense scrub and thickets, woodland and forest, including palm groves and mangroves; also disturbed and agricultural settings, and settlements, including urban and suburban areas. In Puerto Rico, density increases with size of habitat patch. Occurs at all elevations; commoner above 250 m in wetter forest on Dominica.
Food and Feeding. Omnivorous; feeds on variety of arthropods, berries and fruits, also vertebrates. Volumetric analysis indicates that plant food constitutes two-thirds of diet, with remainder divided equally between insects and vertebrates. Many types of fruits taken, including *Cecropia*, *Agave* nectar, and crop fruits such as papaya and bananas. Preys on eggs and nestlings of many other birds, including pigeons and doves (Columbidae), parrots (Psittacidae) and other mimids, and even adult birds taken; also eats lizards, tree-frogs, land crabs. Large items sometimes cached and later retrieved. Often forages in groups. Largely an arboreal forager, mainly at middle levels up to canopy, to 5 m, mostly above 1·5 m; infrequently terrestrial.
Breeding. Extended season when considered overall, Dec–Sept; timing varies over islands, e.g. breeds Jun in Bahamas (San Salvador); multiple broods. Aggressively territorial; will kill birds and destroy nests of potential competitors, e.g. Red-legged Thrush (*Turdus plumbeus*), and will also pirate nest materials. Nest is a bulky construction of twigs and dry grass, often placed in a tree cavity or nestbox, occasionally as open cup in tree or shrub; sites also include buildings, porches, and (Mona I) caves. Clutch 2–3 eggs (reports of 4–6 require confirmation), 27 clutches reported from Mona I were all of 2 eggs; egg colour glossy deep blue-green; hatching asynchronous, incubation period 14–15 days; nestling period 19–21 days. Nestlings susceptible to botfly (*Philornis*) parasitism.
Movements. Resident; some wandering indicated by records of vagrants in Jamaica and Barbados, well outside breeding range.
Status and Conservation. Not globally threatened. Restricted-range species: present in the Bahamas EBA, Hispaniola EBA, Puerto Rico and the Virgin Islands EBA and Lesser Antilles EBA. Generally common on most islands within range; often especially abundant on smaller islets, e.g. Mona and other islets around Puerto Rico, St John (Virgin Is), St Eustacius (N Lesser Antilles). Uncommon on Martinique. Has recently extended N in Bahamas. S Caribbean race *bonairensis*, confined to Bonaire I, was earlier found also farther E, on La Horquilla I (in Hermanos Group, off N Venezuela), but now extinct there (last reported in 1908). Range discontinuous; conspicuously absent from Cuba, Jamaica and mainland Hispaniola, although present on Beata I (off S coast of Hispaniola). Adaptable, successful species; indeed, on Puerto Rico, where it occurs in locally high densities, it is considered a liability because of its predation on nests of the Puerto Rican Amazon (*Amazona vittata*), currently classed as Critical. Regarded as a pest of crop fruits in some regions.
Bibliography. Adolph & Roughgarden (1983), Anon. (1998b), Arendt (1980, 1985a, 1985b, 1997a, 1997b, 2000, 2004), Arendt & Arendt (1986), Arendt *et al.* (2004), Biaggi (1983), Bond (1985), Buden (1987, 1990), Diamond (1973), Faaborg (1985), Faaborg & Arendt (1995), Garrido & Remsen (1996), Hellmayr (1934), Hilty (2003), Hunt *et al.* (2001), John (1992), Keith (1997), Keith *et al.* (2003), Lack (1976), McLaughlin & Roughgarden (1989), Raffaele *et al.* (1998), Ricklefs & Bermingham (1997), Ridgely & Tudor (1989), Robertson (1962), Snyder & Taapken (1978), Snyder *et al.* (1987), Stotz *et al.* (1996), Uhazy & Arendt (1986), Wetmore (1927), Wetmore & Swales (1931), Zusi (1969).

9. Scaly-breasted Thrasher

Margarops fuscus

French: Moqueur grivotte **German**: Schuppenspottdrossel **Spanish**: Cuitlacoche Oscuro

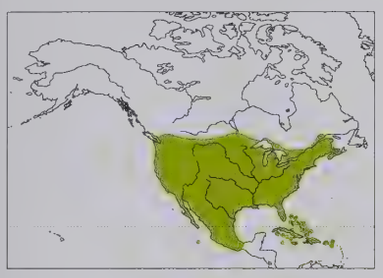
Taxonomy. *Muscicapa fusca* Statius Muller, 1776, Martinique.
Sometimes placed in a monotypic genus *Allenia*; such treatment supported also by recent mtDNA work, but further research needed. Listed delimitations of races uncertain, and not congruent with recent mtDNA data; further study required. Five subspecies recognized.
Subspecies and Distribution.
M. f. hypenemus Buden, 1993 – N Lesser Antilles from St Martin, Saba and St Barthélémy S to Guadeloupe and Marie-Galante.
M. f. fuscus (Statius Muller, 1776) – C & S Lesser Antilles (Dominica, Martinique and, disjunctly, Grenada).
M. f. schwartzi Buden, 1993 – St Lucia, in SC Lesser Antilles.
M. f. vincenti Kratter & Garrido, 1996 – St Vincent, in S Lesser Antilles.
M. f. atlanticus Buden, 1993 – Barbados.
Descriptive notes. 23 cm; 53–98 g, average 67·1 g, *vincenti* mean 59·8 g, *schwartzi* mean 62·7 g, *hypenemus* (from St Kitts) mean 74·4 g. Large brownish mimid, rather short bill only slightly decurved, and reminiscent of a thrush (Turdidae). Nominate race has crown and upperparts dark grey-brown, feathers with darker centres, rump somewhat more rufescent, uppertail-coverts with small whitish spots central spots and tips; wings brownish-black, outer webs of secondaries edged rufous, tertials pale-tipped, greater wing-coverts tipped whitish (single wingbar); tail brownish-black, outer retrices conspicuously white-tipped; chin and throat whitish, streaked brown; underparts rather variable, generally whitish, especially in median portion, densely covered with bold, grey-brown scale-like markings; iris pale yellow; bill black; legs blackish-brown. Differs from *M. fuscatus* mainly in smaller size, shorter and black bill, darker plumage especially on wings and tail, obvious wingbar, narrower white tail markings, more scaly-looking breast. Sexes similar. Juvenile is like adult, but eye dark. Races vary primarily in size and in depth of colour of upperparts: *hypenemus* is largest, paler than nominate; *schwartzi* in intermediate in size, has more white in tail; *vincenti* is smallest, with darker plumage overall, narrower white margins on flank feathers; *atlanticus* is more reddish-brown above, with less white in tail. Voice. Series of varied notes and phrases, somewhat *Mimus*-like but softer, slower, less forceful.

Habitat. Found in range of habitats, from forest to semi-open woodland, also around settlements. More restricted to forest than is *M. fuscatus*; outnumbered latter in rainforest sites in mist-net surveys on St Lucia, Montserrat and St Kitts.
Food and Feeding. Omnivorous, feeding on range of arthropods, fruits, berries; apparently more frugivorous and less omnivorous than related mimids. Largely arboreal; forages high in canopy on Dominica and Guadeloupe, but much lower on Montserrat and St Kitts (which have fewer forest-bird species). On Dominica, forages in same trees and on same fruits as confamilial (longer-billed) *Cinclocerthia ruficauda* and *M. fuscatus*, and Forest Thrush (*Cichlherminia lherminieri*).
Breeding. May–Jun. Nest cup-shaped, placed in bush or tree. Clutch 2–3 eggs, unmarked greenish-blue. No other information available.
Movements. Resident; some wandering, as vagrants recorded in Grenadines.
Status and Conservation. Not globally threatened. Restricted-range species: present in the Lesser Antilles EBA. Common to fairly common in most of N & C Lesser Antillean range and on St Vincent; rare and local on Grenada. Status on St Eustatius and Barbuda uncertain; previously rare, and possibly now extinct. Race *atlanticus*, confined to Barbados, probably extinct; small numbers found in 1920s, and one observed in 1987, but none found in 1998. Race *hypenemus* has recently extended its range N; colonized St Martin in or just before 2002, during which year at least 32 were found during search of a 20-ha study area.
Bibliography. Anon. (1998b), Arendt *et al.* (2004), Bond, J. (1963, 1985), Brewer (2001), Brown & Collier (2003), Buden (1993), Diamond (1973), Faaborg (1985), Faaborg & Winters (1979), Hellmayr (1934), Hunt *et al.* (2001), Keith (1997), Kratter & Garrido (1996), Lack (1976), McLaughlin (1990), Raffaele *et al.* (1998, 2003), Ricklefs & Bermingham (1997), Stotz *et al.* (1996), Terborgh *et al.* (1978), Zusi (1969).

PLATE 46 ➤

PLATE 46

inches 4
cm 10



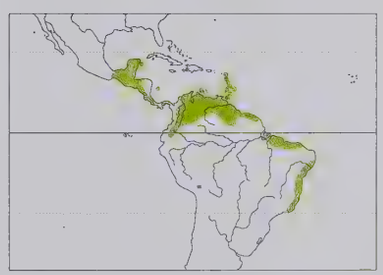
Genus *MIMUS* Boie, 1826

10. Northern Mockingbird

Mimus polyglottos

French: Moqueur polyglotte **German**: Spottdrossel **Spanish**: Sinsonte Norteño
Other common names: Common Mockingbird

Taxonomy. [*Turdus*] *polyglottos* Linnaeus, 1758, Virginia, USA.
Forms a superspecies, and sometimes considered conspecific, with *M. gilvus*; apparent hybrids between the two reported in S Mexico. Reported as interbreeding, probably rarely, with *M. gundlachii* in Caribbean. Race *leucopterus* sometimes merged with nominate. Proposed races *elegans* and *delinificus* (both from Bahamas), described largely on basis of whiter underparts, and *dominicus* (Haiti), supposedly with more white in wings, considered better treated within *orpheus*. Three subspecies recognized.
Subspecies and Distribution.
M. p. leucopterus (Vigors, 1839) – extreme SW Canada (S British Columbia E to S Manitoba) and W USA (E to Nebraska and Texas) S to S Mexico (rarely, to Isthmus of Tehuantepec), including Socorro I (off W Mexico) and many other offshore islands in Pacific Ocean and Gulf of California.
M. p. polyglottos (Linnaeus, 1758) – extreme SE Canada and E USA.
M. p. orpheus (Linneaus, 1758) – Bahamas S to Greater Antilles, Cayman Is and Virgin Is.



Descriptive notes. 23–28 cm; 36–56 g, average 48·5 g. Distinctive mid-sized mimid. Has dusky lores, greyish side of head with obscure whitish supercilium; crown and upperparts plain brownish-grey, upperwing-coverts tipped whitish (two narrow wingbars); base of primaries white (conspicuous white wing flashes in flight); tail blackish-grey, outer retrices white, adjacent two pairs with white inner webs; chin and throat whitish, greyish-brown submalar streaks; upper breast grey, buffier on sides and flanks, belly white, undertail-coverts buffy white; underwing pale, seen in upraised "wing-flashing" typical of genus; iris yellowish; bill blackish; legs dusky. Sexes similar, male on average c. 8% heavier than female. Juvenile is lightly streaked above and below, has legs paler, iris greyish. Races vary only little: *leucopterus* is slightly larger, paler, and relatively shorter-tailed than nominate; *orpheus* is paler than typical nominate, and smaller in Bahamas and Dominican Republic (but similar to nominate in average weight on Cuba, Jamaica and Puerto Rico). Voice. Loud, conspicuous and persistent song (accompanied by visual displays) familiar to many, a sustained, disjointed delivery of harsh to mellow notes and short phrases, of remarkably great diversity but little musicality; often sings nocturnally. Calls include short, explosive "chack" and "cheert" notes; a well-known mimic of other species.
Habitat. Wide range of low, rather open, often scrubby and disturbed vegetation. In E, typical of woodland edge and second growth, and parkland; common in suburbs, around gardens and lawns. In W, common in arid scrubland, as in Sonora, Mojave and Chihuahuan Deserts. In S, e.g. Oaxaca (S Mexico), inhabits thorn-scrub, open tropical deciduous and low oak (*Quercus*) woodland and edge, and low, open chaparral.
Food and Feeding. Omnivorous, feeds nearly equally on insects, e.g. beetles (Coleoptera), hymenopterans and orthopterans, and small, soft fruits. Arthropod prey predominates in breeding season, fruit in winter. Nestling diet initially only small arthropods, later with more fruit. Fruits from wide variety of shrubs and trees taken; smaller fruits plucked from shrubs and trees, larger ones often torn open; fallen fruit eaten on ground. Forages mostly on ground for animal prey; runs and hops on ground, usually in open situations; occasionally pounces on prey from elevated perch, hawks for flying insects, or flies briefly after prey disturbed on ground. Defends winter territory, often small, e.g. around dense fruiting rose (*Rosa*); aggression often directed against other bird species (including other mimids) that are food or foraging-site competitors.
Breeding. Mar–Aug, beginning earlier in S of range; 2–3 broods typical throughout range. Normally monogamous, but polyandry and bigamy reported uncommonly; partners may remain together beyond a single season. Aggressively territorial, defence by both sexes against potential nest predators, e.g. corvids, squirrels (Sciuridae), domestic cats; territory 0·5–2·5 ha (smaller territories often winter ones). Nest construction initiated by male as an open cup made from twigs, this lined with grass and completed by female; nest usually in dense shrub, typically low down (1–3 m), but height extremely variable depending on habitat, recorded to 19 m, and rarely nest placed in cavity or building. Clutch 2–6 eggs, mean number varies latitudinally on mainland, clutch size 3 in Puerto Rico (race *orpheus*); egg colour light to dark greenish-blue with brown to reddish blotch markings, denser at large end, occasionally unmarked; incubation by female, period 12–13 days; chicks brooded by female only, fed by both parents, leave nest after 10–15 days (average 12 days), at 60–70% of adult weight; young become competent in flight after 8 days, fed by parents for up to 3 weeks after departure from nest, during which adults begin renesting for next brood.
Movements. Largely sedentary over most of range. Some populations at N limits of range withdraw S after breeding, and elsewhere considerable local movements made between habitats with differing seasonal resources, i.e. breeding and wintering territories, sometimes even covering hundreds of kilometres. In S Mexico (Oaxaca), permanent resident above 900 m, but also winters down to sea-level. Some long-distance wandering occurs; occasional records well N of normal range in Canada, to islands in Hudson's Bay, and a few vagrants have crossed Atlantic Ocean to reach Europe.
Status and Conservation. Not globally threatened. Common and conspicuous throughout range. During 20th century, this species extended its range N along E coast of USA into E Canadian provinces; also colonized Socorro I, off W Mexico, in late 1970s/early 1980s. Appears to have been favoured by much recent habitat clearance, suburban growth, and expanded agricultural activity. Has spread with suburban growth into previously chaparral-covered hillsides in SW USA. Caribbean range recently expanded E to Virgin Is, towards Lesser Antilles. Nevertheless, population declines documented for most areas of USA over period 1966–1987; these are unexplained and thought not likely to be sustained in long term.
Bibliography. Adkisson (1966), Allen (1947), Amos (1991), Anon. 11. Tropical Mockingbird

Mimus gilvus

French: Moqueur des savanes **German**: Tropenspottdrossel **Spanish**: Sinsonte Tropical
Other common names: San Andres/St Andrew/Large-billed Mockingbird (*magnirostris*); Blue-grey Mockingbird (*antelius*)

Taxonomy. *Turdus gilvus* Vieillot, 1808, French Guiana.
Forms a superspecies, and sometimes considered conspecific, with *M. polyglottos*; apparent hybrids between the two reported in S Mexico. Race *magnirostris* sometimes treated as a separate species; *antelius* may also merit elevation to full species level. Population of *tolimensis* in Pacific lowlands of Central America (El Salvador S to Panama) originates largely from escaped cagebirds imported from Colombia. Ten subspecies currently recognized.
Subspecies and Distribution.
M. g. gracilis Cabanis, 1851 – S Mexico (E from E Veracruz and E Oaxaca) S to Honduras and El Salvador.
M. g. leucophaeus Ridgway, 1888 – Yucatán Peninsula, Cozumel I and other offshore islands.
M. g. magnirostris Cory, 1887 – San Andrés I, in SW Caribbean (off E Nicaragua).
M. g. rostratus Ridgway, 1884 – S Caribbean islands (Aruba E to Blanquilla).
M. g. antillarum Hellmayr & Seilern, 1915 – Lesser Antilles S from Antigua.
M. g. tolimensis Ridgway, 1904 – E El Salvador S to Costa Rica and C Panama, and W & C Colombia S to extreme N Ecuador.
M. g. melanopterus Lawrence, 1849 – N & NE Colombia, most of Venezuela (including Margarita I and Los Testigos), Guyana and N Brazil (Roraima).
M. g. tobagensis Dalmas, 1900 – Trinidad and Tobago.
M. g. gilvus (Vieillot, 1808) – Suriname and French Guiana.
M. g. antelius Oberholser, 1919 – coastal NE & E Brazil (S to Rio de Janeiro).

Descriptive notes. 23–25·5 cm; 88 g (*tolimensis*), means 58·4 g (*melanopterus*), 46·4 g (*antillarum*), 45·5 g (*rostratus*). Dull greyish mimid with short, straight bill. Nominate race has whitish supercilium, darker grey lores; crown and upperparts uniform grey, upperwing-coverts narrowly tipped whitish; wings and tail blackish, outer retrices with broad whitish tips; chin to vent whitish, breast tinged grey; whitish underwing (displayed in wing-flashing); iris colour varies, both geographically and individually, in nominate form typically dull yellowish, sometimes more olive, orange or brownish; bill and legs blackish. Differs from *M. polyglottos* in slightly larger size, no white in wing, less prominent tail markings. Sexes alike, female c. 5% smaller and lighter than male. Juvenile is browner, chest and flanks streaked dusky, eyes dark brown. Races vary mainly in plumage tone, extent of pale markings and size: *antelius* is longer-tailed than nominate, paler grey above, with flanks streaked, reduced white tips on rectrices; *antillarum* is darker above, with little grey on breast, wider but less sharply defined white on wing-coverts, iris commonly dark reddish-brown; *tobagensis* differs from previous in more extensive white tips on lateral rectrices, thicker (stouter but not longer) bill, iris commonly orange-brown; *melanopterus* is larger, paler above, almost pure white below, with more extensive white on outer rectrices, iris orange-brown to olivaceous; *rostratus* is similar to previous, but heavier-billed; *tolimensis* is also similar, but larger, with longer wings and tail; *gracilis* differs in browner upperparts, buffy-grey chest, and white (rather than grey) tips of wing-coverts; *leucophaeus* differs from previous in being more clear grey above, with narrow and grey edgings on wing-coverts, more extensive white on lateral rectrices; *magnirostris* is distinctive, much larger in size, also obviously heavier-billed than other races. Voice. Song, often heard at night, a varied and long-continued sequence of diverse mellow to harsh notes, trills, with considerable repetition of phrases, similar to song of *M. polyglottos*; pauses between phrases give song a discontinuous, staccato quality. Typical

Galapagos Mockingbird (*Nesomimus parvulus*).

call a resonant "pree-ew", alarm a harsh "chuck" or "chek". Said to mimic only rarely, although certain individuals apparently accomplished mimics, even (only captives?) learning music, such as Brazilian national anthem.
Habitat. Generally open, scrubby, edge and savanna habitat, and arid coastal scrubland; common in disturbed habitat, around parks, farmland, habitations, including suburban gardens. Open savanna in N Venezuela; confined to sparse coastal *restinga* scrub in E Brazil, where *M. saturninus* common inland. Avoids closed forest and mangroves. Lowlands and middle elevations; reaches c. 2500 m in Central America and N Andes, occasionally to 2600 m in Colombia, and recently found as high as 3100 m in N Ecuador.
Food and Feeding. Broadly omnivorous. Diet comprises wide variety of arthropods, small fruits and berries, also larger crop fruits such as mango, sapodilla. Known to take bird and lizard eggs; also various birdfeeder offerings. Forages on ground or low in vegetation; hawks swarming termites in air.
Breeding. Extended season, e.g. Jan–Sept in Venezuela and in all months except Aug and Dec in Trinidad, but generally in late dry season to early wet season; at least three broods. Monogamous; co-operative breeding recorded in Panama and Venezuela, young of previous brood help in feeding subsequent brood and in territory defence, up to five adults and subadults found on a territory. Aggressively territorial; repels conspecifics and other species, as well as potential predators. Nest, built by both sexes, of coarse twigs lined with finer material, usually low down (mostly 1–4 m) in shrub or low tree, often not well concealed. Clutch 3 eggs, sometimes 2 or 4, blue-green, spotted or blotched reddish-brown; incubation by both sexes but predominantly by female, period 13–15 days; chicks fed by both parents, nestling period 12–15 days, occasionally to 19 days; young fed by parents after leaving nest, and some remain on territory during raising of later broods.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Common and conspicuous nearly throughout range; less common in newly colonized areas, such as recently cleared highlands, and on Guadeloupe (in Lesser Antilles). First recorded in Ecuador in 1996. San Andrés race *magnirostris*, possibly a separate species, reportedly still common in 1989, despite development on island. Has recently spread N through Lesser Antilles; range has also expanded within some islands, such as Trinidad. Some expansion of range due to individuals escaping from captivity; this apparently the origin of several populations in lowlands of Central America. Benefits from forest clearance and other human activity, as it particularly favours disturbed areas and habitations of all sorts.

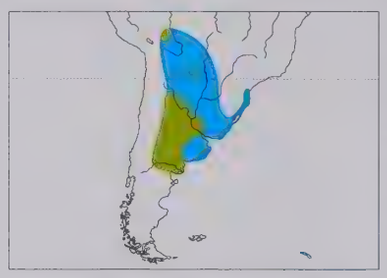
12. Bahama Mockingbird

Mimus gundlachii

French: Moqueur des Bahamas **Spanish**: Sinsonte de Bahamas
German: Gundlachspottdrossel
Other common names: Gundlach's Mockingbird

Taxonomy. *Mimus Gundlachii* Cabanis, 1855, Cuba.
Possibly an island derivative of *M. polyglottos*, with which interbreeding reported but probably rare. Two subspecies recognized.
Subspecies and Distribution.
M. g. gundlachii Cabanis, 1855 – Bahamas, Camagüey Archipelago (N coast of Cuba) and Turks and Caicos Is.
M. g. hillii March, 1863 – S Jamaica.



Descriptive notes. 28 cm; 57–85 g, average 66·8 g. Large brownish mockingbird with long tail. Has dark lores, mottled face, pale supercilium; brownish-grey above, dark streaks from crown to lower back, upperwing-coverts obscurely pale-tipped; outer retrices tipped whitish; throat white, dark malar stripe; underparts light grey, upper breast lightly streaked, flanks distinctly streaked; iris variable, dull yellow to brick orange; bill and legs blackish. Sexes similar, female slightly smaller and shorter-tailed than male. Juvenile is more densely spotted below. Race *hillii* has more prominent streaking on back, larger white tips on tail (mainly inner webs). Voice. Loud series of abrupt, varied notes and phrases, with repetition; reportedly less varied and more musical than song of *M. polyglottos*; males on adjacent territories sing antiphonally. Not known to mimic other species.
Habitat. Coastal strand, semi-arid scrub, open woodland, grassy areas with scattered trees, palmettos, plantations around habitation. Confined to arid scrubby woodland of limestone hills on S coast of Jamaica (race *hillii*). Tends to prefer denser, taller vegetation than that used by *M. polyglottos*; little overlap in Jamaica, where latter species occurs nearby in more open areas. Where sympatric with *Margarops fuscatus*, occupies scrub and woods away from settlements.
Food and Feeding. Omnivorous. Diet varied, from various terrestrial invertebrates to caterpillars, *Agave* nectar, and many small fruits such as figs (*Ficus*), *Bursera*, *Capparis*; also preys on small lizards. Forages mostly on ground, but also to 6 m within vegetation; more arboreal than *M. polyglottos*. On ground, searches leaf litter, turning litter and small stones with bill; extracts snails from shells. Interspecific aggression over food resources common; tends to exclude *M. polyglottos* from preferred feeding sites.
Breeding. Season Feb–Jul, from Apr in Cuba. Monogamous. Aggressively territorial, defends territory by vigorous song; territories overlap with those of *M. polyglottos*. Nest, built by both sexes, a rough open cup of twigs, lined with softer fibres, generally placed low down, range 0·5–4·5 m, in bush, occasionally on ground. Clutch 2–3 eggs, creamy to pinkish-white, with reddish-brown spots and blotches mostly at broad end; no information on incubation and nestling periods.
Movements. Resident; occasional wandering, and vagrants recorded in SE USA (S Florida).
Status and Conservation. Not globally threatened. Restricted-range species: present in Cuba EBA, Bahamas EBA and Jamaica EBA. Widespread and common in Bahamas, but absent from some NW islands; common in restricted range in S Jamaica (Hellshire Hills region). In Cuba, confined to Camagüey Archipelago, in N coast; common on some cays (Cruz, Guillermo), but rare and vulnerable on others. May be declining in parts of range as human habitations, and subsequent spread of *M. polyglottos*, expand on islands, e.g. San Salvador (EC Bahamas).
Bibliography. Aldridge (1984), Anon. (1998b), Bond (1985), Brewer (2001), Buden (1990), Downer & Sutton (1990), Emlen (1977), Garrido (1985), Garrido & Kirkconnell (2000a), Hellmayr (1934), Kaufman (1996a), Kirkconnell & Berovides (2000), Lack (1976), Miller (1978), Mlodinow & O'Brien (1996), Plockelman (1986), Raffaele *et al.* (1998, 2003), Steadman *et al.* (1980), Stotz *et al.* (1996).

13. White-banded Mockingbird

Mimus triurus

French: Moqueur à ailes blanches **Spanish**: Sinsonte Trescolas
German: Weißbinden-Spottdrossel

Taxonomy. *Turdus triurus* Vieillot, 1818, Paraguay.
Thought most closely related to, and perhaps forming a superspecies with, *M. dorsalis*. Monotypic.
Distribution. Breeds W Bolivia, W Paraguay and E Argentina (Salta S to N Río Negro); distribution poorly known, apparently patchy in N of range. Non-breeding E to S & SE Brazil.

Descriptive notes. 20–23·5 cm; 49–54 g, average in Brazil 51·5 g. Medium-sized mockingbird with distinct white wing patches. Has greyish crown, white supercilium, blackish line through eye, speckled ear-coverts; upperparts smoky grey, rump rufous-cinnamon; tail mostly white, black on central feather pairs, increasing amounts of white towards outer rectrices, wings blackish, prominent white patch on secondaries and coverts forming elongated band from shoulder to tips of outer secondaries (white in wing and tail conspicuous in flight, also in male display); whitish below, sides and flanks with cinnamon-brown wash, vent buffier, underwing white; iris sepia brown to yellow-orange; bill and legs blackish. Differs from *M. dorsalis* in having more white in wing, rufous rump. Sexes similar, female slightly smaller than male. Juvenile has less white in wing, and apparently has spotted breast. Voice. Superlative songster, the most outstanding of genus; song, often from exposed perch (average height 4·3 m in *monte* woodland), given throughout year, a long, loud and extended stream of melodic notes and phrases; also excellent mimic, S breeders reported as mimicking species apparently heard in non-breeding quarters in N.
Habitat. Low woodlands of *chaco* and *monte*, savannas; in *cerrado* scrubby woodland in Paraguay; open brushy country and steppe. Occurs around habitations. Generally less prevalent in lower, more open scrub favoured by *M. patagonicus* and *M. dorsalis*; overlaps with former in arid woodlands (*Geoffroya*, *Prosopis*) in SE Argentina, where avoids low *Larrea* scrub occupied by that species. Mainly lowlands below 500 m, but breeds to 2600 m in N Argentina; non-breeders at higher elevations in Bolivia and Chile.
Food and Feeding. Little information available. Probably largely insectivorous in breeding season.
Breeding. Nov–Dec. Displaying male runs along ground, jumps up while holding wings and tail open (white areas conspicuous), also performs song flights above vegetation. Nest is open structure of twigs, lined with plant fibres, flowers and rootlets, placed low in vegetation, often in thorny bush. Clutch 4 eggs, occasionally 3, greenish-blue with reddish-brown spots, thicker at large end; no information on incubation and nestling periods. Frequent host of Shiny Cowbird (*Molothrus bonariensis*).
Movements. Partially migratory, at least in S; non-breeders wintering birds found N to Bolivia and S & SE Brazil in austral winter. Non-breeding range not known precisely. Numerous records in Chile (S to Los Lagos) presumed to refer to vagrant, but possibly a regular non-breeding visitor in that country.
Status and Conservation. Not globally threatened. Common to fairly common throughout most of range. Precise distributions at various seasons not known; breeding records from Bolivia, Paraguay and N Argentina widely spaced, may represent disjunct populations, persistence of which may therefore be somewhat more precarious. Recent report from S Peru (L Titicaca) during breeding season (Dec) requires confirmation.
Bibliography. Araya & Chester (1993), Belton (1985), Brewer (2001), Canevari *et al.* (1991), Chebez *et al.* (1999), Couve & Vidal-Ojeda (2003), Fjeldså & Krabbe (1990), Gambarotta (1985), Gochfeld (1978), Gyldenstolpe (1945), Harris (1998), Hayes (1995), Hellmayr (1934), Jaramillo (2003), Johnson (1967), Klimaitis & Moschione (1987), Marín (2004), Narosky & Yzurieta (1993), Ochoa de Masramón (1975), Olrog (1959), de la Peña (1987, 1989), Ridgely & Tudor (1989), Shardlow & Shardlow (2004), Short (1975), Sick (1993, 1997), Stotz *et al.* (1996), Tobias *et al.* (1993).

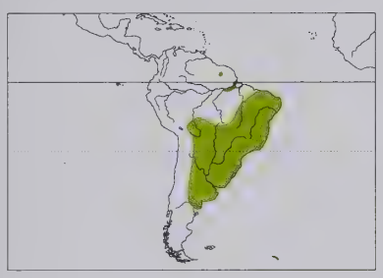
14. Brown-backed Mockingbird

Mimus dorsalis

French: Moqueur à dos brun **German**: Braunrücken-Spottdrossel **Spanish**: Sinsonte Castaño

Taxonomy. *Or[pheus] dorsalis* d'Orbigny and Lafresnaye, 1837, Cochabamba, Bolivia.
Thought most closely related to, and perhaps forming a superspecies with, *M. triurus*. Monotypic.
Distribution. W & S Bolivia (S from La Paz) and NW Argentina (S to Tucumán).

Descriptive notes. 21–25·5 cm; 52–65 g, average 58·7 g. Medium-sized brownish mockingbird. Has prominent whitish supercilium, dusky lores and ear-coverts; crown and upperparts chestnut-brown, brightest on rump, crown with darker streaks; upperwing-coverts tipped narrowly white (two narrow white wingbars), primary coverts white; flight-feathers and tail blackish, bases of primaries white and outer 3–4 rectrices white (conspicuous white wing and tail markings in flight); whitish below, tinged buff on chest, sides and flanks; iris brownish; bill and legs black. Differs from *M. triurus* in slightly



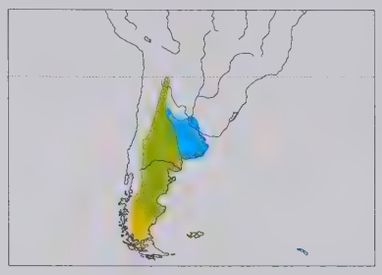
larger size, heavier bill, browner back, less white in wing. Sexes similar, but female slightly smaller than male. Juvenile has dusky spotting on breast. VOICE. Song is a series of repeated harsh notes and chuckles; reportedly much inferior in vocal array and melodic quality to that of *M. triurus*.
Habitat. Arid montane scrub in higher foothills and upper Andean slopes, 1700–4200 m, mostly 2300–3500 m. Inhabits brush, open desert shrubs and hedgerows; commonly found near habitations.
Food and Feeding. Feeds largely on ground, holding tail cocked. No information on diet or foraging behaviour.
Breeding. Breeds Nov–Mar. Cup-shaped nest of twigs, often placed in cactus, sometimes in bush. Clutch 4 eggs, light green with chestnut and grey spots. No other information.
Movements. Resident; report of vagrant in Chile (Arica) apparently questionable.
Status and Conservation. Not globally threatened. Poorly known. Apparently common wherever suitable habitat is to be found. No known threats to persistence of populations.
Bibliography. Brewer (2001), Canevari *et al.* (1991), Chebez *et al.* (1999), Darrieu & Camperi (1993), Dunning (1993), Fjeldså & Krabbe (1990), Flores & Capriles (1998), Gyldenstolpe (1945), Hellmayr (1934), Hennessey *et al.* (2003), Marín (2004), Meyer de Schauensee (1982), Narosky & Yzurieta (1993), Olrog (1959), de la Peña (1987, 1989), Ridgely & Tudor (1989), Stotz *et al.* (1996).

15. Chalk-browed Mockingbird

Mimus saturninus

French: Moqueur plombé **German**: Camposspottdrossel **Spanish**: Sinsonte Calandria

Taxonomy. *Turdus saturninus* M. H. K. Lichtenstein, 1823, Pará, Brazil.
Thought most closely related to, and perhaps forming a superspecies with, *M. patagonicus*. Four subspecies recognized.
Subspecies and Distribution.
M. s. saturninus (M. H. K. Lichtenstein, 1823) – S Suriname and N Brazil (lower Amazon in Pará).
M. s. frater Hellmayr, 1903 – C & E Bolivia and C Brazil (E to Ceará, W Bahia and Rio de Janeiro, S to Mato Grosso and Santa Catarina).
M. s. arenaceus Chapman, 1890 – NE Brazil (Paraíba S to E Bahia).
M. s. modulator (Gould, 1836) – SE Bolivia and Paraguay S to C Argentina, extreme SE Brazil (Rio Grande do Sul) and Uruguay.



Descriptive notes. 23·5–26 cm; 55–73 g. One of the largest *Mimus* species, brownish, with long legs, long graduated tail held semi-erect. Nominate race has dark crown, conspicuous broad white supercilium, blackish line from lores through eye to top of ear-coverts; upperparts brownish with darker striations, rump more buffish-tinged, upperwing-coverts tipped white (rather obscure white wingbars); flight-feathers and tail blackish, conspicuous white tips on all except central rectrices, outer webs white-sided; white below, breast greyer, sides tinged buffy, flanks faintly streaked darker; iris yellow; bill black; legs blackish. Sexes similar, female slightly smaller than male. Juvenile is browner than adult, underparts buffier, dark streaks on breast. Races exhibit minor variation in body size, bill length and plumage: *frater* is more brownish above than nominate, with no buff tinge on rump; *arenaceus* is similar to previous but larger-billed; *modulator* is also very similar, distinguished by more blackish-brown spotting on crown and upper back, lack of grey suffusion on chest, and flanks with decidedly paler buffy tinge and less conspicuous streaks or even unstreaked. VOICE. Loud, varied series of notes, trills, phrases; call note a characteristic, sharp and penetrating "tshrip", alarm a "snorting sha-sha-sha". Habitually mimics other species, including Roadside Hawk (*Buteo magnirostris*) and American Kestrel (*Falco sparverius*), but not known for any degree of virtuosity.
Habitat. Broad variety of non-forest habitat: savannas, forest edge, low open woodland, scattered trees in pastures, *cerrado* bushland in Paraguay and Brazil, also *caatinga* scrub in Brazil, and palm swamp in Suriname. Common around rural settlements, also urban parks and gardens. Inhabits relictual savannas in lower Amazonia (nominate race) and NE Brazil (*arenaceus*). Lowlands; to c. 2500 m in Argentina (near Tucumán).
Food and Feeding. Omnivorous; diet includes insects, e.g. orthopterans and beetles (Coleoptera), also spiders (Araneae), worms, small fruits, seeds, berries. Larger seeds and stones (or pits) of drupes regurgitated. Occasional predator on eggs and nestlings of other birds. Forages largely on ground.
Breeding. Breeds Sept–Jan. Monogamous. Helpers at nest recorded in Brazil and Argentina, in some cases young of previous brood, in other cases verified as unrelated to breeding pair, assist in territorial defence, nest-guarding and brood-feeding. Territorial; territory 6–20 ha in very open habitat, less than 1 ha in optimal habitat; defended also against *M. gilvus*. Nest built over period of 5 days, a loosely constructed, shallow cup, often with old nest used as base, lined with finer materials, placed in crown of low tree, or in dense, often spiny, shrub, 0·5–6·5 m above ground, mostly 1·3–3 m (average 1·9 m at Argentina study site). Clutch 3–4 eggs, pale greenish-blue with dense reddish-brown spots and blotches, especially at larger end; hatching asynchronous; incubation period reported as 12 days in Brazil, also 13–15 days in Argentina; chicks fed by both parents, also by any helpers present, nestling period 15 days in Brazil, 12–14 days in Argentina; nestlings susceptible to botfly (*Philornis*) infestation; young fed by parents for c. a week out of nest, remain on parental territory through subsequent non-breeding season. Common host of Shiny Cowbird (*Molothrus bonariensis*), especially in S (c. 80% of nests parasitized); accepts spotted version of dimorphic cowbird eggs, rejects unspotted version.
Movements. Mostly resident; southern populations (e.g. in SE Brazil) appear to be partially migratory.
Status and Conservation. Not globally threatened. Very common throughout much of range. Occurs in several protected areas, e.g. Serra da Canastra National Park, in Brazil, and Costanera Sur Ecological Reserve, in Argentina. No perceived threats, although nesting losses due to cowbird parasitism are considerable.
Bibliography. Argel de Oliveira (1991), Brewer (2001), Canevari *et al.* (1991), Chebez *et al.* (1999), Chikilian & Bee de Speroni (1985), Couve & Vidal-Ojeda (2003), Darrieu & Camperi (1993), Fjeldså & Krabbe (1990), Fraga (1979, 1985), Gyldenstolpe (1945), Haverschmidt & Mees (1994), Hayes (1995), Hellmayr (1934), Klimaitis & Moschione (1987), Maciel & da Costa (1997), Mason (1985, 1986), Narosky & Yzurieta (1993), de la Peña (1987, 1989, 1995), Ridgely & Tudor (1989), do Rosário (1996), Salvador (1984), Scott & Brooke (1985), Short (1975), Sick (1985, 1993, 1997), da Silva *et al.* (1997), Stotz *et al.* (1996), Tobias *et al.* (1993).

16. Patagonian Mockingbird

Mimus patagonicus

French: Moqueur de Patagonie **German**: Patagonienspottdrossel **Spanish**: Sinsonte Patagón

Taxonomy. *Or[pheus] patagonicus* d'Orbigny and Lafresnaye, 1837, Río Negro, Argentina.
Thought most closely related to, and perhaps forming a superspecies with, *M. saturninus*. Monotypic.
Distribution. NW, C & S Argentina and S Chile (Aisén, Magallanes) S to Strait of Magellan; casual in Tierra del Fuego.

Descriptive notes. 22–25 cm; male 44·4–61·8 g, female 43·8–65·4 g. A smaller, shorter-tailed version of *M. saturninus*. Has brown crown, whitish supercilium extending back from eye, blackish line through eye; upperparts unstreaked greyish-brown, rump buffier, upperwing-coverts with pale tips (two narrow wingbars); wings and tail blackish, flight-feathers edged white, whitish tips of retrices except central pair, narrow white edge on sides of outer rectrices; buffy grey below, throat and belly lighter; iris sepia brown; bill and legs black. Differs from *M. saturninus* in smaller size, shorter tail, shorter and narrower supercilium. Sexes similar, female slightly smaller than male. Juvenile has breast spotted blackish. VOICE. Song, from exposed perch or within vegetation, a warbling series of varied notes and phrases, said to resemble that of *M. thenca* but more melodious, delivered continuously for lengthy periods; mimics other species.
Habitat. Low and open desert shrublands, from scrubby *Larrea* in N part of range, and *Geoffroyia* (*chañar*) open *monte* woodland and *Prosopis* bushland in C region, to Patagonian steppe in S; sea-level to 1800 m. In SE Argentina (Río Negro) occupies low woodland with *M. triurus*, but at lower density than latter and uses lower song perches (3·2–3·6 m) in vegetation.
Food and Feeding. Mainly insectivorous during breeding; also takes fruits and berries (e.g. *Berberis*) outside breeding season. Feeds largely on ground. Conspicuous and tame in some regions, shy in others.
Breeding. Breeds Jan in N Argentina (Tucumán) and Oct–Dec in S Chile. Monogamous; consorts in family groups beyond breeding season. Apparently territorial. Nest an open twiggy cup, lined with soft materials, built low in vegetation. Clutch 3–6 eggs, greenish with brownish spots and blotches; no details available on incubation and nestling periods.
Movements. Resident in N. Migratory in S Argentina and Chile; absent from Patagonian breeding grounds Apr–Sept.
Status and Conservation. Not globally threatened. Relatively common throughout most of range; not common in Chile, but tends to keep to thick cover there and possibly overlooked. No known threats to populations.
Bibliography. Araya & Chester (1993), Bernath (1965), Brewer (2001), Canevari *et al.* (1991), Chebez *et al.* (1999), Contreras & Roag (1976), Couve & Vidal-Ojeda (2003), Darrieu & Camperi (1993), Fjeldså & Krabbe (1990), Gochfeld (1978), Harris (1998), Hellmayr (1934), Humphrey *et al.* (1970), Jaramillo (2003), Johnson (1967), Narosky & Yzurieta (1993), Navas & Bó (1986), Ochoa de Masramón (1975), Olrog (1959), de la Peña (1987, 1989), Ridgely & Tudor (1989), Short (1975), Stotz *et al.* (1996).

17. Chilean Mockingbird

Mimus thenca

French: Moqueur du Chili **German**: Chilespottdrossel **Spanish**: Sinsonte Tenca

Taxonomy. *Turdus thenca* Molina, 1782, Chile.
Most closely related to *M. longicaudatus*, with which forms a superspecies; both appear closest to genus *Nesomimus*. Monotypic.
Distribution. C Chile (W Atacama S to Valdivia).

Descriptive notes. 28–29 cm; 66 g. Large brownish mockingbird with long tail, long, thick bill. Has broad whitish supercilium; brownish-grey above, darker streaks on head, neck and back, rump browner (N birds apparently paler, more grey and less brown); upperwing-coverts with whitish tips (two narrow wingbars); wings and tail blackish, tail feathers (except central pair) tipped white, outer rectrices white-edged; throat whitish, brownish-black malar stripe at side; lighter brownish-grey below, becoming dirty white on belly, flanks buffy brown with elongated blackish markings; iris yellowish olive-brown to sepia brown; bill and legs black. Differs from *M. longicaudatus* in shorter bill, much shorter tail, more black in wing. Sexes alike, female somewhat smaller than male. Juvenile is more streaked and buffier below. VOICE. Song, given throughout year, a series of sweet, variable notes and phrases; lacks harsher and more disjointed quality of *M. polyglottos* song; excellent mimic of other bird species.
Habitat. Wide range of habitats, from sea-level to 2200 m. Breeds in semi-desert and low, succulent coastal scrub, *Bahia* scrubland, interior savanna bushland (*Acacia caven*, *Prosopis*), and dense evergreen *matorral*; reaches highest density in *matorral* on foothill slopes of coast ranges. Occurs on edge and in shrubby patches within relictual low woodland patches (e.g. Bosque Fray Jorge National Park). Also in disturbed habitats, successional scrub and, more rarely, around habitations and in urban areas. Absent from *Nothofagus* and *Cryptocarya* woodland in S; also avoids alien pine (*Pinus*) plantations in C Chile.
Food and Feeding. No details on diet; assumed omnivorous, taking insects and fruits. Forages largely on ground, but also in vegetation to 3 m or more. In dense *matorral* 2 m tall, foraging times spent in three height categories (ground, ground to 1 m, and 1–2 m) were 55%, 28% and 17%, respectively; corresponding figures for 2-m open *Acacia* bushland 92%, 7% and 1%, and for 1-m low coastal scrub 85%, 15% and 0%. Time on ground includes periods spent in turning leaf litter, and digging around plant stems and under fallen branches; time spent above ground includes searching of vegetation for insects. Also perches on telephone poles and utility wires.

Breeding. Nesting from Nov. Monogamous; territorial, presumably throughout year; territory in optimal *matorral* habitat c. 1 ha, larger in *algorrobles* of *Acacia/Prosopis*, and larger still in low coastal scrub. Nest of twigs, some thorny, lined with wool or moss, usually low in vegetation, often in cactus, well protected from approach by thorny or spiny branchesClutch 2–4 eggs, usually 3, blue-green with heavy reddish and purplish markings; no information on incubation and nestling periods.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in Central Chile EBA. Common throughout range; occurs in several protected areas, e.g. La Campana and Bosque Fray Jorge National Parks. No known threats to populations.
Bibliography. Araya & Chester (1993), Araya & Millie (1986), Brewer (2001), Cody (1975), Cody & Mooney (1978), Cornelius *et al.* (2000), Couve & Vidal-Ojeda (2003), Fjeldså & Krabbe (1990), Goodall *et al.* (1957), Hellmayr (1932, 1934), Jaramillo (2003), Johnson (1967), Marín (2004), Martínez del Río *et al.* (1996), Ridgely & Tudor (1989), Rozzi *et al.* (1996), Stotz *et al.* (1996).

18. **Long-tailed Mockingbird**

Mimus longicaudatus

French: Moqueur à longue queue **Spanish**: Sinsonte Colilargo
German: Langschwanz-Spottdrossel

Taxonomy. *M[imus] longicaudatus* Tschudi, 1844, Peru.
Most closely related to *M. thenca*, with which forms a superspecies; both appear closest to genus *Nesomimus*. Nominate race and *albogriseus* appear to intergrade in NW Peru. Race *maranonicus* doubtfully distinct from nominate. Four subspecies tentatively recognized.
Subspecies and Distribution.
M. l. albogriseus Lesson, 1844 – SW Ecuador (S from C Manabí).
M. l. platensis Chapman, 1924 – I de la Plata, off W Ecuador (SW Manabí).
M. l. longicaudatus Tschudi, 1844 – W Peru.
M. l. maranonicus Carriker, 1933 – La Libertad (upper Marañón Valley), in NW Peru.

Descriptive notes. 27–29·5 cm; 54–79 g, average 66·6 g. Large greyish mockingbird with very long, graduated tail. Nominate race has prominent white supercilium, black eyestripe from lores to upper ear-coverts, connecting to rear with black patch on lower ear-coverts; white cheeks, narrow black malar stripe; crown and upperparts brownish-grey, streaked darker, upperwing-coverts pale-tipped, white patch on primary coverts; flight-feathers and tail dusky brown, primary bases whitish, white tips of outer rectrices (both wing and tail patches conspicuous in flight); throat, belly and vent whitish; breast dull brown, feathers with blackish centres at breast sides, and dull buff margins elsewhere; flanks tinged buffy brown, with some blackish streaks; iris sepia brown to yellow; bill and legs dark. Sexes alike, female slightly smaller than male. Juvenile has streaky chest. Race *albogriseus* is somewhat smaller than nominate, also greyer, with larger white tail tips; *platensis* resembles previous but larger, and longer billed; *maranonicus* is very similar to nominate. Voice. Song, to be heard throughout day, is a loud, persistent, continued string of chuckling notes and phrases; not known to mimic other bird species.
Habitat. Found in desert scrub and arid woodland within coastal zone, in brush, hedgerows and tree groves in cleared country and agricultural areas. Recorded to 1900 m in Ecuador (Loja); race *maranonicus* at 2450 m in Marañón Valley (Peru), and perhaps non-breeding to 2950 m (Huaytará).
Food and Feeding. Diet broad, including terrestrial and marine invertebrates, fruits, berries. Forages largely on ground; hops with tail elevated, glides between foraging sites with spread wings and tail. Occurs in loose groups outside breeding season.
Breeding. Late Dec to Jul; season c. 5–6 months in SW Ecuador (Santa Elena Peninsula), source of most information on breeding. Generally monogamous, but two females may lay in one nest. Territorial; extra birds noted on territory, may be young from previous brood. Nest a rough cup of thorny twigs, lined with fine rootlets, other plant material and hair, placed in interior of dense, spiny bush or cactus at height of 0·5–5 m (average 1·67 m); nest-site reused, but new nest built for successive broods. Clutch 3–4 eggs, average 3·9 (clutch size 3 before seasonal rains, averaging close to 4 after rains), colour greenish and more or less heavily spotted and blotched reddish-brown (variable); incubation period 12–13 days; hatching more or less synchronous, nestling period 12–14 days; young fed by parents after leaving nest. Common host of Shiny Cowbird (*Molothrus bonariensis*). Success varies between years, depending on rainfall amount.
Movements. Resident; possible vagrant reported from extreme N Chile.
Status and Conservation. Not globally threatened. Common. Distribution patchy, restricted to discontinuous habitat in barren Peru coast region; range has recently expanded to S. Race *platensis* is the only endemic bird species on I de la Plata, 30 km off Ecuador coast; island protected as part of Machalilla National Park. Race *maranonicus* also has small range, confined to upper Marañón Valley of NW Peru.

Brewer (2001), Butler (1979), Chapman (1926), Clements & Shany (2001), Fjeldså & Krabbe (1990), González & Málaga (1997), Hellmayr (1934), Marchant (1959, 1960), Meyer de Schauensee (1982), Parker *et al.* (1995), Ridgely & Greenfield (2001), Ridgely & Tudor (1989), Ridgely *et al.* (1998), Rodner *et al.* (2000), Stotz *et al.* (1996), Walker (2002), Zimmer (1930).

Genus *NESOMIMUS* Ridgway, 1890

19. **Floreana Mockingbird**

Nesomimus trifasciatus

French: Moqueur de Floreana **German**: Floreanaspottdrossel **Spanish**: Sinsonte de Floreana
Other common names: Charles/Three-banded/Santa Maria Mockingbird

Taxonomy. *Orpheus trifasciatus* Gould, 1837, Floreana Island (formerly Charles Island), Galapagos Archipelago.
Genus considered most closely related to, and putatively derived from, mainland *Mimus longicaudatus*; hybridization between latter and present species recorded in captivity. Forms a superspecies with *N. macdonaldi*, *N. melanotis* and *N. parvulus*; all previously considered conspecific. Birds on Campeón somewehat smaller than those on Gardner-near-Floreana, but difference considered insufficient to warrant naming of geographical races. Monotypic.
Distribution. Islets of Gardner-near-Floreana and Campeón (near Floreana), in S Galapagos Is.

Descriptive notes. 25–26 cm; male 65·7 g, female 59·8 g. Large greyish mimid with rather long, somewhat decurved bill. Has pale eyeline, dark-mottled buffish ear-coverts; crown and upperparts greyish-brown, minimally streaked, upperwing-coverts tipped white (two wingbars); whitish below, dark patch on side of breast, a few obscure spots across breast and on flanks; iris dark brown; bill and legs blackish. Sexes similar, female smaller than male. Juvenile is more streaked than adult. Voice. Loud, melodious song; does not mimic other species.
Habitat. Desert and semi-desert scrub with a few trees and arborescent cacti; low littoral vegetation.
Food and Feeding. Omnivorous, primarily insectivorous. Food includes carrion (seabirds, lizards), probably also seabird eggs. Forages mainly on ground, but also at all heights in vegetation, depending on food resource (e.g. cactus fruit).
Breeding. Oct–Apr; two broods. Co-operative breeder, 4–5 adults per territorial group, group size correlates positively with territory size; territory size averages c. 2 ha; one breeding female per group. Nest a cup of twigs, lined with finer material, placed nearly exclusively in cactus, occasionally in other shrub. Clutch 2–4 eggs; no other information. Most females disperse from natal territory and breed at younger age than males; males tend to inherit parental territory, are older at first reproduction attempt.
Movements. Sedentary.
Status and Conservation. ENDANGERED. Restricted-range species: present in Galapagos Islands EBA. Once abundant on Floreana, where became extinct since before 1888; now restricted to two small adjacent islets. Estimated global population fewer than 300 individuals; population crashes routine during dry "La Niña years". Numbers on Campeón (10 ha) varied from 24 to 53 individuals between 1980 and 1991; 150–200 or more estimated on larger Gardner-near-Floreana (80 ha). Reasons for disappearance from Floreana debated, but probably nest predation by introduced black rats (*Rattus rattus*); as Floreana, unlike other islands of Galapagos, lacks native rats, introduced ones a novelty. Habitat degeneration from browsing goats possibly also a contributory factor. Some concern that, in absence of immigration from Floreana, the birds on these tiny islets may have lost a significant amount of genetic diversity, rendering them more vulnerable to fatal diseases.

Abbott & Abbott (1978), Bowman & Carter (1971), Brewer (2001), Castro & Phillips (1996), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Curry (1986a, 1986c, 1987, 1989), Curry & Anderson (1987), Curry & Grant (1990), Granizo (2002), Grant, N. (1983), Grant, P.R. *et al.* (2000), Harris (1968, 1982), Hellmayr (1934), King (1978/79), Stattersfield & Capper (2000), Stotz *et al.* (1996), Swarth (1931), Wege & Long (1995).

20. **Espanola Mockingbird**

Nesomimus macdonaldi

French: Moqueur d'Espanola **German**: Españolaspottdrossel **Spanish**: Sinsonte de Española
Other common names: Hood (Island) Mockingbird

Taxonomy. *Nesomimus macdonaldi* Ridgway, 1890, Española Island (formerly Hood Island), Galapagos Archipelago.
Genus considered most closely related to, and putatively derived from, mainland *Mimus longicaudatus*. Forms a superspecies with *N. trifasciatus*, *N. melanotis* and *N. parvulus*; all previously considered conspecific. Monotypic.
Distribution. Española and adjacent Gardner-near-Española, in SE Galapagos Is.

Descriptive notes. 26·5–28 cm; male average 76·1 g, female average 64·8 g. Largest of genus, bill very long and decurved. Has obscure thin pale supercilium, black lores, blackish ear patch, faint black malar trace; crown greyish-brown, somewhat streaked; feathers of upperparts with blackish-brown centres and grey to brownish-grey margins, giving streaked or scalloped appearance, the dark centres obscure on hindneck, margins browner on rump; upperwing-coverts tipped off-white; flight-feathers blackish with white tips, remiges and greater coverts with tawny edges, tail dark brown; whitish below, indistinct brown markings on breast, streaky flanks; iris yellow-brown; bill blackish; legs black. All blackish feathers become paler and browner in worn plumage. Differs from congeners in larger size, longer bill, less white in tail, less distinct facial patterning. Sexes similar, female smaller than male. Juvenile is more streaked below than adult. Voice. Loud, strident song ; does not mimic other species.
Habitat. Arid littoral scrub, low thorny mesquite (*Prosopis*) scrub, scrubby woodland with scattered trees (*Bursera*) and arborescent cacti.
Food and Feeding. Omnivorous; wide range of food items, from insects, and fruits and berries, to marine arthropods, small vertebrates, and scavenged items from seabird and hawk nests. Eats carrion from carcasses of seabirds, lizards, sea-lions (Otariinae); readily eats damaged seabird eggs, can open others with powerful bill. Habitually drinks blood, especially in dry season. Forages mainly on ground, but also in vegetation, depending on food resource (e.g. cactus fruits). Occurs in groups of up to 40 individuals outside breeding season. Removes and eats ticks (Acarina) from marine and land iguanas (*Conolophus*). Blood taken from wounds in living sea-lions, from sea-lion placentas, marine iguanas (*Amblyrhynchus*), nestling boobies (*Sula*), from site of Galapagos Hawk (*Buteo galapagoensis*) kill of iguana, even from wounds on legs of humans. Blood-drinking habit peculiar to this one member of genus; possibly facilitated, at least in origin, by consequences of hawk predation.

Breeding. Mar–Apr; timing highly synchronized. Co-operative breeder; often just one breeding pair per group, sometimes more ("plural" breeding groups); generally 7–10 adults per territorial group, group size correlates positively with territory size; territory size averages c. 1·5 ha. Nest a cup of twigs lined with finer material, placed in cactus, occasionally in other shrub. Clutch usually 2–4 eggs, sometimes 1; no information on incubation and fledging periods; young in nest fed by several adults (up to four recorded).
Movements. Sedentary.
Status and Conservation. VULNERABLE. Restricted-range species: present in Galapagos Islands EBA. Common within its tiny range of Española (58 km²) and one adjacent islet. Global population in the range 1000–2500 individuals; total numbers vary among years. Lives at higher densities than others of genus, up to 16 adults/ha. Primary conservation concern over this species stems from the fact that it is confined to two small islands on which its population trends are not known. Extreme weather events in the Galapagos could possibly have adverse effects on this species similar to those suffered by *N. trifasciatus*. No evidence that either Española or Gardner-near-Española has been populated by rats; accidental introduction of alien predators would have major adverse consequences for this species.
Bibliography. Abbott & Abbott (1978), Bowman & Carter (1971), Brewer (2001), Burtt *et al.* (1994), Castro & Phillips (1996), Curry (1987, 1989), Curry & Anderson (1987), Curry & Grant (1990), Granizo (2002), Grant (1983), Harris (1968, 1982), Hatch (1965, 1966), Heinzel & Hall (2000), Hellmayr (1934), Stattersfield & Capper (2000), Stotz *et al.* (1996), Swarth (1931), Swash & Still (2000).

21. San Cristobal Mockingbird

Nesomimus melanotis

French: Moqueur de San Cristobal **Spanish**: Sinsonte de San Cristóbal
German: San Cristobal-Spottdrossel
Other common names: Chatham (Island) Mockingbird

Taxonomy. *Orpheus melanotis* Gould, 1837, San Cristóbal Island (formerly Chatham Island), Galapagos Archipelago.
Genus considered most closely related to, and putatively derived from, mainland *Mimus longicaudatus*. Forms a superspecies with *N. trifasciatus*, *N. macdonaldi* and *N. parvulus*; all previously considered conspecific. Monotypic.
Distribution. San Cristóbal I, in E Galapagos Is.

Descriptive notes. 25–26 cm; male average 53·2 g, female average 48 g. A smaller *Nesomimus*, intermediate in appearance between *N. macdonaldi* and *N. parvulus*, with decurved bill comparatively short. Has obscure narrow whitish supercilium, prominent black lores and blackish ear patch, narrow black malar stripe; crown and upperparts greyish-brown, somewhat streaked, upperwing-coverts tipped whitish (two wingbars); flight-feathers and tail dark brown, outer three rectrices with off-white tips; whitish below, sometimes slightly buff-tinged on throat, breast side with tiny dark spots, flanks with blackish-brown streaking; iris amber to dark reddish-brown; bill and legs blackish. Sexes similar, female c. 10% smaller than male in linear dimensions. Juvenile is more streaked below than adult. VOICE. Loud, melodious and disjointed territorial song typical of genus.
Habitat. Occupies a wide range of habitats, from lowlands up to island summit at 715 m: found in low and open arid scrub in lowlands, also mangroves, to low scrubby woodland with scattered trees (*Bursera*) and arborescent cacti (*Opuntia*), and taller *Bursera* and *Piscidia* woodland patches; also low woodland of introduced guava (*Psidium guajava*). Not all available habitat on island occupied; avoids dense lowland forest, taller, wetter woodland, *Bursera*-dominated scrub, and grassland.
Food and Feeding. Feeds on terrestrial arthropods, including crickets and grasshoppers (Orthoptera); also takes fruits and berries. Occasionally picks ticks (Acarina) off marine iguanas (*Amblyrhynchus*), but not known to drink blood. No evidence of feeding on seabird eggs (perhaps owing to low availability). Forages mostly on ground, searches litter for arthropods; also low in vegetation for fruits.
Breeding. Jan–Apr, later at higher elevations. Territorial, often with additional adult; 25–50% of pairs had extra, subordinate male, but no evidence that latter assists in nest-building, nest defence, or feeding of young; territory 3–5 ha or more, considerably larger than in congeners, territory size increases with group size. Nest, built by both sexes, a bulky structure of twigs, lined with grasses, placed 4–5 m up in crotch of tree. Clutch 2–5 eggs, usually 4, greenish with reddish-brown spots and blotches; incubation by female alone, nestlings fed by both parents; no information on incubation and nestling periods.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in Galapagos Islands EBA. Considered to be common on the single, large island of San Cristóbal (552 km²). Overall density is rather low, at 0·5–0·7 individuals/ha. No perceived threats to population or status, but introduced black rats (*Rattus rattus*) and feral cats on island might pose problems in the future.
Bibliography. Abbott & Abbott (1978), Bowman & Carter (1971), Brewer (2001), Castro & Phillips (1996), Curry (1987, 1989), Curry & Anderson (1987), Curry & Grant (1990), Grant (1983), Harris (1968, 1982), Heinzel & Hall (2000), Hellmayr (1934), Hundley (1963), Stotz *et al.* (1996), Swarth (1931), Swash & Still (2000), Venables (1940).

22. Galapagos Mockingbird

Nesomimus parvulus

French: Moqueur des Galapagos **Spanish**: Sinsonte de Galápagos
German: Galapagosspottdrossel
Other common names: Black-eared/Salvador/Abingdon Mockingbird (*personatus*); Isabela/Albemarle Mockingbird (*parvulus*)

Taxonomy. *Orpheus parvulus* Gould, 1837, Isabela Island (formerly Albemarle Island), Galapagos Archipelago.
Genus considered most closely related to, and putatively derived from, mainland *Mimus longicaudatus*. Forms a superspecies with *N. trifasciatus*, *N. macdonaldi* and *N. melanotis*; all previously considered conspecific. Race *personatus* has sometimes been treated as a separate species; described race *bindloei* (from Marchena I) considered indistinguishable from aforementioned. Six subspecies recognized.
Subspecies and Distribution.
N. p. hulli Rothschild, 1898 – Darwin (Culpepper) I.
N. p. wenmani Swarth, 1931 – Wolf (Wenman) I.
N. p. personatus Ridgway, 1890 – islands of Pinta (Abingdon), Marchena (Bindloe), Santiago (James) and Rabida (Jervis).
N. p. bauri Ridgway, 1894 – Genovesa (Tower) I.
N. p. parvulus (Gould, 1837) – islands of Isabela (Albemarle), Fernandina (Narborough), Daphne, Santa Cruz (Indefatigable) and nearby islets.
N. p. barringtoni Rothschild, 1898 – Santa Fe (Barrington) I.

Descriptive notes. 25–26 cm; male average 56·2 g, female average 51·2 g. Smallish *Nesomimus*, slightly decurved bill relatively shorter and less robust than most others. Nominate race has whitish stripe behind eye, blackish-brown lores and prominent ear patch, obscure malar streak; crown blackish-brown, upperparts greyish-brown, back with darker, brownish streaks, upperwing-coverts tipped whitish (two wingbars); flight-feathers and tail dark brown, remiges edged pale on outer webs, outer rectrices tipped whitish; whitish below, broad whitish collar on sides of neck, few brownish streaks on breast side and flanks; iris yellowish; bill and legs blackish. Sexes similar, female c. 6–8% smaller than male in linear dimensions. Juvenile is more streaked below than adult. Races exhibit minor variations in overall size, coloration and markings: *personatus* is larger than nominate, bill longer, sides and flanks more strongly tinged brown; *wenmani* has paler upperparts, wider wingbars; *hulli* is similar to nominate, but with distinct blackish malar streak, much broader whitish terminal margins of remiges; *bauri* differs from previous in slightly more distinct streaks or spots on back, darker grey crown, more heavily streaked flanks; *barringtoni* has shorter wing than last. VOICE. Loud, melodious territorial song typical of genus; calls harsh, strident. Does not mimic other species.
Habitat. Range of habitats, from low, arid coastal scrub to low *Bursera* woodland with scattered, emergent cacti and scrubby understorey; also mangroves on Genovesa I (where all available habitat was occupied).
Food and Feeding. Omnivorous. Diet largely arthropods, including caterpillars, orthopterans, centipedes (Chilopoda); also fruit and nectar from cactus and other shrubs and trees (*Lantana*, *Bursera*); some vertebrates (lizards) taken. Nestling fed largely with insect larvae. Takes and eats unattended seabird eggs; preys on nestling birds; cleans ticks (Acarina) off land iguanas (*Conolophus*). Incidence of blood-drinking low or zero in most races; carrion-feeding widespread. Observed to steal orthopteran from a large centipede. Forages largely on ground and low in vegetation.
Breeding. Oct–Apr, occasionally to Jul; on Genovesa (race *bauri*) egg-laying normally begins Jan, after first rains of season; normally double-brooded, second attempt after 12-day break. Mostly monogamous, but polygyny occurs in 7% of males and 33% of females (Genovesa). Co-operative breeder, in groups of up to 24 individuals (average about six on Genovesa), which may comprise several breeding pairs (up to four breeding females, each laying in separate nest; known as "plural breeding") and several helpers, latter mostly male offspring of previous broods, others may be failed breeders; territory defined by single dominant male, defended by group throughout year; average territory size c. 2·5 ha (Genovesa), increases with group size, but smaller per breeding pair in "plural groups". Nest of twigs, lined with finer materials, placed low down (up to c. 1 m) in tree or cactus, higher (to 6 m) in taller vegetation. Clutch 4 eggs, occasionally 2 or 3, greenish with reddish-brown spots; incubation period 12–13 days; chicks fed by both parents, assisted by one or more helpers, nestling period 11–17 days. Breeding success higher in wetter "El Niño years"; also, nests with helpers produced average 1·9 fledglings, 20% more than those without helpers; success of nests of subordinate pairs in territory reduced by interference by dominant pair.
Movements. Sedentary; vagrants recorded from Pinzón (Duncan) I, the only island in Galapagos with no breeding mockingbird population.
Status and Conservation. Not globally threatened. Restricted-range species: present in Galapagos Islands EBA. Common, even abundant, on most islands of its range; somewhat less numerous on largest island, Isabela, where perhaps more habitat disturbance and introduced nest predators. The most widespread and the best-studied of the Galapagos mockingbirds; much of the work on this species conducted on Genovesa (17·4 km²), where race *bauri* very common.
Bibliography. Abbott & Abbott (1978), Bowman & Carter (1971), Brewer (2001), Castro & Phillips (1996), Curry (1986b, 1987, 1988a, 1988b, 1989), Curry & Anderson (1987), Curry & Grant (1989, 1990, 1991), Fusani *et al.* (1994), Grant, N. (1983), Grant, P.R. & Grant (1979), Harris (1968, 1982), Hellmayr (1934), Kinnaird & Grant (1982), Skutch (1987), Stotz *et al.* (1996), Swarth (1931), Trimble (1976), Vargas (1987), Venables (1940).

PLATE 47

inches 4

cm 10

Genus *MIMODES* Ridgway, 1882

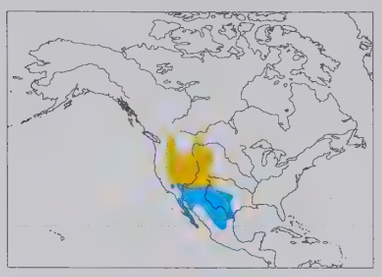
23. Socorro Mockingbird

Mimodes graysoni

French: Moqueur de Socorro **German**: Socorrospottdrossel **Spanish**: Sinsonte de Socorro
Other common names: Socorro Thrasher

Taxonomy. *Harporhynchus graysoni* Lawrence, 1871, Socorro Island, Mexico.
Monotypic genus, presumed derived from *Mimus*. Recent genetic analysis suggests that it belongs in a clade that contains four *Mimus* species (*M. polyglottos*, *M. gilvus*, *M. gundlachii*, *M. saturninus*) and that it should be placed in that genus. Monotypic.
Distribution. Socorro I, in Revillagigedo Archipelago, 600 km W of mainland Mexico.

Descriptive notes. 24–26·5 cm; average 75·5 g. Large, brownish mockingbird with short, straightish bill, lacking prominent wing and tail markings. Plumage is uniformly greyish-brown above, lores, wings and tail slightly darker, indistinct thin pale supercilium, two narrow pale wingbars (indistinct), outer rectrices pale-tipped; whitish below, few dusky streaks on flanks; iris yellow-amber or brownish-red; bill and legs blackish. Distinguished from *Mimus polyglottos* by larger size, browner coloration, lack of prominent white wing and tail markings. Sexes similar, female slightly smaller and 6·5% lighter in weight than male. Juvenile has streakier underparts, wingbars buff, eyes darker. VOICE. Extended delivery of diverse notes and phrases, similar to song of *Mimus polyglottos* but notably more melodious, less repetitive; various call notes, mellow to harsh and nasal.
Habitat. Mixed open woodland and wooded canyons at higher elevations, above 300 m (mostly above 600 m); also a few fig (*Ficus*) groves near coast. Commonest in undisturbed habitat, but absent from low-elevation scrub and all degraded woodlands; little habitat overlap with *Mimus polyglottos* (a recent immigrant). Was previously widespread in all island vegetation types, including scrub, woodland and woodland edge.
Food and Feeding. Omnivorous. Diet includes large insects, young leaves, small fruits (*Ficus*, *Bumelia*), also small vertebrates (lizards), land crabs. Possible predator on nests of small birds, e.g. Tropical Parula (*Parula pitiayumi*) and Socorro Wren (*Troglodytes sissonii*). Foraging habits diverse; feeds on ground, also in vegetation up to canopy; forages along beach, and hawks for flying insects. Scavenges around sheep carcasses, and accepts food items from island visitors. Runs rapidly, with tail cocked.
Breeding. Peak in Mar–May, season possibly Nov–Jul. Apparently monogamous. Territorial, male remains on same territory for more than one season, female less sedentary; seen to chase *Mimus polyglottos* from territory. Nest an open twiggy cup, lined with mosses and epiphytes, placed at average of 3·7 m in tree (average tree height 5·4 m). Clutch 3 eggs, bluish-green with large brownish spots concentrated at wider end; incubation period no more than 15 days; hatching apparently asynchronous, chicks fed by both parents, nestling period maximum 14 days; large fledged young continue to be fed by parents.
Movements. Sedentary.
Status and Conservation. CRITICAL. Restricted-range species: present in Socorro Island EBA. Formerly abundant, up to at least 1958; now greatly reduced. By 1978 numbers had declined drasticly; population estimated at c. 350 individuals in 1994, since when perhaps even fewer. Decline began with human settlement, after 1958; apparently not related to recent colonization of Socorro I around 1980 by *Mimus polyglottos*, which now abundant on island but thought unlikely to be an important competitor, as it is smaller than present species and differs ecologically. Suggested reasons for dramatic decline include predation by domestic cats (introduced in early 1970s), which may have caused extinction of Socorro Dove (*Zenaida graysoni*); various studies, however, reveal little evidence that predation a serious problem. Most likely cause is severe overgrazing by introduced rabbits, pigs and, especially, sheep, which has already destroyed a great deal of the species' habitat and which prevents woodland regeneration. Survival of species will depend on stringent conservation measures following designation of Revillagigedo Archipelago as a Biosphere Reserve in 1994; a conservation programme aimed at removing both sheep and cats from the island has already started.
Bibliography. Anon. (1998b), Anthony (1898), Brattstrom & Howell (1956), Castellanos & Rodríguez (1992, 1993), Ceballos & Valdelamar (2000), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Grayson (1872), Gulledge (1975), Hellmayr (1934), Howell & Webb (1995), Jehl (1983), Jehl & Parkes (1982, 1983), Martínez-Gómez & Curry (1995, 1996, 1998a, 1998b), Martínez-Gómez *et al.* (2001), McLellan (1926), Parkes (1990), Rodríguez-Estrella *et al.* (1996), Santaella & Sada (1991), Stattersfield & Capper (2000), Stotz *et al.* (1996), Villa (1960), Wege & Long (1995).



Genus *OREOSCOPTES* S. F. Baird, 1858

24. Sage Thrasher

Oreoscoptes montanus

French: Moqueur des armoises **Spanish**: Cuitlacoche de las Artemisas
German: Bergspottdrossel

Taxonomy. *Orpheus montanus* J. K. Townsend, 1837, Wyoming, USA.
Monotypic genus, thought most closely related to *Mimus*. Monotypic.
Distribution. Breeds SW Canada (extreme S British Columbia, extreme SW Saskatchewan) S in W USA to E California, C Arizona and NW New Mexico; non-breeding S to C Mexico.

Descriptive notes. 20–23 cm; 40–50 g. Small, plain, mimid with relatively short bill. Plain appearance alleviated by whitish supercilium above dark eyeline, and whitish submoustachial area above dark malar line; plumage otherwise brownish-grey above, wings and tail browner, outer rectrices prominently white-tipped; throat white; rest of underparts whitish, flanks and undertail-coverts buff, with prominent brown streaks, often absent on belly; streaking much less obvious when plumage worn; iris yellow to amber; bill and legs dusky brown. Sexes similar, female smaller than male. Juvenile is paler and streaked above, markings on underparts less distinct. VOICE. Song distinctive, vigorous, far-reaching, a long string of varied notes and phrases with little apparent repetition, maintained for many minutes without break (average in SW Idaho 166 seconds, but ranging to uninterrupted 22 minutes); mimics other species, e.g. Western Meadowlark (*Sturnella neglecta*), Brewer's Sparrow (*Spizella breweri*) and Horned Lark (*Eremophila alpestris*), but mimicry not conspicuous or routine. Calls include guttural "chuck", whistled "whee-er" and scolding notes.
Habitat. Characteristic species of sagebrush (*Artemisia*) plains, especially of intermontane Great Basin Desert. Associated prominently with tall, dense sagebrush, but utilizes other vegetation of similar structure and height (e.g. c.1 m), such as saltbush (*Atriplex*). In non-breeding season, found in arid and semi-arid habitats, including dry brushland and desert.
Food and Feeding. Primarily insectivorous, at least during breeding season; main foods grasshoppers and crickets (Orthoptera), ants (Hymenoptera) and beetles (Coleoptera), occasionally seeds and berries. Forages nearly exclusively on ground, searching beneath bushes and digging for food in tussocks, litter and detritus.
Breeding. Egg-laying begins Apr to early May; two broods apparently typical. Monogamous; territory defended by song, undulating flights, and chasing. Nest, built by both sexes, a bulky open cup of twigs, lined with grass, fur and other soft materials, typically placed within taller shrub, but commonly on ground; territory 0·4–1·7 ha. Clutch 3–7 eggs, mostly 4–5, mean varies among years and sites, eggs blue to greenish-blue, boldly spotted and blotched; incubation by both sexes, period 12–15 days; chicks fed by both sexes (which approach nest on ground), spend up to 13 days in nest, but commonly only 10–11 days; young not capable of flight for c. 1 week after leaving nest, continue to be fed by parents.
Movements. Migratory. Winters immediately S of breeding range, from S California, C Arizona, New Mexico and W Texas S to C Mexico (Baja California, interior S to Hidalgo, occasionally farther S). Present in non-breeding range in lower Colorado Valley Jan–Apr. Arrival on breeding grounds late Mar to Apr; not until Jun in far N (S British Columbia). Vagrants reported N to C Canada and throughout USA (E to Atlantic coast).
Status and Conservation. Not globally threatened. Fairly common to uncommon. Threats largely from changes in and clearance of breeding habitat; wintering habitat in deserts not subjected to much alteration. Conversion of sagebrush habitats to grazing land of crested wheatgrass (*Agropyron cristatus*) eliminates this species; sagebrush fires reduce breeding density dramatically. Listed as a "species of concern" in Washington state, where its sagebrush habitat has been extensively reduced by clearing. In Canada (British Columbia), under consideration for "endangered and threatened" status, as only a few hundred hectares of suitable habitat remain in the several S valleys of the province that provide breeding habitat.
Bibliography. Anon. Genus *TOXOSTOMA* Wagler, 1831

25. Brown Thrasher

Toxostoma rufum

French: Moqueur roux **German**: Rote Spottdrossel **Spanish**: Cuitlacoche Rojizo

Taxonomy. [*Turdus*] *rufus* Linnaeus, 1758, South Carolina, USA.
Forms a superspecies with *T. longirostre* and *T. guttatum*, and the three sometimes considered conspecific. Two subspecies recognized.
Subspecies and Distribution.
T. r. longicauda (S. F. Baird, 1858) – Great Plains from S Canada (SE Alberta E to SW Ontario) S in USA to Colorado and Kansas.
T. r. rufum (Linnaeus, 1758) – SE Canada (SE Ontario E to Nova Scotia) and C & E USA (S to E Texas and Gulf coast).
Descriptive notes. 23·5–30·5 cm; 61–89 g, average 69 g. Large, long-tailed mimid with long, slightly curved bill, long legs. Crown and upperparts are rufous-brown, side of head and neck buffy brown; wings and tail rufous, two white wingbars; throat whitish, pale submoustachial stripe, dark malar stripe; pale buff below, whiter on central belly, heavy black streaks on breast and sides, browner streaks on flanks; plumage brightest in autumn, when fresh; iris orange-yellow; bill blackish, with

On following pages: 26. Long-billed Thrasher (*Toxostoma longirostre*); 27. Cozumel Thrasher (*Toxostoma guttatum*); 28. Grey Thrasher (*Toxostoma cinereum*); 29. Bendire's Thrasher (*Toxostoma bendirei*); 30. Ocellated Thrasher (*Toxostoma ocellatum*); 31. Curve-billed Thrasher (*Toxostoma curvirostre*); 32. Le Conte's Thrasher (*Toxostoma lecontei*); 33. California Thrasher (*Toxostoma redivivum*); 34. Crissal Thrasher (*Toxostoma crissale*).

pale base to lower mandible; legs variable, flesh-coloured to brownish. Differs from *T. longirostre* mainly in much brighter rufous coloration above. Sexes alike, male sometimes slightly heavier than female. Juvenile is rufous with buffy mottling above, wingbars buff, iris grey. Races differ minimally: *longicauda* is paler than nominate, less densely streaked below, also larger on average (wing by 7 mm, tail by 8·5 mm). VOICE. Loud, exuberant territorial song consists of extended delivery of rich, fluty phrases of extraordinary variety, each often twice-repeated; male also emits much quieter song when female close by; occasionally mimics other species, e.g. Northern Flicker (*Colaptes auratus*) and Northern Cardinal (*Cardinalis cardinalis*), but with no great accuracy. Calls various, including typical, abrupt "kek" or "tchuck", also higher whistled or nasal and slurred "teea, teea" notes.

Habitat. Dense shrubbery, well-vegetated residential areas, woodland edge, post-fire second growth; in W of range, also riparian woodland, windbreaks, wooded draws in open country.

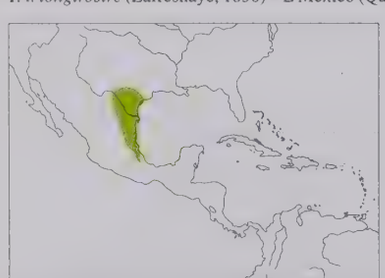
Food and Feeding. Generalized omnivore; feeds on insects and other arthropods, gastropods, seeds and fruits. Insect consumption highest in breeding season; berries and seeds predominate in late summer, autumn and winter. Forages nearly exclusively on ground; searches for insects in leaf litter displaced by sweeping the bill from side to side; excavates hidden prey with bill. Fruits and berries taken from low bushes; large, tougher fruits (e.g. acorns) lodged in crevice and hammered with bill. Maintains and defends territories in wintering areas.

Breeding. Season varies with latitude; in USA, egg-laying from Apr (in SE) to late May (C); two broods typical in SE of range. Monogamous. Strongly territorial, more likely to return to previous territory if last breeding successful there; excludes other mimids (*Dumetella carolinensis*, *Mimus polyglottos*) from territory; territory generally 0·5–1·25 ha. Nest, built mostly by both sexes, a bulky, twiggy, grass-lined open cup, typically placed 1–2 m above ground in dense shrub, occasionally on ground. Clutch 2–6 eggs, usually 3–4, densely spotted brown on white to blue-green background; incubation by both sexes, period 12–13 days, occasionally 11 or 14 days; chicks fed by both parents, spend up to 11–12 days in nest; on leaving, able to run well but flight weak, fed by parents for at least another week.

Movements. Short-distance migrant in N; S populations resident. N breeders winter in SC & SE USA, mostly within breeding range but extending to C Texas (where non-breeding only). Leaves wintering grounds in SE USA in late winter, arrival at breeding grounds between early Mar (Kentucky) and mid-May (Canada). Vagrants recorded at least twice in Europe; one individual remained from Nov 1966 to early Feb 1967 on a coastal headland in S England.

Status and Conservation. Not globally threatened. Common over most of range; sporadic at NW & W edges. Probably expanded its population range and density in E & NE USA with post-settlement forest clearance and expanded scrub habitats; now likely contracting somewhat with forest maturation and mechanized agriculture. Known to suffer losses in fields and orchards treated with insecticides. Given title of the "official bird" for the state of Georgia.

(1994), Van Tyne (1946), Zink *et al.* (1999).



26. Long-billed Thrasher

Toxostoma longirostre

French: Moqueur à long bec **Spanish**: Cuitlacoche Piquilargo
German: Langschnabel-Spottdrossel

Taxonomy. [*Orpheus*] *longirostris* Lafresnaye, 1838, Mexico.
Forms a superspecies with *T. rufum* and *T. guttatum*, and the three sometimes considered conspecific. Race *sennetti* intergrades with nominate in S Tamaulipas (E Mexico). Two subspecies recognized.

Subspecies and Distribution.
T. l. sennetti (Ridgway, 1888) – S USA (SC Texas) and NE Mexico (S to E San Luis Potosí and Tamaulipas).
T. l. longirostre (Lafresnaye, 1838) – E Mexico (Querétaro, S Tamaulipas and Veracruz S to Puebla).

Descriptive notes. 26 cm; 61–89 g, average 68 g. Large, long-legged mimid with long tail, long, decurved bill. Nominate race is greyish-brown above, head somewhat mottled, cheeks greyish, richer brown on back and rump; wings rich brown, two white wingbars; tail plain rufous; throat white, dark malar stripe; whitish below, strongly streaked blackish; plumage brighter in autumn, when fresh; iris orange; bill black; legs brown. Differs from *T. rufum* mainly in being less rufous, more greyish, above. Sexes alike. Juvenile is similar to adult, but feathers buffy-edged above, wingbars buff, iris yellow. Race *sennetti* is slightly larger, with shorter bill, paler and more greyish than nominate, with narrower streaking on underparts and much of belly unstreaked. VOICE. Song, conspicuous in Mar–Jul, much less frequent at other times of year, of repeated rich, fluty to warbled phrases, much like that of *T. rufum* but possibly with less repetition of phrases; no mimicry reported. Calls include harsh "chuck", "tsuck" and "kleak" notes, loud, mellow "cheeoop" calls, also a "verss" call repeated vigorously at dawn and dusk.

Habitat. Dense shrubs, thorny thickets, low, brushy woodland and riparian woodland; to 1500 m.

Food and Feeding. Generalized omnivore, feeds on insects, e.g. grasshoppers and crickets (Orthoptera), beetles (Coleoptera), ants (Hymenoptera) and moths (Lepidoptera), and other arthropods, also gastropods, crustaceans, and berries. Forages largely on ground; searches for prey in leaf litter by vigorous bill-sweeping from side to side; scratches, pecks and probes under litter. Ascends bushes and low trees to take fruits and berries. Winter territory variable in size with habitat, 0·25–1·6 ha; vigorously defended, but unknown whether by individuals or pairs, excludes *T. rufum* and a variety of overwintering thrushes (Turdidae), but ignores *T. curvirostre* in same habitat.

Breeding. Peak of egg-laying Apr–May in Texas, May–Jun in Mexico; two broods likely. Monogamous; strongly territorial; territory size reported as 1·3–3 ha. Nest an open cup of thorny twigs, grass-lined, placed 1·2–2·4 m (average 1·6–1·7 m) above ground, typically in dense, thorny bush under shading trees. Clutch 3–4 eggs, occasionally 2 or 5, eggs thickly covered with fine brown spots on whitish background; incubation by both sexes, period 13–14 days; chicks fed by both parents, leave nest at 13 days, at which time run well but flight weak; young fed by parents for up to several weeks after leaving nest.

Movements. Resident, but winter territories not coincident with breeding territories; may undertake local movements in response to winter food availability.

Status and Conservation. Not globally threatened. Fairly common in most of range. Formerly abundant. Clearance of 95% of the brushland favoured by this species in lower Rio Grande Valley assumed to have had major impact on Texas population; similar loss of habitat has occurred in NE Mexico, presumably with similar negative results. Several large National Wildlife Refuges (Santa Ana, Lower Rio Grande Valley) may be key to S Texas conservation efforts.

Bibliography. Anon. (1998b), Baicich & Harrison (1997), Bent (1948), Blake (1953), Brewer (2001), Fischer (1978, 1979a, 1979b, 1980, 1981a, 1983), Hellmayr (1934), Howell & Webb (1995), Kaufman (1996a), Kingery (1993), Murphy & Fleischer (1986), Oberholser (1974), Price *et al.* (1995), Stotz *et al.* (1996), Sutton & Pettingill (1942), Tweit (1997), Urban (1959), Zink *et al.* (1999).

27. Cozumel Thrasher

Toxostoma guttatum

French: Moqueur de Cozumel **German**: Cozumelspottdrossel **Spanish**: Cuitlacoche de Cozumel

Taxonomy. *Harporhynchus guttatus* Ridgway, 1885, Cozumel Island, Quintana Roo, Mexico.
Forms a superspecies with *T. rufum* and *T. longirostre*, and the three sometimes considered conspecific. Monotypic.

Distribution. Cozumel I, off NE Yucatán Peninsula (Mexico).

Descriptive notes. 21·5–24 cm; 49–60 g, average 52·8 g. Large, long-tailed mimid with fairly long, decurved bill. Plumage is rufous-brown above, cheeks greyish, pale supercilium, wings with two whitish wingbars, tail rufous; throat white, dark malar stripe; underparts whitish, strongly streaked black, spots largest on flanks; belly and crissum white to buffy; iris amber; bill blackish; legs dark brown. Distinguished from similar *T. longirostre* mainly by considerably smaller size (more than 20% by weight). Sexes similar. Juvenile undescribed. VOICE. Song rich, varied warbled and scratchy phrases, reportedly much like that of *T. longirostre*; relatively little repetition of phrases within song bouts.

Habitat. Dense, scrubby and thorny woodland, also semi-deciduous and deciduous forest; lowlands.

Food and Feeding. No detailed information; probably a generalized omnivore like related *T. rufum* and *T. longirostre*. Skulks on or near ground.

Breeding. Season May–Jul. No other information.

Movements. Resident.

Status and Conservation. CRITICAL. Restricted-range species: present in Cozumel Island EBA. Very rare, with very few recent sightings. Formerly common to abundant, with population of up 10,000 individuals estimated in mid-20th century. Numbers drastically reduced following a very severe hurricane in 1988, and only three individuals found (all mist-netted) during ensuing seven years; after another damaging hurricane, in 1995, this species not recorded at all in annual surveys, and feared extinct by some. In Jun 2004, however, a single individual was discovered, the first for almost nine years. Although the two hurricanes assumed responsible for the species' demise, Cozumel I must have suffered similar meteorological phenomena at relatively frequent intervals prior to 1988; it could be expected to have evolved means of surviving the huge damage wrought by such events. Was earlier reported as inhabiting scrubby woodland and dense undergrowth, and edges of tropical forest, but the three individuals found in 1994 and 1995 were well away from scrub (two in deciduous forest, one in semi-deciduous forest). Thorough investigation of this species' ecology may help to provide further explanation for its exceedingly rapid decline. It is probably the mimid at greatest risk of imminent extinction.

Bibliography. Anon. (1998b, 2004c, 2004d), Blake (1953), Brewer (2001), Ceballos & Valdelamar (2000), Hellmayr (1934), Howell (1999), Howell & Webb (1995), Johnson (1988), Klaas (1968), Macouzet & Escalante (2001), Martínez (2004), Paynter (1955), Stattersfield & Capper (2000), Stotz *et al.* (1996), Zink *et al.* (1999).

28. Grey Thrasher

Toxostoma cinereum

French: Moqueur gris **German**: Grauspottdrossel **Spanish**: Cuitlacoche Ceniciento
Other common names: San Lucas Thrasher (*cinereum*)

Taxonomy. *Harporhynchus cinereus* Xántus de Vesey, 1860, Cape San Lucas, Baja California, Mexico.
Thought most closely related to, and forming a superspecies with, *T. bendirei*. Two subspecies recognized.

Subspecies and Distribution.
T. c. mearnsi (Anthony, 1895) – NW & C Baja California (S from c. 31° N and, in E, from 28·5° N), in NW Mexico.
T. c. cinereum (Xántus de Vesey, 1860) – C & S Baja California, including islands off SE coast (San José, Cerralvo).

Descriptive notes. 24–26·5 cm; 59–70 g, male average 63·9 g, female average 54·4 g. Large, greyish thrasher with longish, decurved bill. Nominate race is ashy grey-brown above, side of head browner and mottled, lower back, rump, wings and tail tinged richer brown; upperwing-coverts edged whitish (two narrow wingbars), outer three rectrices with whitish tips, conspicuous from below; throat and underparts whitish, buffier on flanks, dark brown spots on chest, breast and

sides, deltoid to elongated spots on lower side; lower belly buffy white, buffier crissum; plumage with warmer browns and buffs after late-summer moult; iris yellow; bill and legs blackish. Sexes similar in appearance. Juvenile is more rusty brown than adult, especially tips of wing and tail feathers, iris brown. Race *mearnsi* is darker, more rusty-coloured above, more heavily spotted below than nominate. VOICE. Song, usually from elevated perch, long series of bold, varied notes and phrases, each repeated two or more times, rather discontinuous and creaky, in quality reminiscent more of *T. curvirostre* song than that of more closely related *T. bendirei*. Calls a rolling "cheeerr-it" and stacatto "chek".

Habitat. Desert scrub, commonly in taller, more diverse vegetation with emergent trees and columnar cacti; in far S, common in tall thorn-scrub, open woodland, also at higher elevations in chaparral belt with scattered oaks (*Quercus*). Sea-level to c. 1000 m, locally to 1500 m.

Food and Feeding. Diet arthropods, cactus fruits (*Opuntia*, *Pereskiopsis*, *Wilcoxia*), likely also other fruits. Forages largely on ground in cover; excavates litter beneath shrubs; runs rapidly between foraging sites.

Breeding. Mar–Apr in NW coastal area (race *mearnsi*); Mar to mid-Jul, with young from early Apr, in S Cape region (nominate). Apparently monogamous, pairs show some site-fidelity; territorial; territory size c. 2–2·5 ha in thorn-woodland of Cape region and taller desert scrub elsewhere, as small as 1·5 ha in coastal scrub in NW. Nest a twiggy platform, with shallow cup lined with finer material, often placed in shrubby cholla cactus (*Opuntia*), usually at or below 1·5 m; sites more varied in S, including mesquite (*Prosopis*) or other thorny shrub, or small tree, average height above ground 3 m. Clutch size 2–3, occasionally 4, average lower in S (nominate race), eggs pale greenish-white to blue-green with dense purplish and dark to lighter brown spots; no information on incubation and fledging periods.

Movements. Resident.

Status and Conservation. Not globally threatened. Relatively common in suitable habitat throughout range, including on two largest islands in S Sea of Cortés (San José, Cerralvo). Habitat clearance in coastal strip of NW peninsula has been dramatic in last two decades; effects of this, if any, on this species not known.

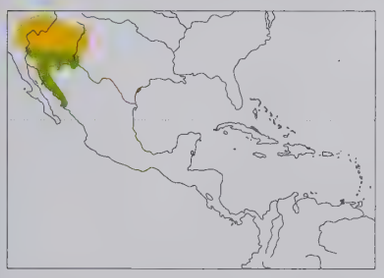
Bibliography. Anon. (1998b), Bancroft (1930), Bent (1948), Blake (1953), Brewer (2001), Brewster (1902), Cody & Velarde (2002), Dunn & Garrett (1984), Grinnell (1928b), Hellmayr (1934), Howell & Webb (1995), Short & Banks (1965), Stotz *et al.* (1996), Wilbur (1987), Zink *et al.* (1999).

29. Bendire's Thrasher

Toxostoma bendirei

French: Moqueur de Bendire **German**: Kaktusspottdrossel **Spanish**: Cuitlacoche Piquicorto

Taxonomy. *Harporhynchus Bendirei* Coues, 1873, Tucson, Arizona, USA.



Thought most closely related to, and forming a superspecies with, *T. cinereum*. Validity of races has been questioned, as these based on plumage differences that may have a seasonal component (through wear). Three subspecies currently recognized.

Subspecies and Distribution.

T. b. bendirei (Coues, 1873) – breeds SE USA (S from SE California, S Nevada, S Utah and S Colorado) S to NW Mexico (N Sonora).

T. b. candidum van Rossem, 1942 – WC Sonora (Mexico).

T. b. rubricatum van Rossem, 1942 – interior S Sonora.

Descriptive notes. 23–25 cm; 60 g. Largish, long-tailed, long-legged mimid with rounded wings, bill slightly decurved and relatively short for genus. Nominate race is drab olive-brown above, ear-coverts paler and lightly streaked, wings and tail slightly darker than back, white markings on corners of outer retrices (more visible from below); throat whitish; underparts whitish-grey, tinged light brown, lightly marked with olive-brown spots, flanks and crissum buff; iris yellow; bill neutral grey, pale horn-coloured base; legs neutral grey. Sexes alike. Juvenile is similar to adult, but upperparts and wing and tail feathers fringed cinnamon-rufous. Race *candidum* is paler, ashy brown, above and whiter below than nominate; *rubricatum* is darker, more reddish, above, larger spots on breast. VOICE. One of the finest songsters, if not the best, of genus; song a loud, near-continuous string of sweet, fluty, warbled varied phrases, each usually repeated 2–4 times before changed; distinguished from songs of congeners (e.g. *T. crissale*, *T. curvirostre*, *T. lecontei*) by its sweet, melodious continuity and lack of harsh or strident notes, song continuity more like that of *Oreoscoptes montanus*; no mimicry reported. Calls single or repeated "chek" or "chup-chup-chup" notes; also a rising "shreee".

Habitat. Open desert scrub with scattered, taller trees, as in sagebrush (*Artemisia*) with scattered juniper (*Juniperus*), Mojave scrub with scattered Joshua trees (*Yucca brevifolia*); avoids denser vegetation in woodland and desert washes. Sea-level and lowlands; up to 1800 m in N of range (Utah).

Food and Feeding. Generalized omnivore; feeds on insects and other arthropods, and seeds and berries. Insects in diet include grasshoppers (Orthoptera), beetles (Coleoptera), ants (Hymenoptera), termites (Isoptera), lepidopteran larvae. Forages largely on ground; searches in ground litter by digging, probing with the bill; excavates hidden prey with bill. Berries taken from low bushes.

Breeding. Egg-laying in USA from late Mar–Apr in California, earlier in Arizona; two broods typical in S of range, possibly single-brooded in N. Monogamous; strongly territorial; territory 5–10 ha, and thus appears to be larger than in *T. curvirostre* and *T. lecontei*. Nest a twiggy but neat grass-lined open cup, less bulky than those of congeners, placed typically 1–1·5 m above ground in dense, often thorny shrub. Clutch 3 eggs, occasionally 4, speckled or blotched on white to pale blue-green background; no information on incubation period; chicks fed by both parents, nestling period c. 12 days.

Movements. Resident in S. Short-distance migrant in N, wintering within S half of breeding range, from S Arizona and New Mexico (USA) S in Mexico to Sonora; leaves breeding sites in California (Mojave Desert) in late Jul and early Aug, returning mid-Mar to May.

Status and Conservation. Not globally threatened. Rather uncommon; locally fairly common in Mexico. Opinions on present status equivocal; may benefit from overgrazing, which favours expansion of junipers, but other habitat alteration in desert habitats likely detrimental to the species. May be negatively affected by off-road vehicle traffic, suburban spread around desert cities such as Hermosillo (Sonora), and Phoenix and Tucson (Arizona), and certainly by large-scale mechanized agriculture, as in Gila Valley (Arizona). Currently listed as a "species of special concern" in California.

Bibliography. Ambrose (1963), Anon. (1998b), Baicich & Harrison (1997), Bent (1948), Brown (1901), Darling (1970), DeGraaf & Rappole (1995), Dunn & Garrett (1984), Emlen (1974), Engels (1940), England & Laudenslayer (1989a, 1989b, 1993), Gilman (1909, 1915), Hellmayr (1934), Howell & Webb (1995), Hubbard (1973), Kaufman (1996a), Kaufman & Bowers (1990), Laudenslayer *et al.* (1992), Mills (1992), Murphy & Fleischer (1986), Pierce (1921), Price *et al.* (1995), Reeves (1997), Righter (1997), Root (1988), Rosenberg *et al.* (1991), Small (1994), Stotz *et al.* (1996), Zink *et al.* (1999).

30. Ocellated Thrasher

Toxostoma ocellatum

French: Moqueur ocellé **German**: Tropfenspottdrossel **Spanish**: Cuitlacoche Ocelado

Taxonomy. *Harporhynchus ocellatus* P. L. Sclater, 1862, Oaxaca, SW Mexico.

Perhaps most closely related to, and forming a superspecies with, *T. curvirostre*; both similarly close to the *T. rufum* superspecies. Monotypic.

Distribution. SC Mexico, from Guanajuato S to near Isthmus of Tehuantepec (Oaxaca).

Descriptive notes. 26·5–29·5 cm; 77·7–88·9 g, average 84·3 g. Large, boldly marked thrasher with longish, decurved bill. Has pale supercilium, greyish-brown crown and upperparts, dark brown wings, rump and tail; upperwing-coverts pale-tipped (two narrow wingbars), outer rectrices tipped pale; throat white, obscure dark malar stripe; underparts whitish to pale buff, breast, belly and flanks boldly spotted black; iris dark reddish-brown to dark amber; bill and legs blackish-grey. Sexes similar, female slightly smaller than male. Juvenile has wing and tail markings buffier, underparts less distinctly spotted. VOICE. Song, from exposed brush-top perch (but drops to ground when approached), a long, discontinuous series of varied notes and phrases, with some repetition; similar in pace to that of *T. cinereum*, more brisk than songs of *T. redivivum* and *T. crissale*. Typical call a smacking "check" note.

Habitat. Scrub, woodland edge, understorey scrub in open pine–oak (*Pinus–Quercus*) woodland, scrub–oak (e.g. México, 2300 m). In Oaxaca, found in dense, chaparral-like brush at 1400 m, extending upslope to 2000 m in brushy gulleys and understorey in oak woodland. Highlands from 1400 m, locally to 3000 m. At higher elevations and in less open habitats than *T. curvirostre*.

Food and Feeding. No details on diet; probably ground and leaf-litter arthropods. Forages largely on ground in dense cover. Rather elusive, difficult to observe.

Breeding. Little information available. Nest bulky, of twigs and grass, located low in dense cover. Clutch 2 eggs, greenish-blue, spotted and daubed with reddish and brown markings.

Movements. Apparently resident on or near territory; observed in same locations in Oaxaca from Mar to Sept.

Status and Conservation. Not globally threatened. Uncommon throughout range; rare in S (Oaxaca); possibly overlooked owing to its retiring habits and difficulty of observation. Reasonably predictable in appropriate habitat.

Bibliography. Anon. (1998b), Binford (1989), Blake (1953), Brewer (2001), Forcey (2002), Hellmayr (1934), Howell (1999), Howell & Webb (1995), Hunn *et al.* (2001), Rojas-Soto *et al.* (2001), Stotz *et al.* (1996), Zink *et al.* (1999).

31. Curve-billed Thrasher

Toxostoma curvirostre

French: Moqueur à bec courbe **Spanish**: Cuitlacoche Piquicurvo
German: Krummschnabel-Spottdrossel

Taxonomy. *Orpheus curvirostris* Swainson, 1827, Tableland of Mexico.

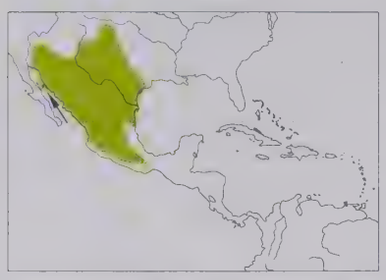
Perhaps most closely related to, and forming a superspecies with, *T. ocellatum*; both similarly close to the *T. rufum* superspecies. Races form two groups, E "nominate group" (also including *celsum* and *oberholseri*) and smaller and less distinctly marked taxa in W "*palmeri* group" (also including *maculatum*, *occidentale* and *insularum*); groups intergrade somewhat in SW USA (Arizona). Recent genetic studies suggest that the two groups may represent separate species. Several races (e.g. *insulararum*, *celsum*) poorly differentiated, perhaps not distinguishable. Seven subspecies currently recognized.

Subspecies and Distribution.

T. c. palmeri (Coues, 1872) – SW USA (SW & C Arizona) S to NW Mexico (S to C Sonora).

T. c. insularum van Rossem, 1930 – Tiburón I and San Estebán I, in Gulf of California off C Sonora coast (NW Mexico).

T. c. maculatum (Nelson, 1900) – NW Mexico (S Sonora, N Sinaloa, SW Chihuahua).



T. c. occidentale (Ridgway, 1882) – WC Mexico (Sinaloa S to Jalisco).

T. c. curvirostre (Swainson, 1827) – C & SC Mexico (S to Puebla and Oaxaca).

T. c. celsum R. T. Moore, 1941 – S USA (SE Colorado, SW Kansas and extreme NW Oklahoma S to SE Arizona, New Mexico and W Texas) and NC Mexico (S to Zacatecas).

T. c. oberholseri Law, 1928 – S Texas S to NE Mexico (S to SC Tamaulipas).

Descriptive notes. 25·5–28 cm; 67–90·5 g, average 79·4 g. Largish, grey-brown long-tailed desert thrasher with long, moderately decurved bill. Nominate race is light greyish-brown above, upperwing-coverts tipped paler (two inconspicuous wingbars); wings and tail browner, inconspicuous light tips on outer rectrices; chin and throat whitish, indistinct brownish malar stripe; breast buffy white, mottled with dusky brown, flanks and crissum cinnamon-buff; iris red or orange to yellow, with orange outer ring; bill blackish-brown; legs dark brown. Differs from *T. bendirei* in longer, more curved bill, and spots on breast larger, more rounded and less well defined. Sexes similar, female slightly smaller than male (c. 6% by weight in race *palmeri*). Juvenile is similar to adult, but rather less distinct wing and tail markings. Races differ mainly in size, and in conspicuousness of markings, W ones smaller and less well marked: *celsum* is very like nominate, but slightly larger, more buff below, tail tips whiter; *oberholseri* is more slaty above, with shorter

wings and tail; *palmeri* is smaller, more uniform below, less distinctly spotted, less white on tail; *insularum* is paler and greyer than previous, with better-defined spotting on breast; *occidentale* is larger, browner above, longer-tailed; *maculatum* is smaller and darker than last. Voice. Song a long series of varied phrases with distinct pauses; less continuous, more disconnected and harsher than songs of *T. bendirei* or *T. lecontei*, but faster and less harsh (fewer guttural notes) than more deliberate songs of *T. crissale* and *T. redivivum*. Call note a bright, sharp and emphatic "whit-whit"; other calls include scolding "chrrr", a "chuck-chuck" chatter. E "nominate group" of races known to mimic Scissor-tailed Flycatcher (*Tyrannus forficatus*) and Northern Cardinal (*Cardinalis cardinalis*) in Texas; no mimicry reported from W "*palmeri* group".

Habitat. Open desert with emergent trees and columnar cacti in Sonoran Desert, also lower scrubland in Chihuahuan Desert, bordering mesquite (*Prosopis*), acacia (*Acacia*) thorn-scrub, and taller, open woodland. Occupies lowest vegetation (c. 1 m tall) in Chihuahuan intermontane region, and tallest (6–8 m) in C Mexican thorn-scrub and deciduous woodland edge. Also well-vegetated gardens.

Food and Feeding. Diet insects, especially beetles (Coleoptera), and other arthropods, also flowers and fruits of various shrubs; cactus fruits important item in diet. Nestling diet insects, some fruit. Forages on ground in open, as well as under shrubs; digs energetically with the bill in accumulated litter, excavates shallow holes, displaces vegetable material with vigorous bill flicks. Ascends vegetation to exploit flowers and fruits.

Breeding. Breeds Feb to early Aug, season may shift later with sparse winter rainfall; two broods usual. Monogamous. Territorial, remains in territory throughout year, likely over successive years if both partners survive; other thrashers (*T. bendirei*, *T. crissale*, *T. lecontei*, *T. longirostre*) tolerated in territory, but some agonistic interactions around nest-site; territory size 2–4·5 ha. Nest a twiggy cup lined with finer material, placed 1–2 m above ground in shrub, preferably in cholla cactus (*Opuntia*) where available; same shrub, and often old nest, utilized in successive broods and years. Clutch size 2–4, average higher in Texas brushland (3·8) than in Sonoran Desert (3·2 in SE Arizona, 2·8 in N Mexico); eggs bluish-green, densely spotted with reddish-brown; incubation by both sexes, predominantly by female, period 12–15 days, usually 14 days; hatching asynchronous, brood reduced in times of low food availability; chicks fed by both parents, more by female, nestling period c. 15 days; young independent and capable of strong flight after 40 days; male may continue to feed fledglings of first brood after female begins second clutch.

Movements. Resident; some local population shifts may occur, probably dependent on habitat and food availability.

Status and Conservation. Not globally threatened. Widespread and common. Main threat is loss of habitat through clearing for agriculture or suburban development, although this species is reasonably tolerant of well-vegetated gardens in suburbia. Degradation of desert vegetation by all-terrain vehicles (ATVs) also an adverse factor.

32. Le Conte's Thrasher

Toxostoma lecontei

French: Moqueur de Le Conte **German**: Wüstenspottdrossel **Spanish**: Cuitlacoche Pálido

Taxonomy. *Toxostoma Le Contei* Lawrence, 1851, Fort Yuma, Arizona, USA.

Closely related to *T. redivivum* and *T. crissale*, and possibly part of same superspecies. Has been suggested that race *arenicola* is a separate species. Proposed race *macmillanorum* (San Joaquin Valley, in California) exhibits only minor plumage differences (e.g. crown darker, flanks lighter) from similarly sized nominate; considered better merged with latter. Two subspecies currently recognized.

Subspecies and Distribution.

T. l. lecontei Lawrence, 1851 – SW USA (SC & SE California E to SW Utah and SC Arizona), S to NW Mexico (NE Baja California, NW Sonora).

T. l. arenicola (Anthony, 1897) – W coast of C Baja California.

Descriptive notes. 24–28 cm; 54·5–75·5 g, average 61·9 g. Smallest of the mainland *Toxostoma* thrashers, with short, rounded wings, long dark tail, long and decurved bill. Has dark-speckled lores, uniform plain grey crown and upperparts, browner uppertail-coverts, wings darker than back; contrasting blackish tail, outer feathers pale-tipped; chin and throat white, submoustachial stripe finely speckled brownish, malar stripe dusky brown; underparts plain brownish-grey, belly buff, contrasting crissum deeper buff; plumage browner after late-summer moult; iris deep chestnut-brown; bill black; legs very dark horn-coloured. Differs from *T. redivivum* and *T. crissale* in smaller size, much greyer plumage. Sexes alike. Juvenile is paler, buffier than adult, legs paler, bill shorter (adult length after 6–7 weeks). Race *arenicola* is darker and shorter-tailed than nominate. Voice. Song a long series of closely connected phrases with some repetition, but great variety; higher-pitched, less deliberate, more continuous than that of *T. curvirostre* and, especially, *T. crissale*, less melodious than that of *T. bendirei*. Female sings occasionally. Typical call an upslurred "chreeep" or "chureep"; distress call a rolling "brrt-wrrt".

Habitat. Low and open desert scrub dominated by shrubby cholla cacti (*Opuntia*) less than 2 m tall, yuccas (*Yucca*), and wide variety of other shrubs no more than c 1 m in height; habitat in Sonoran Desert (SW Arizona, NW Sonora, NE Baja California) has scattered taller trees and cacti. In WC Baja California (race *arenicola*) occupies coastal plains of low, knee-high scattered shrubs, similar to habitat utilized in USA by nominate in San Joaquin Valley (SC California).

Food and Feeding. Food mainly insects, including beetles (Coleoptera), grasshoppers (Orthoptera) and ants (Hymenoptera); also other arthropods, e.g. spiders (Araneae) and scorpions (Scorpiones). Diet may contain up to 10% plant material, chiefly small seeds found at or near ground level, of annuals or fallen seeds from shrubs. Nestling diet initially small arthropods, later larger ones. Feeds mostly on ground arthropods in litter around and under desert shrubs. Forages by vigorous deployment of bill, excavating in litter beneath shrubs, flicking aside fallen plant material in search of items.

Breeding. Breeds in desert spring, Mar–May, earlier in Colorado Valley; likely two broods over most of range, possibly single-brooded in N areas of Mojave Desert. Monogamous. Strongly territorial, occupies same area, if not same specific territory, in successive years, but territoriality relaxed after breeding completed; often near territories of congeners but no interspecific interactions recorded, mild agonistic interactions with *Mimus polyglottos* reported; territory 4–10 ha. Nest built by both sexes, an outer shell of stout twigs lined with finer fibres, rootlets, grasses, placed in dense shrub, normally 1–1·5 m high in Mojave Desert, where shrubby diamond cholla (*Opuntia ramosissima*) preferred. Clutch 2–5 eggs, average 3·3, clutch size significantly larger in mid-season, also in Mojave Desert and San Joaquin Valley; eggs greenish-blue with brown to purplish spots and blotches, often heavier at large end, occasionally unmarked; incubation by both sexes, predominantly by female, period 14–19 days (average 15·8 days); chicks fed by both parents, predominantly by male, nestling period c. 15 days, may be extended during inclement weather; young fed by parents, especially male, for 2 weeks or more after leaving nest, but become more active foragers and dig for own food after 1 week; juveniles may associate and roost together in vicinity of natal territory until end of summer.

Movements. Resident on or near territory throughout year; young disperse locally over a few km.

Status and Conservation. Not globally threatened. Not common anywhere in range. Rather low densities, several pairs/km² in good habitat. Numbers reduced through agricultural development in larger river valleys, as in Arizona (Gila Valley, Salt Valley) and California (valleys of Imperial, Coachella and San Joaquin); also by suburban development around desert cities, and by habitat degradation through clearing, grazing, and activity of all-terrain vehicles (ATVs). In USA, designated a "species of special concern" in California; currently considered a candidate species for "Endangered" or "Threatened" status by USFWS.

Bibliography. Anon. (1998b), Baicich & Harrison (1997), Bent (1948), Engels (1940), Gilman (1904, 1909, 1915), Grinnell (1933), Hanna (1933b), Hellmayr (1934), Howell & Webb (1995), Hubbard (1973), Kaufman (1996a, 2003), Laudenslayer *et al.* (1992), Murphy & Fleischer (1986), Pemberton (1916), Price *et al.* (1995), Sheppard (1970, 1973, 1996), Small (1994), Stotz *et al.* (1996), Zink, Blackwell-Rago & Rojas-Soto (1997), Zink, Dittman *et al.* (1999).

33. California Thrasher

Toxostoma redivivum

French: Moqueur de Californie **Spanish**: Cuitlacoche Californiano
German: Kalifornienspottdrossel

Taxonomy. *Harpes rediviva* Gambel, 1845, Monterey, California, USA.

Forms a superspecies with *T. crissale*, possibly also including *T. lecontei*. Two subspecies recognized.

Subspecies and Distribution.

T. r. sonomae Grinnell, 1915 – SW USA (N California).

T. r. redivivum (Gambel, 1845) – S California and NW Mexico (NW Baja California).

Descriptive notes. 28–32 cm; 78–93 g, average 84·4 g. Largest member of genus; plain and brownish with long legs, long, downcurved bill. Nominate race has buffy-brown head with lighter flecks at side, distinct greyish-buff supercilium; upperparts deep greyish-brown, richer brownish-olive on uppertail-coverts and tail; upperwing-coverts and primaries margined greyish-brown; chin and throat greyish-white to buff, indistinct thin brownish-olive malar stripe; greyish below, darker on flanks, breast creamy to cinnamon-buff or buffy grey, often buffier on central breast, belly creamy to cinnamon-buff becoming deeper tawny-brown on crissum, and duller buff to greyish-brown on flanks, darker towards rear; plumage duller before late-summer moult; iris brown; bill black; legs brown to blackish. Distinguished from *T. crissale* by slightly larger size, pale supercilium, less dark crissum. Sexes alike. Juvenile is similar to adult but duller, with fewer contrasts, breast more brown than cream, crissum less tawny, face unflecked. Race *sonomae* is somewhat larger, browner above and darker-bellied than nominate. Voice. Bold, bright, exuberant series of harsh and varied, mellower phrases, given singly or repeated two or more times, in steady measured but disjointed cadence. Fine mimic of many other species that share habitat. Typical call a loud, ringing and far-carrying "churreep"; also softer "shtupp" call and harsh "chack" or "chock" alarm.

Habitat. Typical habitat chaparral; extends at lower densities to adjacent coastal areas of sagebrush (*Artemisia*) scrub, oak (*Quercus*) woodland with scrubby undergrowth, and on inland foothill slopes to desert edge in scrubby juniper (*Juniperus*), piñon pine (*Pinus*) and Joshua tree (*Yucca brevifolia*) woodlands.

Food and Feeding. Feeds on large arthropods throughout year, nearly exclusively so in breeding season; depends heavily on fruits, mostly small and soft, late summer to late winter. Arthropods include ground-litter insects, especially beetles (Coleoptera), crickets (Orthoptera), hymenopterans (including ants) and lepidopteran larvae and pupae, also spiders (Araneae), millipedes (Diplopoda), isopods. Fruits taken from many chaparral shrubs, include those of poison-oak (*Rhus*) and elderberry (*Sambucus*), and of several other shrubs in families Rosaceae, Rhamnaceae and Solanaceae; occasionally larger, tougher fruits, such as acorns and walnuts (*Juglans*), opened by persistent hammering with the bill. Arthropods taken on ground, usually under cover of shrubs in deep leaf litter and debris; found by vigorously sweeping bill from side to side to displace litter, and by digging with bill in and under fallen branches and around trunk boles; runs swiftly, either between foraging sites or for cover. Sometimes raids gardens for domestic grapes, pomegranates, figs (*Ficus*), citrus, cactus fruits, or seeds at birdfeeders.

Breeding. Breeds early, from Feb–Mar, but earlier records reported, to at least mid-Jul; two broods. Monogamous. Strongly territorial throughout year, territories looser in late summer to autumn; both sexes share nearly equally in territory defence, aggressive toward nest predators such as West-

ern Scrub-jay (*Aphelocoma californica*) and Common Raven (*Corvus corax*), also towards potential competitors such as *Mimus polyglottos*; territory c. 1–2 ha in prime habitat, to 5 ha or more in marginal habitat (e.g. coastal sagebrush, piñon–oak–juniper woodland). Nest built by both sexes, a bulky platform of twigs, with cup lined with fine roots, grasses, dried forbs or other fibres, generally 1·5–3 m above ground in dense shrub. Clutch size 3–4, second clutches significantly larger (by average 0·29 eggs), eggs pale blue, variously dotted and blotched with fuscous to buff-brown to greyish markings, usually over most of surface, rarely unspotted; incubation by both sexes, period 14 days or slightly shorter; chicks fed by both parents; young leave nest after 14–17 days, capable of weak flight only, remain on territory and fed by parents for several weeks more; second clutch started often before young of first brood gain independence.

Movements. Resident; limited dispersal of young within a few km of natal site.

Status and Conservation. Not globally threatened. Restricted-range species: present in California EBA. Uncommon to locally common. Historically, suffered to some degree from use of pesticides in orchard and garden crops; loss of habitat, to agriculture or suburban development, a more significant factor. Predictably common in undisturbed, contiguous chaparral habitat, but disappears in fragments of less than 10 ha in extent. Preservation of habitat fragments with size greater than 20 ha should ensure persistence of the species.

Bibliography. Anon. (1998b), Baicich & Harrison (1997), Bent (1948), Bolger *et al.* (1991), Cody (1998), Cody & Mooney (1978), Davis (1952), Engels (1935, 1940), Grinnell (1917), Hanna (1936), Hellmayr (1934), Howell & Webb (1995), Kaufman (1996a, 2003), Laudenslayer *et al.* (1992), Murphy & Fleischer (1986), Oberholser (1918), Price *et al.* (1995), Root (1988), Sargent (1940), Sgariglia & Burns (2003), Small (1994), Stotz *et al.* (1996), Woods (1939), Zink *et al.* (1999).

34. Crissal Thrasher

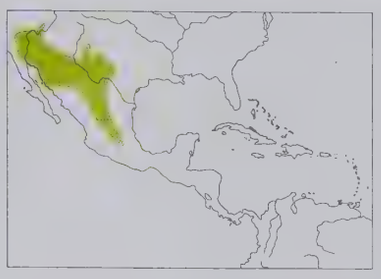
Toxostoma crissale

French: Moqueur cul-roux **German**: Rotsteiß-Spottdrossel **Spanish**: Cuitlacoche Culirrojo

Taxonomy. *Toxostoma crissalis* Henry, 1858, New Mexico, USA.

Specific name previously given as *dorsale*, but that apparently a printer's error in original description; now suppressed in favour of present name, which was the one intended by describer. Forms a superspecies with *T. redivivum*, possibly also including *T. lecontei*. Races intergrade. Four subspecies recognized.

Subspecies and Distribution.



T. c. coloradense van Rossem, 1946 – extreme SW USA (lower R Colorado in SE California and SW Arizona) S to NW Mexico (extreme NE Baja California, NW Sonora).

T. c. crissale Henry, 1858 – SW USA (SW Utah S to SE California and S Arizona, also New Mexico and W Texas) S to NC Mexico (S to WC Coahuila).

T. c. trinitatis Grinnell, 1927 – Valle de Trindad (NE Baja California) in NW Mexico.

T. c. dumosum R. T. Moore, 1941 – C Mexico (E Durango and S Coahuila S to Hidalgo).

Descriptive notes. 26·5–30·5 cm; 61–75 g, average 63 g. Large greyish mimid with long tail, long legs, long and strongly downcurved bill. Nominate race has blackish lores, contrasting white submoustachial stripe; greyish-brown above, cheeks and ear-coverts buffy brown, flecked whitish, wings and tail somewhat darker than back, tips of outer retrices paler buffy brown (more visible from below); throat and chin whitish, contrasting blackish malar stripe; underparts similar in colour to upperparts but paler, crissum rich chestnut-brown (rather conspicuous); plumage brighter after late-summer moult; iris brown to straw-coloured; bill and legs blackish. Distinguished from similar *T. redivivum* by head pattern and underpart coloration. Sexes alike, female on average

slightly smaller than male. Juvenile is generally paler, duller, more rusty brown on wing-coverts and tail-coverts, iris initially grey. Races differ slightly in size and plumage tone: *trinitatis* is darker than nominate, greyer above and below, wing and tail darker; *coloradense* is paler than nominate above and below, slightly larger; *dumosum* is smaller than nominate, and much darker, especially on crissum. Voice. Song a sweet, strong, melodious, near-continuous string of varied phrases, with relatively little repetition; smoother and less discontinuous, and with fewer staccatto notes, than that of *T. redivivum*; rarely mimics other species. Call note distinctive, far-reaching "choit" or doubled "choidle-choit".

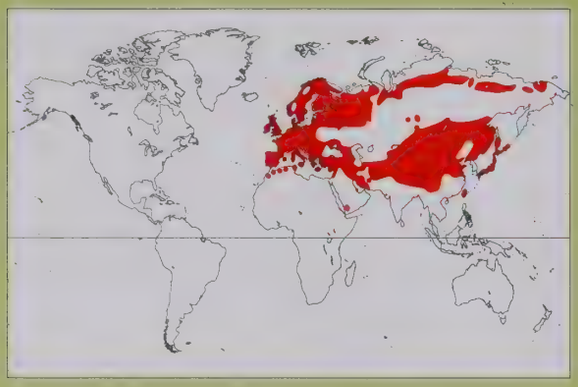
Habitat. Inhabits dense, low scrubby vegetation in desert washes and drainage channels; scrubby mesquite–juniper (*Prosopis–Juniperus*) brush in foothills adjacent to desert lowlands; scrub understorey of open pine–oak (*Pinus–Quercus*) woodland. From near sea-level up to 2500 m; mostly in uplands.

Food and Feeding. Largely insectivorous; minor amounts of seeds and berries taken outside breeding season. Insect prey mainly beetles (Coleoptera), ants (Hymenoptera), crickets and grasshoppers (Orthoptera), lepidopteran and dipteran larvae. Feeds on ground; forages for insects under bushes, rarely in open; searches leaf litter displaced by sweeping bill from side to side; digs, picks and probes with bill. Fruits and berries taken from low bushes such as boxthorns (Rhamnaceae) and sumacs (Anacardiaceae).

Breeding. Egg-laying from Feb–Mar in lower deserts, Apr in higher deserts; two broods typical in Sonoran Desert, likely single-brooded in N range (Mojave Desert). Monogamous. Strongly territorial throughout year, territory may overlap or abut those of congeners (*T. lecontei*, *T. curvirostre*, *T. bendirei*) and of *Mimus*, but no interspecific interactions reported; territory generally in range 4–7 ha. Nest an open cup of twigs, lined with grass, rootlets and feathers, not bulky, placed typically c. 1 m above ground in dense shrub, higher (to 2·5 m) in taller mesquite vegetation; may be reused by same pair or by other species. Clutch 2–3 eggs, occasionally 1 or 4, glaucous blue to pale blue and unspotted (unlike those of congeners); incubation by both sexes, period reported as 14 days; chicks fed by both parents, leave nest after 11–16 days, legs then well developed but bill and wings short; fed by parents for several further weeks, may remain on parental territory until next breeding effort (up to 10 months).

Movements. Resident; some populations may make local post-breeding movements to lower elevations.

Status and Conservation. Not globally threatened. Nowhere common, but reliably found in preferred habitats; easily overlooked, calls often the only clue to its presence. May be negatively affected by grazing, off-road vehicle traffic, various desert developments; certainly by large-scale mechanized agriculture, as in Gila Valley (Arizona). May have been favoured by spread of alien salt-cedar in valleys of Colorado and Pecos (New Mexico–Texas). In USA, currently classified as a "species of special concern" in California.



Bibliography. Anderson *et al.* (1998), Anon. (1998b), Austin (1970), Baicich & Harrison (1997), Bent (1948), Cody (1999), Finch (1982), Gilman (1902, 1909, 1915), Hanna (1933a), Hellmayr (1934), Howell & Webb (1995), Hubbard (1973, 1976), Kaufman (1996a, 2003), Kozma & Matthews (1997), Kozma *et al.* (1999), Laudenslayer *et al.* (1992), Murphy & Fleischer (1986), Oberholser (1920b), Price *et al.* (1995), Root (1988), Rosenberg *et al.* (1991), Small (1994), Stott & Sams (1959), Stotz *et al.* (1996), Zink *et al.* (1999).

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family PRUNELLIDAE (ACCENTORS)

- Small, mainly terrestrial birds with pointed bill, compact body and horizontal posture; mostly dark grey or brown, usually streaked, above, paler below.
- 14·5–18 cm.

- Eurasia.
- Largely montane, mainly in alpine or subalpine zone above tree-line, or montane forest or scrub; one widespread species also in lowland scrub and gardens.
- 1 genus, 13 species, 36 taxa.
- No species threatened; none extinct since 1600.

Systematics

The members of the family Prunellidae are distributed across the Palearctic Region, from Iberia and north Africa east to Japan, the greatest concentration of species being found in the mountainous regions of Central Asia. The remote montane distributions of most accentors mean that they have received little attention from ornithologists, but studies of the two most accessible species have revealed extraordinary breeding biology (see Breeding) that belies their rather unspectacular appearance.

Taxonomy within the Prunellidae is relatively straightforward, because all 13 species are classified in a single genus, *Prunella*. Their affinity to other oscine passerine groups, however, has for long been regarded as problematic. Early classifications, in the late 1800s, placed the accentors variously among the Old World warblers (Sylviidae), the finches (Fringillidae), the thrushes (Turdidae) or even the tits (Paridae). In the first half of the twentieth century, anatomical affinities were also noted with Old World flycatchers (Muscicapidae), wagtails (*Motacilla*), mockingbirds (Mimidae), wrens (Troglodytidae), babblers (Timaliidae) and dippers (Cinclidae), among others. The position of this enigmatic group is still not fully resolved. The shape of the bill and the associated jaw musculature suggest an affinity with the thrushes, but other features, such as the scutellated tarsus and the syringeal musculature, differ from those of Turdidae. An affiliation to the finches and the buntings (Emberizidae) may be signalled by the possession of a crop, a muscular gizzard and an operculum over the nostril, but these similarities could be a consequence of convergent evolution, rather than of shared ancestry. Analysis of egg-white proteins suggests that the accentors are most closely related to the Sylviidae and the Muscicapidae, but this is contradicted by evidence from DNA–DNA hybridization of Dunnocks (*Prunella modularis*) with other oscine passerines. This phylogeny positions the accentors close to the sparrows (Passeridae), the weavers (Ploceidae), the waxbills (Estrildidae) and the wagtails and pipits (Motacillidae); together, these are grouped within a superfamily Fringilloidea.

The placing of all accentors in the one genus reflects the general uniformity in their structure and appearance. Nevertheless, there are some constant differences in appearance and habitat among groups of species. The Alpine Accentor (*Prunella collaris*) and the Altai Accentor (*Prunella himalayana*) are relatively large prunellids, 25–45 g in weight, that breed at high elevation, usually well above the tree-line, although they may descend to lower altitudes in winter. These two species were once thought to be sufficiently distinct as to warrant their own genus, *Laiscopus*, but all recent works have placed them in the genus *Prunella*. The "dunnock group", comprising the Dunnock, the Japanese Accentor (*Prunella rubida*) and the Maroon-backed Accentor (*Prunella immaculata*), are smaller, weighing about 20 g, have no strongly contrasting markings, and are usually found in scrub or forest habitats. The third group contains six species: the Siberian Accentor (*Prunella montanella*), the Black-throated Accentor (*Prunella atrogularis*), the Brown Accentor (*Prunella fulvescens*), the Mongolian Accentor (*Prunella koslowi*), Radde's Accentor (*Prunella ocularis*) and the Yemen Accentor (*Prunella fagani*). All are of similar size to the members of the "dunnock group", with a weight range of 17–22 g, and most have a pale supercilium and some dark markings around the crown, cheeks or throat. Radde's Accentor was once regarded as a subspecies of the Brown Accentor, and the Yemen Accentor as a subspecies of Radde's Accentor, but it is now generally agreed that each warrants full species status. These six prunellids inhabit mountainous regions from Yemen to China or are found at high latitudes along the northern limits of Siberian coniferous forest.

The two remaining members of the family, the Robin Accentor (*Prunella rubeculoides*) and the Rufous-breasted Accentor (*Prunella strophiata*), do not appear to have any close affinities, although the latter possesses the striking head pattern characteristic of the previous species group.

Morphological Aspects

The general morphology and appearance of accentors reflect their terrestrial habits and omnivorous diet. The body is compact, with a short neck, and the tail, comprising twelve feathers, is generally of moderate length, although the Alpine and Altai Accentors have a rather short tail. The legs are fairly short, and the usual gait is hopping or a shuffling walk, often with bent legs, giving the appearance of crouching. Accentors will also run over short distances, particularly when chasing prey. The tarsus is scutellated in front and smooth behind; the toes are strong, and the claw on the hind toe is the longest.

Many flights made by accentors are short, rapid and close to the ground, which is hardly surprising in view of the skulking, ground-dwelling habits of the family. Nevertheless, the flight is strong, and species such as the Alpine Accentor may undertake

long undulating flights, particularly when living in flocks outside the breeding season. The wing shape varies across species, from being short and rounded to being fairly long and pointed. In the case of such species as the Black-throated Accentor and the Dunnock, subspecies that are migratory have wings that tend to be more pointed than those of sedentary races.

The bill is adapted for gleaning insects and seeds from vegetation and the ground, and its peculiar morphology is the principal cause of the controversy over the systematic position of the family (see Systematics). It is of medium length and tapers to a point from a laterally wide base; the basal width is especially noticeable in the Altai and Alpine Accentors. The bill is brown or black, but in the two aforementioned species the basal portion is yellow, particularly on the lower mandible. The nostril is covered by an operculum and is free from feathering.

Accentors are predominantly brown or grey, with a variable amount of streaking, on the upper side. The underside is generally rather uniform in colour, although several species also have patches of rufous or ochre coloration, particularly on the breast and flanks; these feathers may have pale margins, producing an impression of scales. This cryptic coloration often makes accentors difficult to locate in their typical scrubby or rocky habitats. The patterning of the head and neck is the most striking feature of many members of the family. Altai and Alpine Accentors have a white chin and throat bordered by black dots, in the latter case with black speckling that can produce the appearance of barring. Several of the smaller prunellids have a prominent white or buff supercilium, contrasting with black or dark brown markings on the crown, ear-coverts or throat. Some of these species bear a close resemblance to each other, perhaps indicating recent divergence as a result of geographical isolation.

The sexes are very similar, and often indistinguishable in the field. This is despite the intense reproductive competition that exists among both sexes of at least two species (see Breeding), and which might have been expected to result in the evolution of sexually selected plumage dimorphism, as it has in many other avian taxa. The juvenile plumage is similar to that of adults, although the underparts are usually strongly streaked and any patterning of the head is less distinct.

A prominent morphological adaptation of at least two accentor species results from their extraordinary mating systems (see Breeding). In Dunnocks and Alpine Accentors, the cloacal structure of both sexes exhibits spectacular modification, in the case of the female for the advertising of fertility and in the male for the storage of sperm prior to insemination. The cloaca of the female Alpine Accentor appears unremarkable when the bird is at rest, but during the pre-copulatory display (see Breeding) she presents to males a partially everted, bright red, vascularized cloaca that can be easily seen by a human observer. Female Dunnocks have a similar display, although the colour of the cloaca is far less intense.

Male morphological adaptations for sperm competition are equally dramatic. Alpine Accentor testes constitute an astonishing 8% of the body weight during the breeding season. In passerines, prior to insemination, sperm are stored in the seminal glomera, adjacent to the cloaca, producing a cloacal protuberance that varies in size according to the level of sperm production. The Alpine Accentor, with a body length of some 18 cm, has a bulbous cloacal protuberance 16 mm in diameter, which is probably larger, in relation to body size, than that of any other bird species. The Dunnock's testes are also relatively large, about 3·4% of the body weight, 64% larger than expected for a bird of its size, and males of this species also have a large cloacal protuberance during the breeding season. As with so many other aspects of their biology, no information is available on the cloacal morphology of other members of the family.

Adult accentors have a single complete annual moult in the late summer or autumn, following the end of breeding. The moult of the Dunnock starts with the primary feathers and lasts for about two months. In the case of other accentors, limited evidence suggests a more rapid moult. This might be expected in view of the fact that these species generally live at higher altitude and are therefore likely to experience more severe time constraints on breeding and moulting prior to the onset of migration or adverse environmental conditions. Juveniles undergo a partial moult, including the head and body feathers, some wing-coverts and, in some species, the tertials and the tail feathers.

Habitat

The accentors occur almost exclusively within the Palearctic Region, where they are predominantly birds of montane zones at middle to high latitudes. The Alpine Accentor has the widest distribution within this region, occurring from western Europe and north Africa eastwards to as far as Japan. Since this species breeds in the alpine zone of mountains, at an approximate elevational range of 1800 m to 5000 m, its distribution is patchy, resulting in

The morphology of all thirteen species constituting the accentor family is homogenous enough to enable them to be combined in a single genus. Within this assemblage, however, several distinct subgroups can be identified. The largest of these, containing six species distributed from Yemen to Japan, is characterized by strong head-patterns, usually involving some combination of dark crown, cheeks and throat; the ***Siberian Accentor*** *is a classic example. At first glance, members of this group resemble some* Emberiza *buntings, but the bill is tapered from a broad base to a pointed tip, a feature unique to* Prunella.

[*Prunella montanella*, Isikawa, Japan. Photo: Hirozo Maki]

the evolution of many subspecies; nine are usually recognized. At the other extreme, the monotypic Yemen Accentor has a very restricted range, confined to the mountains of Yemen, in the south-west corner of the Arabian Peninsula. The Dunnock is the most catholic member of the family, being found in a variety of montane and lowland habitats from subarctic regions of Scandinavia and Russia southwards to the Mediterranean, and breeding from sea-level up to 2000 m and above. The ranges of many of the other species are poorly known. For example, the southern extension of the Siberian Accentor's breeding range, through southern Siberia to the Altai Mountains, could be continuous rather than patchy; further fieldwork in this rather difficult terrain is desirable. Information on the range of the Mongolian Accentor in Mongolia and north-central China is particularly sparse.

Broadly speaking, the Prunellidae can be grouped into those that breed mainly above the tree-line in the alpine/subalpine zones, or in barren montane regions with scrubby vegetation, and those that breed in thicker scrub and woodland below the tree-line. The first group consists of the Alpine, Altai, Robin, Rufous-breasted, Brown, Mongolian, Radde's and Yemen Accentors, while the Dunnock and the Siberian, Black-throated, Japanese and Maroon-backed Accentors belong to the second group. The Maroon-backed Accentor from the eastern Himalayas and China is unusual within the family in that it exhibits a preference for damp areas deep in coniferous forest.

The Dunnock is the only accentor that has expanded into lowland temperate habitats. In the northern and eastern parts of the its range, it is still found in the dense scrub habitats of alpine and arctic regions, where the species probably evolved. Elsewhere, however, Dunnocks are common birds of lowland woodland and farmland, and in parts of western Europe the extension has continued, making them one of the most abundant birds of parks and gardens. In Britain, this process of urbanization started at least 200 years ago, and perhaps much earlier. The only other prunellid species to breed at such low altitudes are the Siberian Accentor, which extends into subarctic taiga habitats, and the Alpine Accentor, which is reported as breeding on sea cliffs on the Russian coast of the Sea of Japan.

Non-breeding habitats occupied by the Prunellidae are less easily defined. As a result of the absence of dietary specialization within the family, and because of the capacity of its members to switch from a diet dominated by invertebrates to one dominated by seeds (see Food and Feeding), accentors are able to exploit a wide range of habitats. All species for which sufficient information is available exhibit some degree of altitudinal migration (see Movements), although the extent of these movements is very variable within species, in some cases depending on environmental conditions; species such as the Brown Accentor and the Altai Accentor show a remarkable ability to overwinter in their breeding habitat, despite the severity of the winter at such high altitudes. For most accentors, the seasonal movement to lower elevations takes them to more heavily vegetated habitats and often brings them into cultivated areas, where they are commonly associated with villages and livestock.

Adult accentors are monomorphic, such that it is usually impossible to differentiate between males and females in the field. Juveniles, in turn, tend to be muted versions of adults, usually more heavily streaked on the underparts and less distinctly marked on the head, features that often accentuate their bunting-like appearance. As yet, this juvenile ***Rufous-breasted Accentor*** *lacks the strong head pattern and broad rufous chestband that it will acquire at the next moult. The distinctive traits of adults are much reduced, making it a little more difficult to identify.*

General Habits

Accentors can be characterized as unobtrusive birds. They are exclusively diurnal, but their mode of foraging, their preference for remote, often scrubby habitats and their cryptic coloration render them rather inconspicuous members of the Palearctic avifauna. Testament to this is the fact that, although accentors do not fit the typical passerine model of monogamous pairs living on exclusive territories (see Breeding), it is only since the 1980s that the extraordinary breeding systems of even the most familiar prunellids have been described in reasonable detail. Indeed, for many accentor species, basic information about their behaviour and breeding biology is partially or entirely lacking.

Although the nests of accentors are generally dispersed, this does not necessarily reflect a strict territorial system. The extent of territoriality differs sharply between, at one extreme, the large overlapping ranges of Alpine Accentors and, at the other, the smaller and strongly defended territories of Dunnocks (see Breeding), and it is difficult therefore to draw any general picture or to speculate about the less well-studied species. Nevertheless, anecdotal observations of Altai Accentors, Robin Accentors and Brown Accentors suggest a territorial system reminiscent of that of Alpine Accentors, while observations of Black-throated and Japanese Accentors suggest a territorial system more akin to that of Dunnocks.

Outside the breeding season, most accentors form flocks, sometimes with other bird species. The Brown Accentor, the Alpine Accentor and the Altai Accentor are the most gregarious of the family, the last of those three gathering in flocks of 100 or more individuals. The remaining species either collect in small parties or are encountered singly or in pairs. Dunnocks are essentially solitary outside the breeding season, although they may form temporary feeding aggregations, in which males are dominant over females.

Sun-bathing is a frequent activity, at least of Alpine Accentors and Dunnocks. This often entails the opening and raising of one wing in a characteristic posture. Interestingly, this is reminiscent of the "wing-waving" display that is frequently seen in the breeding season during agonistic interactions among males or among females in contests over territories. Interactions at territory boundaries also include song-duels among males and a display in which the feathers are fluffed up and the bill pointed downwards.

No information is available on the roosting behaviour of most accentors, but details are known for the two most-studied species. Dunnocks roost, usually in twos, 1–2 m above the ground in dense bushes or hedges, whereas Alpine Accentors roost in rock crevices, and sometimes communally during the winter.

Voice

Accentors are vocal birds, often having surprisingly loud and melodious songs and calls. Their songs can be broadly described as warbles composed of trills combined with clear notes, and sometimes with whistles or buzzing sounds. Each song is usually rather short, but songs are often delivered in bouts from a prominent position on the ground or in a bush or tree. Some species also sing in flight. One of the more remarkable features of the family is that, in the case of the Alpine Accentor and the Dunnock, the two species that have been studied in any detail, females produce complex songs of the type that is usually asso-

*The **Alpine Accentor** and Altai Accentor* (Prunella himalayana) *form a closely related species pair, distinguished from the rest of the genus by a suite of features. They have shorter tails than their congeners, and a pale yellow base to the bill, whereas in other prunellids both mandibles are uniformly black or brown. The flanks of these species are richly marked with rufous, and the throat is white, often speckled or barred with black in the Alpine Accentor. These differences prompted some earlier taxonomists to place these two species in a genus of their own,* Laiscopus, *but all recent treatments have included them within* Prunella. *Both are birds of high altitudes, their breeding ranges coinciding with major Eurasian mountain ranges. In many cases, habitats occupied during the breeding season are inhospitable in winter, when post-breeding flocks are driven downslope by harsh weather. Because of their need to cover large distances when foraging in barren terrain, as well as their seasonal migrations, the wings of these species are longer and more powerful than those of most other accentors.*

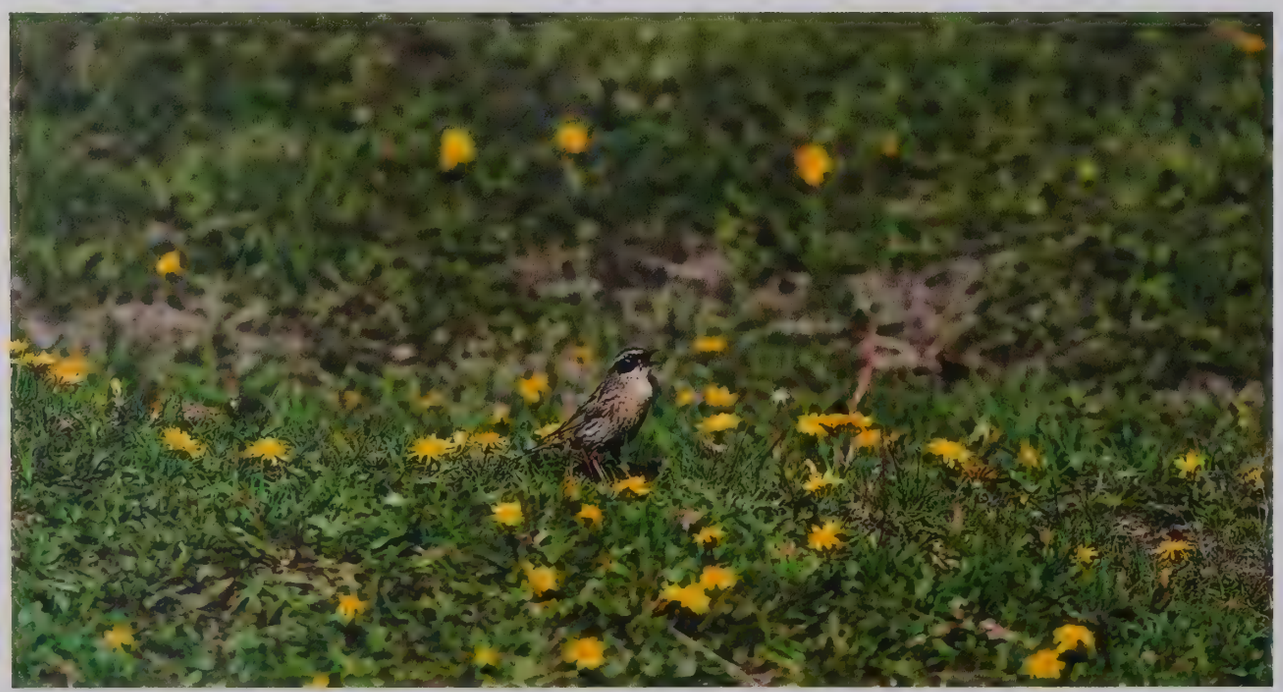
[*Prunella collaris collaris*, Sabiñánigo, Huesca, Spain. Photo: Javier Ara Cajal]

ciated with the function of mate attraction and territory defence by males. Studies by N. Langmore have shown that this behaviour is related to the unusual mating systems of these two species (see Breeding).

The song of the male Alpine Accentor is often produced in flight and bears a deceptive similarity to the song of the Eurasian Skylark (*Alauda arvensis*). It is characterized by a series of trills and ripples interspersed with fine, clear, fluty whistles, the whole making a strikingly rich verse that may last for 10 seconds or more. The female's song contains a lower diversity of elements, has a slower tempo and is more repetitive, features that make it easily distinguishable from the male's song in the field. Observations and experiments reveal that this unusual ability of females to sing has the function of advertising female fertility, and is a consequence of competition among females for the parental care offered by males (see Breeding). The complexity of a female's song increases with age, progressing from the simple multiple trills of yearlings to the complex songs containing several different syllables given by older females. As female reproductive success also increases with age, it appears that the song is a sexually selected signal to males that a female is fertile and of high quality and that males should, therefore, copulate with her.

With Dunnocks, the male's song is a rapid warble comprising trills and a number of sharply modulated units. It is shorter than that of the Alpine Accentor, and usually lasts for 1·5–3·5 seconds. Singing starts in early spring, continuing until the end of breeding, and throughout this period song-duels among males competing over territories and status are frequent. Individual male Dunnocks have large repertoires of song types that are formulated from a smaller repertoire of 10–15 constant song phrases. Males switch song types much more rapidly in the context of mate attraction than they do when singing spontaneously or when

*During the breeding season, the **Altai Accentor** frequents sparsely vegetated habitats at very high altitudes. It occupies the zone between the tree-line and the snow-line, favouring the bases of cliffs, barren slopes and rocky meadows, and tending to avoid more scrubby areas. Both this species and the closely related Alpine Accentor* (Prunella collaris) *range higher than almost any other passerine; the latter has been recorded up to 8000 m on the upper slopes of Mount Everest. In winter many individuals descend to more sheltered locales, including grassy meadows and valleys. The Altai Accentor ventures down to 1000 m, and the Alpine Accentor sometimes reaches sea-level.*



[*Prunella himalayana*, May-Saz, Kyrgyzstan. Photo: Hanne & Jens Eriksen]

involved in song-duels with other males; when advertising for a mate they change type every two songs, compared with every 20 songs in the latter situations. Experiments in which the songs of neighbouring males and those of same-territory males were played back to females have demonstrated that females can recognize individual males by their songs, and that female responsiveness is linked to their quest for copulations and, hence, for paternal care for their brood (see Breeding).

Female Dunnocks generally use simple "tseep" calls in territorial conflicts with other females, but, when left alone by the mate, they may use either trills or complex songs to attract his attention. The context for this unusual behaviour is very similar to that outlined above for female Alpine Accentors: song is a consequence of competition among females for the parental care provided by males. Not surprisingly, therefore, female song is more frequent when the competition for paternal care is greater; faecal analysis of androgen levels has shown that this facultative response to competition is regulated by a female's testosterone level.

The songs of Radde's, Siberian, Black-throated and Robin Accentors bear some similarity to that of the Dunnock, being sweet and melodious. The Brown Accentor also has a similar song, although this has been described, perhaps unfairly, as being "like a bad, slow robin [*Erithacus rubecula*]". The song of the Rufous-breasted Accentor has been likened to that of a Northern Wren (*Troglodytes troglodytes*), although more complex and without the latter's vehemence.

The main contact calls of the smaller accentor species are a simple monosyllabic or trisyllabic note, or a brief trill. The characteristic vocalization of the Altai and Alpine Accentors is a rippling or twittering call, usually given from the ground; it is often

***Radde's Accentor** is restricted to Asia Minor, where it usually breeds at 2000-3500 m above sea-level. At these altitudes much of the terrain is bare and rocky, but this species tends to occur where low scrubby vegetation provides a modicum of cover. It tends to be found in gulleys or sheltered slopes where a sparse growth of barberry* (Berberis), *juniper* (Juniperus) *or cedar* (Cedrus) *has taken hold. It spends much of its time hopping furtively and inconspicuously under this vegetation, but it sometimes emerges boldly onto adjacent turf, as this photograph attests.*

[*Prunella ocularis*, Aladag Mountains, Turkey. Photo: Hanne & Jens Eriksen]

With its pale eyes and richly coloured mantle, the ***Maroon-backed Accentor*** *looks slightly out of place in the family, and its habits are no less unusual. Although it occurs at high altitudes in the eastern Himalayas and the outlying ranges of southern China, it favours wooded habitats, often near water. It is especially fond of damp areas in ancient humid forests of conifers and rhododendrons, making it the most forest-based member of the family. In winter, it descends to lower altitudes, where it is most often encountered in secondary forests and forest margins.*

[*Prunella immaculata*, Jiuzhaigou, Sichuan, China. Photo: Bernard van Elegem]

difficult to locate, although this may be attributable to the terrain as much as being a property of the call. A loud chirruping flight call is often the first indicator of the presence of Alpine Accentors, particularly when the birds are associating in flocks outside the breeding season.

Young Alpine Accentors have loud begging calls, uttered both before and after fledging, that can frequently be heard at a considerable distance as they echo from rocks. This vocal begging by chicks is prompted by the calls of food-bearing adults as they approach the nest. The volume and intensity of begging calls would be expected to increase the vulnerability of nests to predators, but it has been argued that such loud vocalizations are related to this species' unusual mating system. Multiple paternity within a brood (see Breeding) reduces the degree of relatedness among the chicks, thereby increasing competitiveness and reducing the incentive for nestlings to avoid attracting predators.

Food and Feeding

During the breeding season, insects dominate the diet of all accentor species for which detailed information is available, but seeds are also an important element in the diet, particularly in winter. Species living at high altitude typically forage among rocks, stones, lichens, moss and grassy vegetation, often favouring the melting edge of snowfields. Those residing at lower elevations spend much of their time in foraging under cover of vegetation, thereby giving the appearance of being secretive, although the human observer can often approach them quite closely without causing alarm. Foraging prunellids move by walking or by making small hops, their progress being accompanied by almost ceaseless pecking movements; on occasion, they may also make aerial sallies to catch flying prey. The Rufous-breasted Accentor has been described as rodent-like because of its low shuffling manner of foraging, and Dunnocks also forage in this shuffling style.

The invertebrate diet includes virtually every order of insects that accentors are likely to encounter. It comprises, among others, springtails (Collembola), bristletails (Thysanura), two-tailed bristletails (Diplura), flies (Diptera), orthopterans, lepidopterans, bugs (Hemiptera), hymenopterans and beetles (Coleoptera), as well as other invertebrates such as spiders (Araneae), harvestmen (Opiliones), small snails and earthworms. The seeds of alpine plants are important constituents in the summer diet of most accentors that have been examined, and include those of the families Gramineae, Polygonaceae, Leguminosae, Rosaceae, Ranunculaceae, Primulaceae and Compositae. The plant component of the diet increases and becomes more diverse during the winter as the birds descend to lower altitudes and encounter the seeds of a greater diversity of plant taxa, especially trees such as Pinaceae, Cupressaceae and Betulaceae. Several species, including the Rufous-breasted Accentor and the Alpine Accentor, also take berries, among which those of heaths (Ericaceae), crowberry (*Empetrum*), bramble (*Rubus*), holly (*Ilex*) and even mistletoe (Loranthaceae) have been recorded.

Faecal analysis carried out on a population of Alpine Accentors in the Pyrenees, in south-west France, was revealing. In samples collected from adults during the breeding season, coleopterans and dipterans predominated, being found in, respectively, 92% and 70% of faeces; the next commonest groups were hymenopterans, with 19%, spiders, with 14%, and hemipterans, with 8%. These invertebrate taxa are dominant constituents of the "fallout fauna" that is deposited on mountain tops by the wind after having been swept up from lower altitudes. Very little plant material was recorded in the diet at this time of year, in June–August. It is noticeable that the adult accentors, when feeding young, are quick to exploit short-term gluts in food, such as those presented during brief periods when bibionid flies or grasshoppers (Acrididae) are superabundant. Dunnocks have a similar predominance of invertebrates in the diet during the breeding season, beetles being found most frequently, with spiders, flies, snails, lepidopterans and hemipterans also commonly represented. The proportion of the adult Dunnock's diet made up by invertebrates rises from 10% in February to 100% during breeding, and averages about 50% over the entire year.

The muscular gizzard and crop that characterize the Prunellidae (see Systematics) are clearly an adaptation to cope with this seed-dominated winter diet. The process of breakdown and digestion of seeds is further assisted by the consumption of grit, behaviour that has been observed for several members of the family. In Dunnocks, grit up to 2·2 mm in diameter has been recorded, and this material is taken particularly during the winter months, when the vegetable component of the diet is high.

Some accentor species are commonly found close to human habitation, especially in winter, and they exploit the feeding opportunities offered by this association, such as by feeding in barns

*Accentors are relatively unobtrusive birds, subdued in plumage and retiring in disposition. Many of the species, especially those confined to remote or inhospitable regions, remain essentially unstudied. On the basis of random photographs and anecdotes, however, it seems that all accentors are as fond of preening, sunbathing and bathing in water as are most passerines. This **Robin Accentor**, for example, is making good use of a mountain stream in Ladakh.*

[*Prunella rubeculoides*, Tso-Kar, Ladakh. Photo: Otto Pfister]

and close to livestock. In Europe, Alpine Accentors are sometimes observed at birdtables, where they take fat, bread and seeds. Dunnocks, too, frequently forage beneath birdtables, where they specialize on small bread crumbs that other birds ignore. They can often be seen as they pick up tiny items spilt on the ground, long after other bird species have left a feeding site.

For the Dunnock and the Brown, Black-throated, Altai and Alpine Accentors, the diet of nestlings has been quantified and been found to be similar to the summer diet of adults. Invertebrate prey are presented to the nestlings bill-to-bill, many items usually being delivered in a single load. Any seeds that are given to nestlings are regurgitated from the adult's crop.

Breeding

Breeding densities of accentors in alpine habitats may be surprisingly high, but few data exist for most of the species. Alpine Accentors reach densities of 26 individuals per km² in prime habitat in the French Pyrenees, and the Altai Accentor is described as a dominant member of the alpine avifauna in the Tien Shan Mountains of Central Asia. Perhaps commoner still is the Black-throated Accentor, for which a figure of 70 individuals per km² has been reported in juniper (*Juniperus*) scrub in the Tien Shan. The highest breeding density, however, is attained by the Dunnock. In Cambridge Botanic Garden, in England, as many as 640 breeding adults per km² were recorded, although the density is much lower, at 0·6–5 pairs per km², in the extensive forests in which the species probably originated.

The basic breeding biology of the Prunellidae, so far as details are known, shows little variation among the species. Most accentors appear to be double-brooded, although this has not been confirmed for several of them, including the Siberian Accentor, which may not even reach its breeding grounds until June. Nests are cup-shaped and are constructed from grass, moss, roots and similar material, with a lining of hair and other soft material. They are built by the female and are placed variously in rock crevices, on the ground, in low bushes or in trees. Females lay clutches of 2–5 clear blue or blue-green eggs, which they incubate for 10–15 days, and the nestlings are fed by both sexes for a further 10–15 days. The nestlings of all species for which information is available have an orange or red mouth with a distinct black spot on each side of the base of the tongue. All of these details are unexceptional. In contrast, studies of two species, the Dunnock and the Alpine Accentor, have revealed that every other aspect of their reproductive lives is quite extraordinary.

Research on the Dunnock, undertaken by N. B. Davies and colleagues in Cambridge, in England, has shown that this species has an exceptionally variable mating system. Within a single population, Dunnocks can be variously monogamous, polygynous, polyandrous or polygynandrous. In other words, one male defends the territory of a single female or defends the territories of two females, or two males share defence of one female's territory, or two or more males share defence of the territories of two or more females. This variability arises from variation in the males' ability to monopolize females, which, in turn, depends on the size of a female's territory. Polyandrous females have relatively large territories, the mean size being 0·55 ha; as these cannot be defended by a single male, a second male settles, often after a prolonged battle with the resident male. When female territories are small, a male may be able to defend two of them, thus becoming polygynous; in such cases, the mean female territory size was found to be 0·23 ha. Female territory size is determined by food resources; when Davies provided some females with extra food, these individuals reduced their territory size and were less likely to be polyandrous. It appears, therefore, that ecological factors determine female distribution, which, in turn, influences the dis-

*Accentors are vocal birds, often singing from prominent perches. Their songs, unremarkable in strength and melody, are often pleasant ditties composed of rapidly delivered whistles, chirps and trills. The most interesting feature of vocal behaviour in well-studied prunellids is not the song itself, but the fact that females are such accomplished singers. It is not known whether females sing to attract males in the **Japanese Accentor**, but given the complex breeding systems reported this seems likely to be the case.*

[*Prunella rubida*, Yamagata, Japan. Photo: Hirozo Maki]

tribution of males. It is interesting to note that similar variation in mating system has been recorded for a Finnish population of Dunnocks living at much lower density. So, the variability described here is not simply due to the fact that Dunnocks in Cambridge occur at high density in an artificial suburban environment.

The various mating combinations generate intense conflicts of interest within and between the sexes. When two males share a polyandrous or polygynandrous territory, they compete for copulations. Such males, incidentally, are never close relatives. One male, referred to as the "*alpha*" male, is dominant over the other, the "*beta*" male; the *alpha* male guards the fertile female and is sometimes able to monopolize copulations, in the same way as monogamous and polygynous males are. Nevertheless, *beta* males are extremely persistent and they are often able to copulate with fertile females. They are encouraged to do so by the female, which attempts to evade the guarding efforts of the *alpha* male in order to sneak away with the *beta* male. Mating is always preceded by a unique pre-copulatory display in which the female solicits, with her wings drooped and quivering, and her tail raised and vibrating rapidly from side to side. In response to this display, the male hops from side to side behind the female, pecking at her cloaca. The display lasts for about a minute, during which time the male pecks about 30 times. The female's pink and distended cloaca makes pumping movements, and she eventually ejects a drop of sperm from previous copulations. At this point, the two make cloacal contact for a fraction of a second and sperm is injected. This performance is repeated throughout a female's ten-day mating period. The likely function of the display is that it enables the male to increase the chance that his own sperm, rather than that of a rival male, reaches the site where the female stores sperm, thereby enhancing his chances of gaining paternity. Studies have shown that monogamous females mate 0·5 times per hour, while polyandrous females do so two times per hour.

The paternity of resulting broods is correlated with male mating success. Monogamous and polygynous males gain full paternity of broods, whereas, in polyandrous and polygynandrous systems, paternity is often shared between the *alpha* male and the *beta* male, the proportions reflecting the relative mating success of each. This explains the conflict among males. Females make particular efforts to copulate with both males because the extent to which males provision broods is closely related to their mating success and, hence, their paternity. This is important from a female's perspective: the more assistance she obtains from males, the lower is the rate of nestling starvation, so that brood sizes are then larger and the fledglings are in better condition. Conflict exists between females and *alpha* males because, on average, the extra young produced when a *beta* male helps in brood-rearing does not compensate the *alpha* male for the fact that he has lost some paternity of the brood to the *beta* male. Studies have shown that male breeding success increases with age, because older males are more likely than young males to achieve *alpha* status; the breeding success of females is not related to age.

The positive effect of male care on productivity also generates conflict among females. In polygyny and polygynandry, each female may receive less than the full-time care of a male; indeed, in some cases females receive no male help at all in rearing a brood. The result is that the rate of nestling starvation is high, and fewer chicks survive to fledging. This cost of shared paternal care causes females in polygynous and polygynandrous systems to attempt to disrupt the breeding attempts of other females which are rivals for the male's attentions. Escalated fights among females in such systems are frequent, and, even though males usually try to intervene and to separate the warring females, these disputes sometimes result in one female abandoning her breeding attempt. For the other female, competition for male care is thereby reduced.

These strategies, designed to maximize paternity, in the case of males, and paternal care, in the case of females, result in intense conflict between the sexes over the preferred mating system. A male does best in a polygynous system, because he is able to copulate with two females and thereby gain paternity of two broods. He fares least well in a polyandrous relationship, as he often has to share paternity of a single brood with the other male on the territory. Male productivity in monogamous and polygynandrous mating systems is intermediate between these two. In contrast, the female does best in polyandry, because, provided that she copulates with both males, both will help her to raise her offspring, and the number of fledglings produced increases as the amount of male care increases. Polygyny is the least desirable system for a female, as she often has to share the paternal care of one male with another female. Again, monogamy and polygynandry can be seen as a compromise between the interests of males and females, because, with these systems, productivity is intermediate and neither sex realizes its maximum potential reproductive success.

Studies of Alpine Accentors in the Japanese Alps, the French Pyrenees and the Swiss Alps have revealed that this species, too, has an unusual mating system. Polygynandrous groups of two to five males and two to five females occupy large, more or less ex-

The diet of high-altitude prunellids, such as the ***Brown Accentor****, is largely made up of insects during the breeding season. Their prey is captured either on the ground or in flight during brief aerial sallies. Needless to say, insects are available on a strictly seasonal basis in Asiatic mountains, and accentors are faced with three options in winter: to switch from insectivory to granivory; to migrate downhill; or both. The Brown Accentor is one of very few resident high-altitude prunellids, overcoming the constraints imposed by its environment through the strategy of eating insects in summer and seeds in winter.*

[*Prunella fulvescens fulvescens*, near Son Kul, Kyrgyzstan. Photo: Hanne & Jens Eriksen]

*The **Dunnock** is the only member of the family to have colonized temperate lowlands, and as a result it is familiar to most Europeans. It visits bird tables in winter, where it can be picked out from the brazen throng of sparrows* (Passer) *by its furtive demeanour, and the tiny hops by which it progresses when foraging. This odd shuffling gait is accompanied by almost constant pecking movements as the Dunnock works over the last scraps, picking tiny morsels from the ground.*

[*Prunella modularis*, Kerham village, Ploemeur, Morbihan, France Photo: Erwan Balanca/ Bios]

clusive ranges of about 20 ha of alpine habitat. Within a single group, the males have almost completely overlapping ranges, while female ranges tend to be somewhat smaller, although still showing extensive overlap with each other. As with Dunnocks, there is a dominance hierarchy among males and no evidence that relatedness plays any part in the association of either males or females. The behavioural dynamics within polygynandrous groups are very similar to those of Dunnocks: males compete to gain paternity, and females compete to gain paternal care for their offspring. Because of the larger group size of Alpine Accentors, however, competition among males and among females is even more intense than that observed with Dunnocks. These conflicts have two notable consequences. First, Alpine Accentors have an even higher copulation rate than that of Dunnocks; a female may copulate up to 1000 times for each clutch that she lays. Copulations are, again, preceded by a display, although males do not peck at the female's cloaca, and there may be several cloacal contacts during each copulation bout. Secondly, females compete with each other to attract males by producing complex songs during the fertile period and by exposing the scarlet cloaca to solicit copulations (see Morphological Aspects and Voice); as a result, a female may copulate with all the males in her group in the week prior to egg-laying.

Once the Alpine Accentor's eggs hatch, the nestlings are fed by the female and up to three males, the extent of an individual male's care being determined by his mating success and, consequently, his paternity of the brood. Unlike the situation with the Dunnock, the amount of male care does not affect the number of fledglings produced, but the young are in better condition the more paternal care they receive, and this is likely to influence their subsequent survival. The breeding success of both sexes of the Alpine Accentor increases with age. In the case of males, this is because older individuals are more likely to acquire dominant *alpha* male status, thereby gaining a greater share of paternity than that achieved by young males, while older females breed earlier and lay larger clutches than do younger ones.

The different mating systems of the Dunnock and the Alpine Accentor probably result from differences in food availability in their respective habitats. In the French Pyrenees, invertebrate abundance in Alpine Accentor habitat, at about 2200 m, was compared with that in Dunnock habitat, at about 1350 m. It was found that, at high altitude, invertebrates are less abundant and more patchily distributed in both time and space, presumably because of the more variable environmental conditions and the fact that much of the invertebrate fauna at high elevations is "fallout" from

*In summer, the **Alpine Accentor** subsists on an intake of insects, most of which are carried up to the montane zone by winds from lower altitudes. In winter, the focus switches to seeds and other plant matter, with insects only accounting for 10% of the diet. The small flocks which form at this time of year are a regular sight at some Alpine ski resorts, where they are attracted to scraps of food. When snow lies less than 5 cm deep, accentors are adept at digging their way to the ground in search of sustenance, but if conditions deteriorate they are forced downslope.*

[*Prunella collaris collaris*, Alta Ribagorça, Catalunya, Spain. Photo: Jordi Bas]

*Some accentors, including the **Robin Accentor**, perform a unique pre-copulatory display in which the female solicits with wings aquiver and tail raised. The male responds by repeatedly pecking her cloaca, from which she ejects a drop of sperm. Copulation ensues. It is no accident that this display has evolved in species with complex breeding systems, wherein more than one male has access to a fertile female. Males try to maximize paternity, and females try to convince multiple males that they fathered her brood. A visible ejection of sperm from previous matings thus benefits both parties.*

[*Prunella rubeculoides*, Sumdo, Ladakh. Photos: Otto Pfister]

the aerial plankton (see Food and Feeding). In order to exploit this patchy food resource, Alpine Accentors need very large ranges, which are not defendable by individual males or females. In contrast, the relatively predictable food supply at lower altitudes allows female Dunnocks to defend comparatively small, exclusive ranges, for which the males then compete, with varying success according to female territory size.

No investigations of similar depth have been carried out on other prunellids, and the extent to which the mating systems of the Dunnock and the Alpine Accentor are representative of the family as a whole is unknown. Nevertheless, in the case of two other species that have been studied in some detail, the Brown and Japanese Accentors, females are often assisted by more than one male when feeding nestlings, indicating a polyandrous or polygynandrous mating system. Brown Accentors are also known to be occasionally polygynous. Otherwise, anecdotal observations of the behaviour of Altai and Siberian Accentors during the breeding season suggest that these two prunellids may not always be monogamous. With the exception of the Dunnock and the Alpine Accentor, however, all members of this family merit more intensive study, particularly as they may provide further clues to the ecological basis for the evolution of mating systems.

Black-throated Accentor nests are parasitized by Horsfield's Cuckoo (*Cuculus horsfieldi*) in Central Asia, and those of Brown Accentors in the Tien Shan Mountains are parasitized occasionally by the Common Cuckoo (*Cuculus canorus*). In Britain, the Dunnock has the dubious distinction of being one of the main hosts of the latter species. It is estimated that about half of the female Common Cuckoos that breed in Britain lay their eggs in the nests of Dunnocks, although only about 2% of Dunnock nests are parasitized in this way. Despite this exploitation, which invariably results in the ejection by the cuckoo hatchling of all of the host's own offspring, Dunnocks have not evolved the ability to discriminate the parasite's egg from their own eggs, even though the pale spotted cuckoo egg is very different in appearance. Since most other regular hosts of the cuckoo can detect eggs that are so different from their own, it is puzzling that the Dunnock shows no such discriminatory ability. Davies and M. de L. Brooke have postulated that Dunnocks are recent hosts, in evolutionary time, and that their failure to reject cuckoo eggs is an example of evolutionary lag. It is known that Common Cuckoos have parasitized Dunnocks for over 600 years, but theory suggests that it may take thousands of generations for discrimination to spread through a host population if the parasitism rate is low. If the Dunnock became a regular host only when extensive forest clearance led to its becoming a common lowland species, between 2500 and 6500 years ago (see Habitat), there may not yet have been sufficient time for this discriminatory ability to evolve.

Movements

Some species of accentor are sedentary, others are partial or total migrants, and most exhibit movements from high-altitude breeding areas to lower-lying terrain during the winter. The Siberian Accentor undertakes the most extensive migratory movement of all accentors. It vacates the summer breeding range in the boreal and subarctic regions of Russia by late September, although southern parts of the breeding range may be occupied until November. The entire breeding population, from the River Pechora in the west to the Bering Sea in the east, spends the winter in Korea and eastern China. One subspecies of the Black-throated Accentor, the nominate race, is also migratory, moving from the forests of the northern Urals southwards to Iran, Afghanistan, Pakistan and the western Himalayas. This wintering range overlaps that of the other subspecies, *huttoni*, which breeds in the mountains of Central Asia and is a local altitudinal migrant or migrates over a relatively short distance.

The Dunnock is even more variable in its movements, being either sedentary or an altitudinal, partial or long-distance migrant. The northern populations, those from Fennoscandia and north-west Russia south to east-central Europe, make annual post-breeding shifts in a southerly and westerly direction. Many reach the Mediterranean Sea and its islands. By contrast, Dunnocks breeding in western Europe are essentially sedentary; even their local dispersive movements only rarely exceed 30 km in distance. In south-east Europe, this species is resident or partially migratory, with some local altitudinal migration. Most movement in this region is over relatively short distances, but the subspecies *obscura*, which breeds in the Caucasus region, eastern Turkey and north Iran, has been recorded as far south as Egypt.

Of the remaining members of the family, the majority can be characterized as having local seasonal movements that are associated with descent from high-lying breeding habitats to lower elevations, usually below the snow-line. The extent of these movements depends on environmental conditions and the topography of the region. Some prunellids remain on the breeding grounds throughout the year, but others may move over large distances in very mountainous regions. For example, Alpine Accentors that breed in the Pyrenees and other montane regions of Spain may be encountered almost anywhere in Iberia during the winter months. For most accentors, however, the distance and scale of seasonal movements are little known, largely because of these species' poorly defined ranges and a paucity of ringing studies.

*During the breeding season, the **Alpine Accentor** lives in groups of 2-5 males and 2-5 females, thus ensuring that intra-sexual competition is intense. Male testes account for 8% of body weight, while females have bright red cloacas and copulate up to 1000 times for each clutch, ranking them amongst the most sexually active of all birds. The advantage of a large breeding unit becomes apparent during the provisioning phase, when the combined effort of group members supplies enough invertebrate prey to fuel the rapid development of nestlings.*

[*Prunella collaris collaris*, Valais, Switzerland. Photo: Jacques Gilliéron]

Relationship with Man

The Dunnock is the only accentor that is closely associated with humans throughout the year. Given this degree of intimacy, it is perhaps surprising that its extraordinary mating system (see Breeding) was not described until the early 1980s. Indeed, ignorance of the species' sex life led the Reverend F. O. Morris, in 1856, to describe the Dunnock as "unobtrusive, quiet and retiring… sober and unpretending in its dress, while still neat and graceful", with a pattern of behaviour that "many of a higher grade might imitate, with advantage to themselves and benefit to others through an improved example." He would have been appalled had his parishioners taken his advice and emulated the Dunnock's habits. Some 70 years later, Viscount Grey of Fallodon had equally high regard for the Dunnock, describing its song as having "spirit and uplift", and attributing its unobtrusiveness to "not so much fear of man, as an inclination to apologise for its presence". Subsequently, a succession of brief papers reporting observations of the pre-copulatory cloaca-pecking display hinted at an unusual mating system, but it was not until the first studies of individually colour-ringed Dunnocks were conducted that the astonishing variability in this mating system and the sexual conflict that underlay it were revealed.

The relationship between Dunnocks and Common Cuckoos (see Breeding) featured in Chaucer's 1382 work *The Parlement of Foules* and also, over two centuries later, in Shakespeare's *King Lear*. Chaucer was firmly on the side of the Dunnock when he condemned the cuckoo as "Thow mordrer of the heysugge [an Old English name for the Dunnock] on the braunche that broghte thee forth! Thow rewtheless glotoun!"

Notwithstanding these two interesting examples, it could not be claimed that accentors have achieved any notable cultural prominence. They have not been kept widely as pets, despite their pleasant song; perhaps this was not regarded as sufficient compensation for their superficially unspectacular plumage. Nevertheless, the Dunnock was introduced into New Zealand by

*The **Dunnock** was once considered the archetypal boring brown bird, a model of restraint and modesty, but this all changed when intensive research revealed its sexual habits to be somewhat deviant. It transpired that the life of this particular bird was not as dreary as it looked, and that instead, unnoticed in the hedgerows and flower beds of Europe, promiscuous males and duplicitous females were locked in elaborate conflicts of interest. The available evidence suggests that polygamous breeding systems apply throughout the family, or nearly so, but information is lacking for several species.*

[*Prunella modularis mabbotti*, Álava, Spain. Photo: José Luis Gómez de Francisco]

European settlers, initially in 1868, since when it has spread to occupy a wide range of habitats, colonizing many offshore islands, including even subantarctic Campbell Island.

Accentors have probably received greatest attention as model systems for studies in evolutionary ecology. The study of Dunnocks in the Cambridge University Botanic Garden, in England, carried out by Davies and characterized by his use of elegant field experiments, has reached a wide audience through its status as a "classic" study in behavioural ecology. Detailed research on Alpine Accentors in Europe and Japan, led by Davies and M. Nakamura, respectively, has provided fresh insights into sexual conflict and the ecological basis for the evolution of avian mating systems. It would be fascinating to know how the mating systems of other accentors vary in relation to their ecological setting. If any ornithologist has the inclination and stamina needed to conduct equivalent studies on any of the remaining, neglected members of this family, he or she can be confident that the efforts expended would bring ample rewards in terms of scientific discovery.

*The breeding biology of the **Alpine Accentor** has been studied in the French Pyrenees. Here it was found that the nest, which is a cup of grass, moss and plant fibres lodged in a rocky recess, is constructed by the female. She then lays 3-4 eggs, which she incubates herself for 11-15 days. After hatching, the nestlings are fed by the female, with the assistance of up to three males, each adjusting his effort according to his mating success, and thus his likelihood of paternity. The nestling period lasts 12–16 days, during which older broods receive around eight feeds per hour, and after which an average of 2·8 young fledge per successful nest.*

Status and Conservation

None of the Prunellidae is regarded as being globally threatened. Although the population sizes of most species are unknown, their geographical distributions suggest that, in general, they are not of current conservation concern. The Yemen Accentor has the narrowest range of any member of the family, being restricted to the high mountains of western Yemen, in the south-west corner of the Arabian Peninsula. There is a potential threat of habitat destruction in this fragile environment, where an increasing human population could lead to further exploitation of the sparse vegetation. At present, however, there is no evidence that this is a significant problem. Even so, the Yemen Accentor has been recorded from only about half a dozen localities during the breeding season, and this fact, combined with the possibility of habitat loss within its tiny range, has resulted in the species being placed in the conservation category of Near-threatened.

The Mongolian Accentor may also have a limited range, in this case in the mountains and semi-deserts of Mongolia and north-central China, but there is no reason to suspect that it is vulnerable. Its status is uncertain, but it is thought to be probably rare. This is a typically secretive and quiet accentor, and is very poorly known. Fieldwork is required in order to determine its true status, as well as to gain an understanding of its ecology and biology.

The Dunnock, although still common, has recently been listed as a species of medium conservation concern in the United Kingdom on the basis that its breeding population has declined by 25–49% over the past 25 years. Declines of this magnitude are, sadly, commonplace among farmland and woodland bird species in the UK, and a similar downward trend is now being detected across western Europe in the populations of many species that were once abundant. Such declines may be linked to agricultural intensification, but the reduction in Dunnock numbers has not been attributed to any specific factor.

In northern and eastern Europe, Dunnocks are still associated primarily with coniferous forests, where they occur at relatively low density. In Finland, however, a spectacular increase in the second half of the twentieth century, from about 8000 pairs in the 1950s to 400,000 pairs in the 1980s, offers clues as to why Dunnocks are so abundant in western Europe. Changing management of forests has created forest clearings and new plantations, thereby providing the dense scrubby habitat that the Dunnock prefers, rather than the pure coniferous forests with little understorey that used to predominate. It may be that extensive clearance of forests in western Europe in the last few thousand years has created the hedgerows and scrub habitats favoured by this species.

*The **Yemen Accentor** has the smallest range of any accentor, being restricted to the high mountains of western Yemen, where it is known from only six sites in the breeding season. Its limited distribution, and the fact that the sparse montane vegetation which it inhabits is easily damaged by collection of wood for fuel, or overgrazing, have led to its inclusion in that holding-bay for potentially threatened birds, the Near-threatened category. Further fieldwork is required to assess the size and stability of its population, as well as the degree to which it is threatened.*

Genus *PRUNELLA* Vieillot, 1816

1. Alpine Accentor

Prunella collaris

French: Accenteur alpin **German**: Alpenbraunelle **Spanish**: Acentor Alpino
Other common names: Collared/Rock Accentor

Taxonomy. *Sturnus collaris* Scopoli, 1769, Kärnten, south Austria.
Most closely related to, and forming a species group with, *P. himalayana*; the two are sometimes placed in a separate genus, *Laiscopus*, because of larger size and distinct plumage differences in comparison with current congeners. Birds from Corsica, described as race *tschusii*, considered inseparable from nominate. Nine subspecies recognized.
Subspecies and Distribution.
P. c. collaris (Scopoli, 1769) – mountains from SW Europe E to Slovenia and Carpathians, and NW Africa (Moroccan Atlas).
P. c. subalpina (C. L. Brehm, 1831) – SE Europe (Croatia E to Bulgaria, S to Greece, including Crete) and SW Turkey.
P. c. montana (Hablizl, 1783) – N & E Turkey and Caucasus S to Iran and E to Turkmeniya.
P. c. rufilata (Severtsov, 1879) – from Kyrgyzstan E along Tien Shan, and from NE Afghanistan and extreme N Pakistan E along Pamirs to W China (Kunlun Mts).
P. c. erythropygia (Swinhoe, 1870) – from Altai Mts E to SE Russia, S to N & E Mongolia and NE China; also Japan (C Honshu).
P. c. whymperi (Stuart Baker, 1915) – W Himalayas (Ladakh E to Kumaon).
P. c. tibetana (Bianchi, 1904) – E Tibetan Plateau (S from Nan Shan, E to Gansu).
P. c. nipalensis (Blyth , 1843) – Nepal, Sikkim, Bhutan, SC China (SE Xizang, SW Sichuan, N Yunnan) and N Myanmar.
P. c. fennelli Deignan, 1964 – Taiwan.
Descriptive notes. 18 cm; male 40 g and female 36 g (*collaris*), male 45 g and female 39 g (*erythropygia*), sexes combined c. 30 g (*rufilata*, *whymperi*). Large, attractive accentor with strong bill, more upright carriage than most congeners. Nominate race has grey head and breast, slight black streaking on crown and nape, white throat with black scale-like marks; mantle and back grey-brown, broadly streaked black, lower back and rump brownish-grey, more rufescent uppertail-coverts, also streaked black, with pale edges giving scaly appearance; upperwing strongly marked, median and greater wing-coverts black with white tips (two contrasting spotted wingbars), dark secondaries with pale buff tips forming noticeable wing panel; tail feathers dark brown with white tips (in flight appearing as series of white spots or terminal band); belly pale grey, breast side and flanks bright chestnut, becoming more whitish-streaked towards rear; undertail-coverts dark brown with white feather margins (scaled appearance); iris brown; bill blackish, conspicuous yellow base (more extensive on lower mandible); legs dark pinkish-grey or brown. Sexes alike, female slightly smaller than male. Juvenile resembles adult but duller, with unspeckled throat, brownish-grey head

and chest, brown breast and flanks; buff wingbars less well defined than in adult, may be retained by some first-year birds. Races vary in size and colour: *subalpina* is similar to nominate, but paler grey on head and chest, less barring on throat, paler upperparts and flanks; *montana* is also close to nominate, but crown and neck olive-grey, streaks on mantle brown (rather than black), chestnut on flanks more extensive, spreading to side of breast and belly and down to undertail-coverts; *rufilata* differs from previous in having chestnut below more uniform, with less white streaking; *whymperi* has darker head, chest and upperparts, giving stronger contrast with white throat; *nipalensis* is darker than last; *tibetana* is generally paler than previous, with more white streaking on flanks; *erythropygia* has dark head, upperparts and chest combined with deep chestnut uppertail-coverts, scapulars and belly; *fennelli* is greyer and less brown on head and chest and paler below than last. Voice. Male song, usually from ground (often a prominent rock) but also in flight, loud and musical, a varied and sustained warble containing low-pitched trills and ripples and clear fluty whistles, may last up to 10 seconds, typically 6·5 seconds, resembles song of Eurasian Skylark (*Alauda arvensis*); male also delivers quiet subsong with closed bill. Female song (associated with competition to solicit copulations from males) at its simplest a series of trills, sometimes elaborated with multiple syllables and lasting 2 seconds or more. Characteristic call loud, pleasant rippling, with variable number of syllables, e.g. "truiririp", with purring effect; also, distinctive loud chirruping flight call.

Habitat. In breeding season, principally low cliffs, screes, rocky mountain slopes and alpine meadows above tree-line and up to snow-line; avoids areas of shrubs or trees; often close to snow patches. Breeds almost exclusively in mountain ranges: at 3600–5000 m in W Himalayas and Pakistan; mostly above 4000 m in Nepal, and observed at almost 8000 m on Mt Everest; in alpine zone above 2600 m in Japan; in W Palearctic often at lower altitudes, e.g. 1800–3000 m in Switzerland, Caucasus and Pyrenees. On Russian coast of Sea of Japan, breeds on cliffs and on rocky islands. Outside breeding season, usually at lower elevations in rocky and scrubby habitats, often close to human habitation in villages and near livestock, including woodland edges, roadsides, gardens and farms; in Europe occasionally encountered at sea-level, but only down to 1800 m in Nepal and W Himalayas.

Food and Feeding. Diet largely insects, including orthopterans, beetles (Coleoptera), earwigs (Dermaptera), heteropteran bugs, mayflies (Ephemeroptera), lepidopterans, flies (Diptera) and hymenopterans; also spiders, small snails and earthworms. Also some vegetable matter. In faecal analyses in SW Europe (Pyrenees), beetles and flies were commonest constituents. Seeds of herbs (Leguminosae, Polygonaceae) and grasses eaten mostly in late summer and winter, when seeds of pines (*Pinus*) may also be taken; also eats cereals and berries. Grit regularly taken by adults. Diet of young similar to that of adults, flies being dominant in Pyrenees, Italian Alps, Poland and Russia. Forages mainly on ground, among rocks, stones, grass, herbs, moss and lichens; particularly favours melting edges of snow patches. Proceeds with small hops or by walking, and occasionally takes insects in flight; may jump to snatch seeds and berries from low vegetation. In winter, may take crumbs and fat from birdtables and feed in barns. Often in winter flocks of 4–12 individuals, and much larger aggregations of up to 120 noted in Romanian Carpathians; sometimes with *P. himalayana* in Asia.

Breeding. Breeds May–Aug; double-brooded. Detailed studies in Europe (Pyrenees) and in Japanese Alps. Polygynandrous mating system, 2–5 males share large overlapping ranges of 2–5 females, group ranges (9–38 ha) more or less exclusive; males compete to mate with fertile females, females compete to attract males; solicitation display by female, which has high copulation rate (up to 1000 per clutch), usually involving several males. Nest, built by female, a cup made from grass, moss and plant stems, lined with hair and feathers, sited in rock crevice or beneath rock or grass tussock on cliff or shallower slope. Clutch 3–4 eggs; incubation by female, period 11–15 days; chicks fed by both sexes, but contribution of each male varies; of 38 broods studied in Pyrenees, 5% fed by female alone, 68% by female and one male, 24% by female and two males, 3% by female and three males; male care influenced by share of matings, hence paternity; total feed rate c. 8/hour for older broods; nestling period 12–16 days. In Pyrenees, 2·8 young per successful nest, 18% of broods preyed on after hatching; predators include mustelids and adder (*Vipera berus*).

Movements. Resident or altitudinal migrant, on local scale or over considerable distance. Movements in C & E Asia not well known, but breeding population in NE China winters in E provinces; otherwise, thought to be mainly local altitudinal migrant. In Europe, information only partial, but may be resident, local altitudinal migrant or extensive wanderer; some move to suitable habitat in lowlands, such as Gibraltar, S Spain and France (Côte d'Azur), but sparsely distributed in these areas; regular visitor and passage migrant on Balearic Is, and singles and flocks seen during migration on Tuscan Is (between Corsica and Italy); in Middle East, rare non-breeding visitor S to Cyprus, Israel and Jordan. N African breeders descend in winter to lower altitudes, where may be augmented by visitors from Europe. Adults more likely than young birds, and males more likely than females, to remain on breeding grounds throughout year. Males return to alpine zone in Mar–Apr, females typically in early May.

Status and Conservation. Not globally threatened. Common to locally common. No estimate of global numbers available; European population estimated to be c. 55,000–73,000 "pairs", with largest concentrations in Spain (18,000), Italy (14,000), Austria (8000) and Switzerland (5000). Recorded breeding densities in prime habitats 26 birds/km² in French Pyrenees, 12–16 birds/km² in Swiss Alps, 10–15 birds/km² in Slovakian Tatras, and 10 birds/km² in Tien Shan; density, however, varies greatly from year to year, probably dependent on differences in weather conditions and snow cover. Predation by cats and others in non-breeding season thought possibly to result in some local declines.

2. Altai Accentor

Prunella himalayana

French: Accenteur de l'Himalaya **German**: Himalajabraunelle **Spanish**: Acentor del Himalaya
Other common names: Himalayan Accentor, Rufous-breasted(!)/Rufous-streaked Accentor

Taxonomy. *Accentor Himalayanus* Blyth, 1842, Himalayas.
Most closely related to, and forming a species group with, *P. collaris*; the two are sometimes placed in a separate genus, *Laiscopus*, because of larger size and distinct plumage differences in comparison with current congeners. Monotypic.

Distribution. Mountains from S Russia (Altai region E to mountains E of L Baikal) and NW Mongolia S to Tien Shan and Pamirs; non-breeding in Himalayas (E to Sikkim). Range limits not well known.

Descriptive notes. 15 cm; 25–29 g. Has grey head with some black streaking; mantle and back chestnut-brown with dark streaks, rump paler brown; wings dark rufous-brown, two white wingbars; tail brown, pale terminal spots; chin and throat white, bordered by black dots; breast, upper belly and flanks striped rufous and white, lower belly creamy white; iris reddish; bill black, base of lower mandible yellow; legs yellowish. Sexes alike. Juvenile is similar to adult but paler, throat mottled grey, breast rich buff and belly creamy buff, both with dark streaks. Voice. Male song, from rock perch and in aerial pursuit of female, a loud warbling with trills and fluted whistles, similar to that of *P. collaris* but less musical and more trilling; also reminiscent of song of Red-fronted Serin (*Serinus pusillus*). Call "tee-tee", like that of a finch (Fringillidae); low twitter or constant warble during foraging while on passage.

Habitat. In summer, stony alpine meadows and bare rocky hillsides with sparse cover, usually avoiding scree and boulders; 2800–5500 m. In winter, on grassy, rocky hillsides and valleys at lower altitude, typically 2000–4500 m, exceptionally down to 1000 m.

Food and Feeding. Mostly invertebrates in summer; in winter, seeds supplemented by berries. Recorded as feeding flies (Diptera), lepidopterans, beetles (Coleoptera), orthopterans, spiders (Araneae) and small snails to nestlings. Forages inconspicuously on ground, with low crouching gait. In winter forages in flocks of 30–100 or more individuals, sometimes accompanied by *P. collaris* and Plain Mountain Finches (*Leucosticte nemoricola*).

Breeding. Season May–Aug; probably double-brooded, but details poorly known. Has been described as monogamous, but mating system and parental roles not determined; observations of 4–5 birds in flight pursuit during courtship, reminiscent of polygynandrous *P. collaris*. Some aggression among males and among females recorded, but no information on territoriality. Nest a bulky cup of roots, grass and other plant fibres and moss, lined with hair and fur, placed on ground in hollow under grass tussock or rock. Clutch 4–6 eggs; incubation by female alone, period 13 days at one nest; chicks fed by both sexes, no information on nestling period. Productivity little studied; 4·45 young reared per successful nest, and two out of nine nests destroyed by predators in Tien Shan.

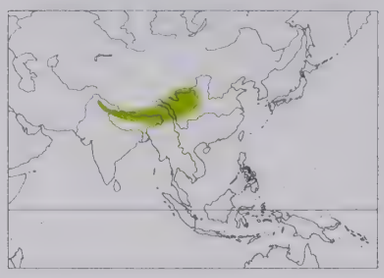
Movements. Poorly known. Post-breeding migration to lower altitudes, particularly from N slopes and ridges in Tien Shan; non-breeding range includes Himalayas from N Pakistan E to Bhutan, and perhaps other regions where not recorded in summer. In Tien Shan, returns to breeding grounds in Apr.

Status and Conservation. Not globally threatened. Locally common. No estimates of numbers available; in S Siberia, described as second most abundant species in alpine tundra area of Sayano-Shushensky Reserve, with 10 birds/km², and common also in W Sayan Mts. In winter, fairly common to uncommon in N Indian Subcontinent; occasional breeding-season records in e.g. N Pakistan and Kashmir, but no confirmed breeding there.

Bibliography. Ali & Ripley (1987a), Ali *et al.* (1996), Bräunlich (2002), Cheng Tsohsin (1987), Dementiev *et al.* (1968), Étchécopar & Hüe (1983), Flint *et al.* (1984), Grimmett & Inskipp (2003), Grimmett *et al.* (1998, 2000), Hüe & Étchécopar (1970), Inskipp & Inskipp (1991), Inskipp *et al.* (1999), Knystautas (1993), Kovshar (1979), MacKinnon & Phillipps (2000), Majumdar *et al.* (1992), Meyer de Schauensee (1984), Roberts (1992), Rogacheva (1992), Stepanyan (1990), Vaurie (1959).

3. Robin Accentor

Prunella rubeculoides



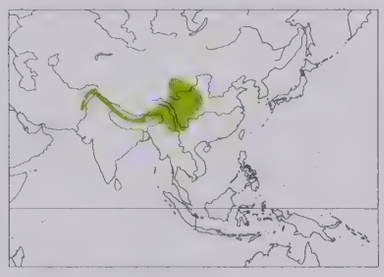
French: Accenteur rougegorge **German**: Rostbrustbraunelle **Spanish**: Acentor Petirrojo
Other common names: Robin Hedge-sparrow

Taxonomy. *Accentor rubeculoides* F. Moore, 1854, Nepal.
Apparently no close affinities within genus. Geographical variation slight; proposed races *muraria* (described from NW Kashmir), *fusca* (from C Xizang, in SW China) and *beicki* (from N Gansu, in NC China) show little difference from populations elsewhere in range. Treated as monotypic.

Distribution. Himalayas (from Baltistan and Ladakh E to Bhutan) and SW & C China (S & SE Xizang E to NE Qinghai, N Gansu and W Sichuan).

Descriptive notes. 16–17 cm; 23 g. Has grey head and throat, brown upperparts with dark streaking on mantle and back; wings and tail greyish-brown, two pale wingbars; breast and breast side rufous, belly and vent cream-coloured, rufous-brown streaks on lower flanks; iris reddish-brown; bill dark grey to blackish; legs dull red-brown. Sexes alike. Juvenile has dark streaks on head and neck, buff breast with dark streaks, diffusely streaked flanks. Voice. Short sweet song, described as "si-tsi-si-tsi-tsu-tsitsi", may accompany collective display by males; usual call a metallic trill.

On following pages: 4. Rufous-breasted Accentor (*Prunella strophiata*); 5. Brown Accentor (*Prunella fulvescens*); 6. Siberian Accentor (*Prunella montanella*); 7. Mongolian Accentor (*Prunella koslowi*); 8. Black-throated Accentor (*Prunella atrogularis*); 9. Radde's Accentor (*Prunella ocularis*); 10. Yemen Accentor (*Prunella fagani*); 11. Dunnock (*Prunella modularis*); 12. Japanese Accentor (*Prunella rubida*); 13. Maroon-backed Accentor (*Prunella immaculata*).



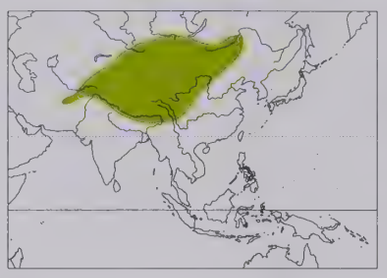
Habitat. Breeds in damp, boggy areas of scrub, particularly willow (*Salix*), and tussock grasses, often adjacent to lakes and streams in valley bottoms; usually at 3500–5500 m, but down to 3000 m in places (Suru Valley, in Ladakh). In winter, still found to 5000 m but also at lower altitudes, down to 2700 m in Ladakh and, in India, to 2500 m (Sikkim) and even as low as 1000 m (Himachal Pradesh). Preference for bare, stony and rocky habitats in winter, when frequently found near human habitation.
Food and Feeding. Small seeds and invertebrates, perhaps including small crustaceans; seeds predominate in winter. Forages on ground, usually in open grassy places; commonly in small flocks in winter months.
Breeding. Season May–Aug; double-brooded. No information on mating system or parental roles in breeding; collective display involving fluttering flight by several males. Nest a bulky cup of grass and moss, lined with fur, hair or feathers, usually sited on ground among clumps of sedge, occasionally in hollow in bank or in low vegetation bordering stream. Clutch 3–5 eggs; chicks fed by both adults; no information on incubation and fledging periods.
Movements. Resident; some post-breeding movement to lower elevations, details unknown.
Status and Conservation. Not globally threatened. Fairly common in suitable habitat through much of range. No estimates of numbers available. Local in Pakistan, common only on Deosai Plateau; uncommon in Bhutan. Locally rather uncommon in China.
Bibliography. Ali & Ripley (1987a), Ali *et al.* (1996), Bangs (1932), Cheng Tsohsin (1987), Étchécopar & Hüe (1983), Grewal *et al.* (2002), Grimmett & Inskipp (2003), Grimmett *et al.* (1998, 2000), Inskipp & Inskipp (1991), Inskipp *et al.* (1999), Li Mingcai *et al.* (2003), MacKinnon & Phillipps (2000), Meyer de Schauensee (1984), Ripley (1982), Roberts (1992), Vaurie (1959, 1972), Zheng Guangmei & Zhang Cizu (2002).

4. Rufous-breasted Accentor

Prunella strophiata

French: Accenteur à poitrine rousse **German**: Strichelbraunelle **Spanish**: Acentor Pechirrufo

Taxonomy. *A.[ccentor] strophiatus* Blyth, 1843, Nepal.
Apparently no close affinities within genus. Two subspecies recognized.
Subspecies and Distribution.
P. s. jerdoni (W. E. Brooks, 1872) – E Afghanistan and W Himalayas (from Kumaon E to W Nepal).
P. s. strophiata (Blyth, 1843) – E Himalayas (E from C Nepal), C China (E Qinghai, Gansu and SW Shaanxi S to SE Xizang, N Yunnan and W Sichuan) and N Myanmar.



Descriptive notes. 15 cm; 18 g. Has conspicuous supercilium white in front of eye, becoming broader and ochraceous above and behind eye, and blackish lateral crownstripe; blackish cheeks, narrow white crescent below eye; crown and upperparts brown with black streaks; wings and tail dark brown, two indistinct pale wingbars; throat whitish, variably streaked dark, streaks often forming indistinct malar stripe and/or throatband; broad rufous chestband, often with some thin dark streaks; rest of underparts pale cream with dark streaking, especially on flanks; iris brown; bill blackish; legs dull orange-brown. Sexes alike. Juvenile has supercilium whitish, lacking ochraceous colour, pale tips of crown and back feathers giving speckled appearance, buff-washed breastband and paler belly both entirely streaked. Race *jerdoni* is paler and less heavily streaked than nominate. Voice. Song, delivered from rock or occasionally in flight, very frequent at start of breeding, a melodious warbling and trilling verse, reminiscent of song of Northern Wren (*Troglodytes troglodytes*) but longer and quieter and with more trills. Call a fast, penetrating "tr-r-r" or "trr-r-rit".
Habitat. In summer, occupies upper limits of birch (*Betula*), oak (*Quercus*) and pine (*Pinus*) forests with rhododendron (*Rhododendron*) scrub, and subalpine scrub of juniper (*Juniperus*), willow (*Salix*), *Berberis* or *Viburnum* above tree-line; occasionally higher in alpine meadows; usually breeds from 2700 m to 3600 m in W Himalayas, up to 5000 m in E Nepal, and generally c. 2400–4300 m in China. In winter, found in more open scrubby habitats and fallow fields at lower altitudes, 1300–3600 m in Nepal and Bhutan; as low as 500 m in W of range.
Food and Feeding. Invertebrates, including worms; small seeds, berries and fruit. Forages in skulking manner on ground beneath bushes, often in clumps of *Viburnum* or willow.
Breeding. Season May–Aug; double-brooded. No information on mating system. Nest a deep cup of moss, dried stems and lichen, lined with grass, hair and feathers, typically placed low down in thicket of scrub, occasionally up to 3 m from ground in small conifer. Clutch 3–5 eggs; incubation and care of young apparently by both sexes, but few observations and no information on periods.
Movements. Resident, with local altitudinal movements; descends to lower elevations in winter months.
Status and Conservation. Not globally threatened. Most widespread and abundant accentor in W of range; probably less numerous in China. No estimate of numbers available. Status in Myanmar uncertain; possibly only non-breeding visitor.
Bibliography. Ali & Ripley (1987a), Ali *et al.* (1996), Bangs (1932), Bates & Lowther (1952), Cheng Tsohsin (1987), Étchécopar & Hüe (1983), Grewal *et al.* (2002), Grimmett & Inskipp (2003), Grimmett *et al.* (1998, 2000), Hüe & Étchécopar (1970), Inskipp & Inskipp (1991), Inskipp *et al.* (1999), MacKinnon & Phillipps (2000), Meyer de Schauensee (1984), Ripley (1982), Roberts (1992), Robson (2000), Smythies (1986), Vaurie (1955, 1959), Zhang Cizu *et al.* (1997), Zheng Guangmei & Zhang Cizu (2002).

5. Brown Accentor

Prunella fulvescens

French: Accenteur brun **German**: Fahlbraunelle **Spanish**: Acentor Pardo
Other common names: Pale Accentor

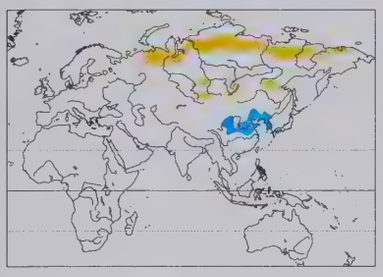
Taxonomy. *Accentor fulvescens* Severtsov, 1873, Turkestan.
Forms a species group with *P. montanella*, *P. koslowi*, *P. atrogularis*, *P. ocularis* and *P. fagani*; last two formerly treated as races of present species or as forming a superspecies with it. Racial differentiation complicated owing to individual variation (partly age-related, also influenced by plumage wear) and occurrence of intermediates. Described race *sushkini* (from extreme S Xizang, in China) synonymized with *khamensis*. Six subspecies recognized.
Subspecies and Distribution.
P. f. dahurica (Taczanowski, 1874) – E Kazakhstan (Tarbagatay), SC Russia (Altai and Sayan Mts E to Transbaikalia), Mongolia (except W & SW) and NE China (NW Manchuria).
P. f. mongolica Sushkin, 1925 – W & SW Mongolia (Achit Nur, Gobi-Altai) and N China (W Nei Mongol, N Ningxia).
P. f. fulvescens (Severtsov, 1873) – SE Kazakhstan and W China (E to E Xinjiang and NE Xizang) S to C Afghanistan, and W Himalayas (E to extreme N India).
P. f. dresseri Hartert, 1910 – W China (S Xinjiang and Qaidam Basin S to Kunlun Mts).
P. f. nanschanica Sushkin, 1925 – C China (NE Qinghai and SW Gansu S to S Sichuan).
P. f. khamensis Sushkin, 1925 – S fringe of Tibetan Plateau in SW China (S & SE Xizang, E to Qamdo region) and adjacent N Nepal and N Sikkim.

Descriptive notes. 15 cm; 20 g. Nominate race is olive-brown with sandy-grey tinge above (slightly darker in W Himalayas), mantle and scapulars with faint darker streaking; long, broad creamy-white supercilium, contrasting dark brown ear-coverts, grey neck side; tail and flight-feathers blackish-brown with buff margins; pale tips of dark median and greater wing-coverts form two indistinct wingbars; buff below, paler on throat and belly, and rich pinkish-buff, almost apricot on breast; iris yellow-brown; bill dark grey; legs pale reddish-brown to yellowish-brown. Sexes alike. Juvenile has narrower, less distinct supercilium, paler ear-coverts, more rufous back than adult, throat pale with dusky spots, underparts rich buff, some dark brown streaking on breast. Races vary largely in ground colour and amount of streaking on upperparts and depth of ochraceous colour below: *dahurica* is darkest, crown almost blackish, upperparts cold dark grey, distinctly streaked from hindneck to lower mantle and scapulars, rump uniform dull brown-grey, entirely cinnamon-buff below (belly paler only when plumage worn); *mongolica* is very like nominate, differing only in slightly darker and browner (less olive) upperparts, especially rump, and darker buff (less creamy) belly; *dresseri* is palest, light sandy-drab to medium buff-grey above, faint narrow brown-grey streaks on lower mantle and scapulars (also crown when plumage fresh), creamy below, slightly warmer pink-buff on breast and sometimes flanks; *nanschanica* is similar to nominate, but upperparts and flanks heavily and contrastingly streaked black, bill shorter than in other races; *khamensis* is heavily streaked like previous, but ground colour darker, streaking above more extensive (reaching uppertail-coverts), breast rich ochraceous, becoming buff on belly. Voice. Song, from top of bush, tree or rock, only rarely in flight, fairly loud, low warble with trills, "tuk-tileep-tilee-tileep-tileep", 2–3 seconds long; likened to that of *P. atrogularis* or an inferior song of European Robin (*Erithacus rubecula*) but more monotonous in composition and rhythm. Call "ziet-ziet-ziet", like that of a bunting (Emberizidae).
Habitat. In summer, found on open rocky or stony alpine and subalpine slopes, also in juniper (*Juniperus*) scrub, in high barren valleys; prefers drier regions, but not the driest; at 2400–3500 m in Tien Shan, but to 5100 m in W Himalayas and SW China (Xizang). In winter, found in same habitats, and upper limit of pine (*Pinus*) forest, but also extends below tree-line, down to 1500 m; also frequent in villages.
Food and Feeding. Mainly invertebrates and seeds. Adult diet not studied in detail, but invertebrates dominate in summer; seeds, supplemented by small berries, in winter. In Tien Shan, nestling diet dominated by flies (Diptera) and homopteran bugs, with significant proportions also of orthopterans, spiders (Araneae), lepidopterans, beetles (Coleoptera) and small snails. Forages mainly on ground, also in bushes and even tree crowns; occasionally takes insects in flight. Searches leaf litter in manner of a thrush (Turdidae), and may dig through 4–5 cm of snow to reach soil surface. Outside breeding season, usually in small, confiding parties of up to about ten individuals.
Breeding. Season Apr or May, depending on altitude, to Aug; double-brooded. Mating system apparently variable: polygyny, polyandry, monogamy and possible polygynandry recorded in Tien Shan. Territorial; territory c. 1 ha, nests usually separated by more than 100 m. Nest, built by female, a cup of plant stems and grass, lined with wool, hairs and feathers; placed in diverse sites, mostly in juniper bush or spruce tree (*Picea*), also in building, rock crevice, or beneath rocks or vegetation, 74% sited less than 2 m from ground but up to 8 m high, proportion on ground greater at higher altitudes. Clutch 3–5 eggs; incubation by female alone, sometimes fed on nest by male, period 10–12 days; nestlings fed by both sexes, 40% of 20 broods fed by female and two males; males sometimes feed chicks at nests belonging to different females in rapid succession; nestling period 10–15 days; female may start new nest when fledglings still dependent. In Tien Shan, 77% of nests successful, main nest predators crows (Corvidae), raptors and mustelids. Nests sometimes parasitized by Common Cuckoo (*Cuculus canorus*).
Movements. Resident and local altitudinal migrant. Some descend below tree-line in winter months, but many remain on breeding grounds throughout year. Little evidence that non-breeding range differs substantially from summer range.
Status and Conservation. Not globally threatened. Widespread and relatively common in suitable habitat through much of range. Scarce to locally common, with densities of 3–4 birds/km², in S Russia; occurs in Sayano-Shushensky Reserve. No estimate of numbers or population trends available, but appears not to be at any risk.
Bibliography. Ali & Ripley (1987a), Bangs (1932), Cheng Tsohsin (1987), Cramp (1988), Dementiev *et al.* (1968), Étchécopar & Hüe (1983), Flint *et al.* (1984), Grewal *et al.* (2002), Grimmett & Inskipp (2003), Grimmett *et al.* (1998, 2000), Hüe & Étchécopar (1970), Inskipp & Inskipp (1991), Knystautas (1993), Kovshar (1975, 1979), MacKinnon & Phillipps (2000), Mauersberger *et al.* (1982), Mey (1988), Meyer de Schauensee (1984), Roberts (1992), Rogacheva (1992), Stepanyan (1990), Stephan (1994), Vaurie (1959, 1972), Xing Lianlian (1996), Zheng Guangmei & Zhang Cizu (2002).

6. Siberian Accentor

Prunella montanella

French: Accenteur montanelle **German**: Bergbraunelle **Spanish**: Acentor Siberiano
Other common names: Mountain Accentor



Taxonomy. *Motacilla montanella* Pallas, 1776, Dauria, Siberia.

Forms a species group with *P. fulvescens*, *P. koslowi*, *P. atrogularis*, *P. ocularis* and *P. fagani*. Population breeding in NC part of range (between R Khatanga and R Lena) of uncertain racial identity; probably belong to nominate race, and tentatively included within it. Two subspecies recognized.

Subspecies and Distribution.

P. m. montanella (Pallas, 1776) – breeds extreme NE Europe and W Siberia (from Bol'shezemel'skaya tundra, on W side of Ural Mts) E to R Lena and, in S Russia, patchily from upper R Ob, upper R Yenisey region (N of Krasnoyarsk) and Altai E to Amur region.

P. m. badia Portenko, 1929 – breeds NE Siberia from R Lena E to Anadyrland, S to W shore of Sea of Okhotsk.

Descriptive notes. 14·5 cm; 17·5 g. Male nominate race has greyish-brown crown with black edge, contrasting long, broad creamy-yellow supercilium; ear-coverts blackish, buff at rear; side of neck grey; mantle, back and wings brown, mantle with rich chestnut streaks, rump and tail greyish-brown; whitish tips of median and greater wing-coverts form two narrow wingbars (obvious only at close range); throat and breast rich yellow-buff, flanks rich buff, dark chestnut streaks on breast and flanks, creamy central belly shading to greyish on vent; iris yellowish-brown; bill dark, ochre base of lower mandible; legs dull orange-brown. Female differs from male only in having brown less rich and streaks less well defined. Juvenile is less rufous than adult, has duller head pattern and underparts, large brown spots on chest and breast. Race *badia* is slightly smaller than nominate, also darker, with richer chestnut mantle, deeper ochre-buff underparts, streaks on flanks more rufous. Voice. Song, from top of bush or tree, melodious and quite powerful, generally reminiscent of *P. modularis* song; possibly two song types, one close to that of latter, the other more buzzy. Contact call trisyllabic, "dididi".

Habitat. Breeds in boreal and subarctic zone, chiefly along N limits of coniferous and deciduous forests, in valleys, often close to riverbanks in dense tangles of bushes and trees such as willow (*Salix*); also in spruce (*Picea*) taiga, and on mountains to tree-line in sparse spruce and birch (*Betula*) woodland. In winter, occupies thickets and shrubs, particularly alongside rivers and streams.

Food and Feeding. Diet mostly insects; in winter also seeds, including crowberry (*Empetrum*) Amaranthaceae and Betulaceae. Young fed on insects, especially beetle (Coleoptera) larvae. Forages mainly on ground, by pecking at soil, grass and dead leaves; also in trees and bushes. Foraging sites include those adjacent to snowfields.

Breeding. Season Jun–Aug; probably double-brooded in S of range, but one brood in Urals. Little information on mating system or territoriality; nominate race recorded in groups of 2–6 pairs, with nests closely spaced, but nests of *badia* usually far apart. Nest a compact cup of twigs, moss, leaves and plant stems, lined with fine grasses and hairs, built 0·4–8 m above ground in fork of low tree or in thick shrub. Clutch 4–6 eggs; incubation by female, period at one nest 10 days; no further information.

Movements. Migratory; entire population winters in C & E China and Korea. Leaves N Urals and E Siberia in early Sept, but present until Oct or Nov in S of breeding range; return passage through Mongolia from late Mar and in E Russia in Apr–May, arrival on N breeding grounds in Jun; S breeding grounds very poorly known, occupied from early May. Vagrants recorded in W Europe, Japan and W North America (Alaska, British Columbia, Washington, Idaho).

Status and Conservation. Not globally threatened. Locally common to uncommon or rare. Population in small European part of range estimated to be c. 16,000 pairs; no comparable figures from elsewhere. Variable abundance in breeding areas; in Bol'shezemel'skaya tundra (NW Russia), 3 pairs/km² in fragmented spruce scrub and river terraces, up to 5 pairs/km² in dense riverine birch, willow and juniper (*Juniperus*) scrub; density also varies annually (dependent on weather conditions), e.g. 7·4 birds/km² bred in Ary-Mas Reserve (in SE Taymyr Peninsula) in 1983, far more than in 1981. Generally scarce in E part of range, although 5 birds/km² in Amur region of Russian Far East. No information on population trends.

Bibliography. Ali & Ripley (1987a), Austin & Kuroda (1953), Bowler (1994), Brazil (1991), Cheng Tsohsin (1987), Cramp (1988), Daimon (1999), Dementiev *et al.* (1968), Estafiev (1977, 1979), Étchécopar & Hüe (1983), Flint *et al.* (1984), Hagemeijer & Blair (1997), Heath *et al.* (2000), Kaufman (1997), Knystautas (1987, 1993), MacKinnon & Phillipps (2000), Mauersberger (1993), Mey (1988), Meyer de Schauensee (1984), Morgan (1998), Morozov (1987), Portenko (1973), Rogacheva (1992), Snow & Perrins (1998), Sonobe (1982), Stepanyan (1990), Stephan (1994), Tsutsubuchi & Fujimaki (1998), Uspenski (1965), Vaurie (1959), Xing Lianlian (1996), Zhang Cizu *et al.* (1997), Zheng Guangmei & Zhang Cizu (2002).

7. Mongolian Accentor

Prunella koslowi

French: Accenteur de Koslov **German**: Steppenbraunelle **Spanish**: Acentor Mongol
Other common names: Koslov's Accentor

Taxonomy. *Accentor Koslowi* Przevalski, 1887, Alxa Mountains, north China.

Forms a superspecies with *P. atrogularis*, the two belonging to a species group that also includes *P. fulvescens*, *P. montanella*, *P. ocularis* and *P. fagani*. Geographical races *tenella* (described from Uliastaj, in W Mongolia) and *pallida* (probably from S Altai) proposed, but differences attributed to individual variation. Monotypic.

Distribution. Poorly known. Mountains and semi-deserts of W, C & S Mongolia (including Gobi-Altai) and NC China (Helan Mts and Zhongwei region, in Ningxia).

Descriptive notes. 15 cm. Crown and upperparts are brown with dark streaks; wing and tail feathers brown with buff edges, wing-coverts with white tips (two indistinct wingbars); throat grey, underparts buff; iris brown; bill blackish; legs brownish-pink. Sexes alike. Juvenile undescribed. Voice. Song reported as quiet and reminiscent of that of *P. fulvescens*; no information on calls.

Habitat. Thin scrub in semi-desert and dry mountains. No information on altitudinal range.

Food and Feeding. No information on diet. Forages in skulking manner close to or beneath bushes.

Breeding. Two records; nest placed close to ground; clutch 4–5 eggs. No other information.

Movements. No information, although reported as returning to breeding ground near L Orog Nuur in mid-May.

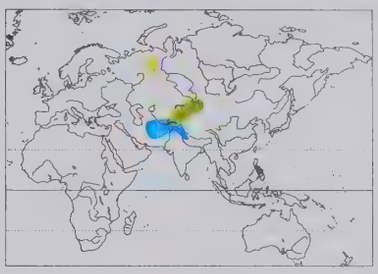
Status and Conservation. Not globally threatened. Status uncertain; probably rare, but secretive and quiet, possibly overlooked. Possibly only a non-breeding visitor in China. Fieldwork required in order to establish this species' precise range, as well as details of its ecology and biology.

Bibliography. Bräunlich (2002), Cheng Tsohsin (1987, 2002), Étchécopar & Hüe (1983), Kozlova (1928, 1933), MacKinnon & Phillipps (2000), Mauersberger *et al.* (1982), Meyer de Schauensee (1984), Stattersfield *et al.* (1998), Stepanyan & Bold (1976), Vaurie (1959).

8. Black-throated Accentor

Prunella atrogularis

French: Accenteur à gorge noire **German**: Schwarzkehlbraunelle **Spanish**: Acentor Gorginegro



Taxonomy. *Accentor atrogularis* J. F. Brandt, 1844, Semipalatinsk, north-east Kazakhstan.

Forms a superspecies with *P. koslowi*, and appears also to be close to *P. ocularis*; all three belong to a species group that also includes *P. fulvescens*, *P. montanella* and *P. fagani*. Proposed C Asian races *lucens* (described from R Tzagma, in C Tien Shan) and *menzbieri* (from Katon-Karagai, in SW Altai) regarded as synonymous with *huttoni*. Original spelling of species name has repeatedly been quoted as "*atragularis*", but this is erroneous. Two subspecies recognized.

Subspecies and Distribution.

P. a. atrogularis (J. F. Brandt, 1844) – breeds in N & C Ural Mts, in NW Russia; non-breeding in SW Asia.

P. a. huttoni (F. Moore, 1854) – breeds in mountains of WC Asia, from Altai Mts S to Pamirs; non-breeding in SW Asia.

Descriptive notes. 15 cm; 19 g. Nominate race has crown and nape greyish-brown with black streaks and black border, long pale cream supercilium; blackish ear-coverts separated from black of chin and throat (pale-spotted in fresh plumage) by thin pale malar stripe; side of neck grey; mantle and scapulars grey-brown, streaked blackish-brown, back, rump and tail olive-brown; wings blackish-brown, tertials and secondaries edged buff, white spots at tips of median and greater wing-coverts (indistinct wingbars); below, pronounced white gorget around black throat, grading to rich buff on breast and flanks, flanks with brown streaks and chest side with less distinct spots; belly and vent cream-coloured; dark areas become darker and underparts paler when plumage worn; iris brown; bill blackish, paler base of lower mandible; legs brownish to yellow-brown or pinkish-brown. Sexes alike. Juvenile has head pattern more poorly defined than adult, with narrower supercilium, no grey patch on neck, also duller, less clearly streaked upperparts, throat grey-brown with pale speckling (rather than black), underside more streaked. Race *huttoni* lacks white gorget, is darker above and below than nominate, with larger throat patch, heavier streaks on flanks, also has longer bill, relatively rounded wings (presumably associated with more sedentary habits). Voice. Song, from top of shrub or small tree, a pleasant verse with buzzes, piping sounds and a distinctive long, low-pitched "hwee", resembles songs of *P. modularis* and *P. montanella*; song of race *huttoni* rendered as "teets-reetee-teets-reeteee-teets-reetee-tsee-feetee". Contact call a soft trill; alarm at nest a quiet "teeteetee".

Habitat. In summer, favours low, thick, thorny scrub and avoids open habitats: in clumps of stunted spruce (*Picea*) in subalpine zone in Urals; race *huttoni* found in coniferous and deciduous forests and in scrub, often with juniper (*Juniperus*), in C Asia; to 3000 m. Where breeding range overlaps with that of *P. montanella* (in NW Russia), present species is concentrated in S montane region, rather than in boreal lowlands to N. Diverse habitats at lower elevations in winter; sandy semi-desert with some tamarisk (*Tamarix*) scrub in Afghanistan, and semi-arid hills in Pakistan (Punjab Salt Range); orchards and dense vegetation in damp valleys in N Pakistan, and scrub-jungle, tea plantations and other cultivated habitats in India; to 2500 m, mostly below 1800 m.

Food and Feeding. Primarily insects and other small arthropods, and worms and snails; also seeds, mainly in winter. Diverse arthropod prey include springtails (Collembola), lepidopterans, beetles (Coleoptera), bugs (Hemiptera), also spiders (Araneae) and mites (Acarina). Plant food mainly seeds of grasses and herbaceous plants, including Amaranthaceae, Compositae, Leguminosae, Ranunculaceae, Rosaceae and Umbelliferae; also of trees, e.g. Pinaceae, Cupressaceae and Betulaceae. Nestling food similar to that of adults; in Tien Shan, homopteran bugs and flies (Diptera) dominant. Forages on ground in dense shrubs, woods, grassy clearings, and banks of rivers and streams. In winter, forages in scrubby forest, bushes, and patches of weeds and reeds, either solitarily or in small parties.

Breeding. Information mostly from studies of race *huttoni* in Tien Shan Mts. Breeds May–Aug; two, possibly three, broods. Presumed monogamous, as no indication to contrary, but further study needed. Strictly territorial; territory 2–12 ha in Tajikistan. Nest, built by female, a bulky cup of moss, twigs, grasses and stems, lined with fine grass and hairs, placed usually below 3 m (but up to 13 m up) in tree or shrub, mostly in spruce or juniper. Clutch 3–5 eggs; incubation by female alone, period 11–14 days; nestlings fed by both sexes, more by female (62% of feeds) than by male (38%), chicks 8–13 days old fed 11–16 times per hour; young fledge at 11–14 days. Of 140 nests in Tien Shan, 56% successful, most losses due to predation. Nests in C Asia parasitized by Horsfield's Cuckoo (*Cuculus horsfieldi*).

Movements. Nominate race migrates S from Ural Mts to wintering grounds in E Iran, Turkmenistan and Uzbekistan S to Afghanistan and NW Indian Subcontinent and extreme SW China; departs from Aug, reaching Pakistan and N India mid-Oct; heads N from winter quarters in Mar, arriving S Urals in Apr. C Asian population (*huttoni*) partially migratory; makes altitudinal movements, but some migrate to same winter quarters as those of nominate race; birds that remain in mountains may stay close to breeding territory. Races mix over much of non-breeding range, but not evenly; nominate recorded mostly from Afghanistan, also N Pakistan and E to China, and *huttoni* mostly from C Asia and Kashmir, but also W to Afghanistan.

Status and Conservation. Not globally threatened. Locally fairly common to rare. Population of nominate race on European side of Urals estimated at 3500–4000 pairs, with recorded densities in Pechora Basin 20 birds/km² of spruce with herb layer, 1 bird/km² of spruce with moss layer, and 9–24 birds/km² of birch (*Betula*), larch (*Larix*) and willow (*Salix*); generally rare in Europe, where listed as Vulnerable. Few data for race *huttoni*, but in Tien Shan 70 birds/km² of juniper scrub; regarded as rare in China, but more information needed; breeds in Sayano-Shushensky Reserve, in extreme N of range in SC Russia.

Bibliography. 9. Radde's Accentor

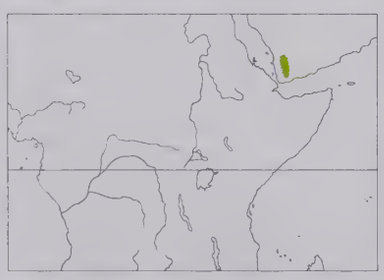
Prunella ocularis

French: Accenteur de Radde **German**: Steinbraunelle **Spanish**: Acentor de Radde
Other common names: Spot-throated/Spotted Accentor

Taxonomy. *Accentor ocularis* Radde, 1884, Mount Kiz Yurdi, Talysh Mountains, Azerbaijan-Iran border.
Was formerly often considered conspecific with *P. fulvescens* and/or *P. fagani*, but appears more closely allied to *P. atrogularis*, with which it shares some features and perhaps constitutes a superspecies; all four belong to a species group that also includes *P. montanella* and *P. koslowi*. Monotypic.
Distribution. S & E Turkey, Armenia, W & SE Azerbaijan and mountains of N, SW & E Iran.



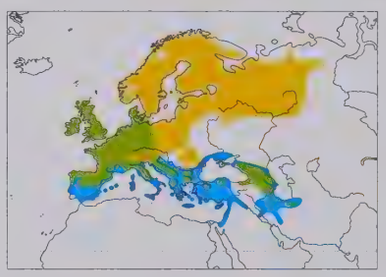
Descriptive notes. 15·5 cm; 20–25 g. Has blackish-brown crown and ear-coverts, conspicuous broad white supercilium; hindneck grey, mantle and back olive-brown with black streaks; wings grey-brown, two wingbars formed by creamy margins of median and greater wing-coverts; throat white to pale buff, broken dark malar stripe; breast and upper belly warm cinnamon-buff (breast side mottled when plumage worn), rest of underparts creamy white, flanks streaked blackish-brown; iris brown; bill blackish-brown, base of lower mandible yellowish to horn-coloured; legs reddish-brown. Distinguished from similar *P. fagani* by unstreaked darker crown and ear-coverts, more olive-toned upperparts, less distinct malar stripe, more richly coloured breast, less streaking below. Sexes similar, female with less contrasting head pattern than male. Juvenile resembles adult, but warmer tone and less contrast in markings, supercilium less distinct, throat and breast streaked. Voice. Song, from top of bush or rock, short and fast, twittering, with warbles and bubbling quality, similar to that of *P. modularis*; call "ti-ti-ti" or "tseep", thinner and less penetrating than that of *P. modularis*.
Habitat. In Turkey, breeds in rocky pastureland with scattered barberry (*Berberis*) bushes, at 1900–3000 m; in Transcaucasia, on rocky mountain slopes with scrubby juniper (*Juniperus*), cedar (*Cedrus*) and other vegetation, at 2000–3500 m. In winter, also in shrubby areas adjacent to mountain streams, down to 1000 m.
Food and Feeding. Poorly known. Diet includes insects and seeds. Forages on ground among rocks, scrub and low vegetation, also alongside streams and at edge of snow patches.
Breeding. Few records. Nests found Jun–Aug; probably double-brooded. No information on mating system. Nest a cup of twigs, leaves and stems, lined with hair, wool, grass and moss, placed low down in low bush, in one case 1 m from ground. Clutch 3–4 eggs; incubation period 11–12 days; nestling period c. 12 days; nestlings and fledglings fed by both sexes.
Movements. Probably mostly resident, with altitudinal movement and some short-distance migration. In Turkey, normally winters at nearby lower levels, extending regularly S to N Israel, and vagrant N Arabia. Iran population also migrates altitudinally; thought to winter in lowlands S of breeding range, but distribution poorly known.
Status and Conservation. Not globally threatened. Rather uncommon to rare, with fragmented distribution. Minimal population data; estimate of 500–5000 pairs, probably more, in Turkey and probably a maximum of several hundred pairs in Armenia and Azerbaijan. Listed by BirdLife International as Vulnerable in Europe; habitat degradation in lower-lying non-breeding areas thought to represent main threat.
Bibliography. Adamian & Klem (1999), Ali & Ripley (1987a), Alström (1991), Bara (2003), Baumgart *et al.* (2003), Beaman *et al.* (1975), Cramp (1988), Dementiev *et al.* (1968), Dunn (1994), Flint *et al.* (1984), Gaston (1968), Hagemeijer & Blair (1997), Hansson *et al.* (1998), Harrison (1982), Heath *et al.* (2000), Hüe & Étchécopar (1970), Knystautas (1993), Loskot (1994a, 2003), Martins (1998), Meiklejohn (1948), Norton (1958), Porter *et al.* (1996), Roberts (1992), Rogers (2001), Snow & Perrins (1998), Stepanyan (1990), Vaurie (1955, 1959).

10. Yemen Accentor

Prunella fagani

French: Accenteur d'Arabie **German**: Jemenbraunelle **Spanish**: Acentor del Yemen
Other common names: Arabian Accentor

Taxonomy. *Accentor fagani* Ogilvie-Grant, 1913, Yemen.
Formerly considered a race of *P. ocularis*, or even of *P. fulvescens*, but now regarded as a distinct species; all three belong to a species group that also includes *P. montanella*, *P. koslowi* and *P. atrogularis*. Monotypic.
Distribution. Mountainous region of W Yemen.



Descriptive notes. 15 cm; 22 g. Has dark crown and ear-coverts slightly streaked, conspicuous white supercilium; hindneck grey, mantle and back warm brown with black streaks; wings brown, two pale wingbars formed by creamy tips of median and greater wing-coverts; throat pale whitish-buff, distinct dark-spotted malar stripe; breast, flanks and upper belly buff, streaked dark brownish, vent creamy white; iris brown; bill blackish-brown, base of lower mandible yellowish; legs reddish-brown. Distinguished from similar *P. ocularis* by less black and more streaked head markings, generally warmer upperparts and duller underparts, stronger malar stripe, more extensive streaking below. Sexes alike. Juvenile resembles adult, but with less contrast in markings, less distinct supercilium and malar stripe, more streaking on throat and breast. Voice. Song, usually from rock or small bush, short and fast, 6–9 clear notes e.g. "drsi-drsi-drsi-du-du-du", ending with scratchy sound, shorter and more staccato than songs of *P. modularis* and *P. ocularis*; sometimes interspersed with more trilling notes. Call similar to "tseep" of *P. modularis*, sometimes uttered trisyllabically.
Habitat. In summer, rocky mountain slopes with short grassy and scrubby vegetation, often associated with scree or cliffs; also on cultivated terraces. At 1850–3000 m; also at lower altitude in non-breeding season.
Food and Feeding. Diet insects and seeds. Forages on ground. No other information.
Breeding. Breeds in spring. One nest documented, of small twigs, with cup of fine herbs lined with feathers, sited low down in shrubby vegetation. No other information.
Movements. Some altitudinal migration, probably mainly to S of breeding range.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in South-west Arabian Mountains EBA. Very local; known from just six localities in breeding season, and occurs at fairly low density; relatively common at only one site. Has smallest range of any accentor species; breeds within a zone of relatively high rainfall and dense human colonization that has been heavily cultivated for thousands of years. Further expansion of human population could lead to potential habitat destruction through increased exploitation of the montane vegetation (e.g. by collection for fuelwood, overgrazing by stock); no evidence that this is a significant problem at present.
Bibliography. Brooks *et al.* (1987), Collar *et al.* (1994), Cornwallis & Porter (1982), Cramp (1988), Evans, M.I. (1994), Jennings (1995), Martins (1986, 1998), Martins *et al.* (1996), Porter *et al.* (1996), Rands *et al.* (1987), Redman (1987), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Varisco *et al.* (1992), Vaurie (1955).

11. Dunnock

Prunella modularis

French: Accenteur mouchet **German**: Heckenbraunelle **Spanish**: Acentor Común
Other common names: Hedgesparrow, Dykie, European Dunnock, Hedge Accentor

Taxonomy. *Motacilla modularis* Linnaeus, 1758, Europe = Sweden.
Forms a superspecies with *P. rubida* and *P. immaculata*. Eight subspecies currently recognized.
Subspecies and Distribution.
P. m. hebridium Meinertzhagen, 1934 – Hebridean Is (W Scotland) and Ireland.
P. m. occidentalis (Hartert, 1910) – Britain (except Hebrides) and W France.
P. m. modularis (Linnaeus, 1758) – breeds N & C Europe E to Urals, S to Alps and Romania.
P. m. mabbotti Harper, 1919 – breeds SC France, Iberian Peninsula, Italy and Greece.
P. m. meinertzhageni Harrison & Pateff, 1937 – breeds S former Yugoslavia and Bulgaria.
P. m. fuscata Mauersberger, 1971 – mountains of S Crimea.
P. m. euxina Watson, 1961 – breeds N & NW Turkey.
P. m. obscura (Hablizl, 1783) – breeds Caucasus region, NE Turkey and N Iran.
Introduced (probably *occidentalis*) in New Zealand.

Descriptive notes. 14·5 cm; 19–20 g. Male nominate race has smoky-grey head, neck, throat and breast; grey-brown cheeks with fine pale streaks; mantle and back warm brown with blackish-brown streaks, rump and tail duller brown and unstreaked; wings blackish-brown, warm brown margins of secondaries and wing-coverts, faint wingbar formed by pale tips of greater coverts; below, grey of chest fades through greyish-white breast to white on centre of belly; breast side and flanks pale brown, streaked blackish-brown, undertail-coverts greyish-buff; iris reddish-brown; bill blackish; legs light reddish-brown. Female is very like male but less richly coloured, with, in particular, head and neck paler with brown wash, mantle less heavily streaked. Juvenile is generally less grey than adult, with general plumage tone buffer, head and underparts heavily streaked. Races differ mainly in coloration: *hebridium* is much darker than nominate, with darker grey head and breast, belly less white, more rufous tone on upperparts and more extensive streaking; *occidentalis* is intermediate between previous and nominate, with more extensive brown on hindneck and crown, no white on belly, darker brown flanks than nominate; *mabbotti* is close to nominate in appearance but darker and greyer, like previous except for paler underparts; *meinertzhageni* differs from last mainly in heavier streaking on mantle, greyer underparts; *euxina* is relatively pale above, lighter grey crown streaked with pale brown, brown (rather than black) streaks on mantle, also underparts more extensively grey, flanks less streaked; *fuscata* is similar to previous but darker, with better-defined mantle streaks, although still greyer than nominate, grey of underparts more extensive with just a little white on vent; *obscura* is brownest race, with buff wash on head, neck and belly, paler brown ground colour and streaks on upperparts, slight white scaling on throat and breast. Voice. Male song, in bouts from exposed perch, rarely in flight, a short (2–4 seconds) but pleasant warble, sometimes surprisingly loud, containing trills and sharply modulated units; male has repertoire of 10–15 phrases, these mixed to form larger number of song types, one type usually sung several times before switching (switching more frequent in context of female attraction than in male-male duels); sharing of songs among neighbouring males results in local dialects. Male also has subsong with different structure. Female produces combination of trills or complex songs in context of mate attraction. Juvenile starts singing in first autumn, full song develops in following spring. Most familiar call "tseep", used for contact outside breeding season by both sexes, loud higher-pitched version as alarm; faint trills also used to maintain contact.
Habitat. Highly variable across range. Occupies scrub and stunted woodland in alpine, subarctic and tundra habitats in N & E; found in montane habitat to just above tree-line in parts of range, including spruce (*Picea*) and larch (*Larix*) forests up to 2200 m in Switzerland, birch (*Betula*), maple (*Acer*) and juniper (*Juniperus*) scrub to 2600 m in Caucasus, and juniper and rhododendron (*Rhododendron*) scrub to 2000 m in Pyrenees. In N of range, found mostly in coniferous, broadleaf and mixed forests, particularly alongside water; in Bialowieza Forest (Poland-Belarus) also in mixed forest, particularly with alder (*Alnus*), ash (*Fraxinus*) and spruce. In W of range, from UK, Belgium and W Germany S to Iberia, mainly in lowlands, exploits managed woodland with thick understorey, hedges and farm woodland, suburban and urban gardens, parks and any other habitat with scrubby vegetation; shift to lowlands from likely ancestral habitat in alpine and subarctic regions unique within family. Introduced populations in New Zealand have successfully colonized scrub and woodland habitats from sea-level to 1600 m.
Food and Feeding. Diet largely arthropods, supplemented by seeds in winter; in Britain, volume of seeds in faeces was 90% in February, 0% in April (52% across year). Household scraps (e.g. suet,

breadcrumbs) also taken. Proportions of different invertebrates in diet vary across range and with season; beetles (Coleoptera, especially of families Carabidae, Curculionidae, Scarabaeidae, Chrysomelidae and Staphylinidae) and spiders (Araneae) generally dominate, but springtails (Collembola), stoneflies (Plecoptera), orthopterans, earwigs (Dermaptera), bugs (Hemiptera), lepidopterans, scorpion flies (Mecoptera), flies (Diptera), hymenopterans, harvestmen (Opiliones), pseudoscorpions (Pseudoscorpiones), small snails and earthworms also taken. Plant food equally diverse, includes seeds of, among others, docks (*Rumex*), legumes, pines (*Pinus*), birch, nettles (*Urtica*), poppies (Papaveraceae), primrose (*Primula*), grasses, sedges (Cyperaceae), willowherb (*Epilobium*) and thistles (especially *Cirsium*); also berries of heaths (Ericaceae), bramble (*Rubus*), holly (*Ilex*) and elder (*Sambucus nigra*). Nestling diet similar to spring-summer diet of adults; coleopterans, dipterans and spiders in 50–75% of faecal samples in Britain; peak in lepidopteran larvae (83%) recorded in Jun; young also fed with seeds, including those of Norway spruce (*Picea abies*) in Russia. Forages chiefly on ground under cover of bushes and other vegetation, by gleaning or sorting through leaf litter; occasionally probes soil; rarely takes prey in flight. In winter, often forages beneath birdtables, but rarely seen on raised platforms. Spends 94% of time in foraging in Jan, 54% in May (more when feeding young). Usually feeds alone; in winter, may gather in small groups at rich food sources.

Breeding. Breeds Mar–Jul over much of range, May–Aug in Russia; two broods, occasionally three, per season. Following account based on detailed study in Cambridge, UK. Mating system variable, in sample of 254 cases monogamy 42%, polygyny 4%, polyandry 30%, polygynandry (2–3 males with 2–3 females) 24% (monogamy, polyandry and polygynandry occur also in low-density populations in Finnish spruce and birch forests); female territories (c. 0·2–0·7 ha) exclusive, defended by one male or, in shared territory (c. 0·3–0·7 ha), by 2–3 males. On shared territory, dominant (*alpha*) male guards and copulates with female, subordinate (*beta*) male competes and sometimes copulates; high copulation rate (0·5–2·5 times per hour), preceded by cloaca-pecking display; female encourages *beta* male to mate. Nest, built by female alone, a cup of twigs, stems, roots, grass and moss, lined with hair, wool, sometimes feathers, placed 0·5–3·5 m above ground in bush, hedge or tree. Clutch 3–6 eggs; incubation by female alone, period 12–13 days; of 264 broods, 8% fed by female alone, 59% by female and one male, 33% by female and two males; male care influenced by share of matings, hence paternity of brood; seeds fed by regurgitation, invertebrates fed bill-to-bill; total rate of nestling feeds varies with mating system, c. 12 per hour for pair-fed brood and c. 15 for trio-fed brood of 10-day-old chicks; nestling period 11–13 days. Productivity per successful brood varies with male care, from 0·8 fledglings (female alone) to 2·4 (female with one male) and to 3 fledglings (female with two males); c. 30% of all breeding attempts and c. 15% of hatched broods fail as a result of predation, including by cats, crows (Corvidae) and mustelids. Brood parasitism by Common Cuckoo (*Cuculus canorus*) rather frequent, c. 2% of nests in UK.

Movements. Resident, altitudinal migrant, partial migrant and total migrant. Fennoscandian, Russian, Polish, N German and other NE populations (nominate race) migrate to Turkey, S Russia, and Mediterranean region from SW Iberia E, including islands, to Israel and N Egypt; passage to N Africa regular, but involves few individuals. Recoveries indicate migration on broad front along NE/SW axis; autumn passage in Aug–Nov, spring return Feb–Apr. SE populations (Crimea and Turkey E to Iran) resident or partially migratory; some local altitudinal movement from Caucasus to Black Sea coast, but race *obscura* recorded as far S as Egypt. Populations in Britain, Ireland and France mainly sedentary, with local dispersive movements rarely exceeding 30 km. Sedentary in Iberia.

Status and Conservation. Not globally threatened. Generally common to very common. Estimated global population 10,500,000–23,200,000 pairs. Russian population estimated at 1,000,000–10,000,000 pairs; in rest of Europe c. 9,500,000–13,100,000 pairs, largest populations being in Britain (2,100,000), Germany (2,000,000) and Sweden (1,500,000). In prime habitat in England (Cambridge) reaches density as high as 640 adults/km²; 40–120 birds/km² in woodland and young plantations, habitats favoured across much of Europe. Population trends variable; in Finland, increased from c. 8000 pairs in 1950s to c. 400,000 pairs in 1980s, this attributed to changes in forest management creating dense scrubby habitat. Recently listed as a species of medium conservation concern in UK because of 25–50% decline in numbers since 1975; no specific factor identified as responsible.

Bibliography. 12. Japanese Accentor

Prunella rubida

French: Accenteur du Japon **German**: Rötelbraunelle **Spanish**: Acentor Japonés
Other common names: Japanese Hedge-sparrow

Taxonomy. *Accentor modularis rubidus* Temminck and Schlegel, 1848, Japan.
Forms a superspecies with *P. modularis* and *P. immaculata*. N populations described as race *fervida*, but variation considered insufficient to warrant recognition of geographical races; birds in extreme N (Sakhalin) possibly a distinct race, further study needed. Monotypic.

Distribution. Breeds Sakhalin, S Kuril Is and Japan (S to Shikoku).

Descriptive notes. 15 cm; 19 g. Has chestnut crown and nape, grey edging of nape feathers; ear-coverts cinnamon-brown with fine pale streaks; mantle rich chestnut with black streaks, rump and tail rufous-brown; wing-coverts and flight-feathers darker brown with paler rufous-brown edges; throat to lower belly brownish-grey, flanks with rufous streaks, vent and undertail-coverts rufous-brown; iris brown; bill blackish; legs yellowish-brown. Differs from *P. modularis* mainly in browner general coloration. Sexes alike. Juvenile has buffer tone on upperparts and underparts than adult, head and underside streaked. VOICE. Song, from bush or tree, an inconspicuous trill, "tsee-tsee syuu tsee-tsee-syuu", but few details on vocalizations.

Habitat. In summer, chiefly in thickets and the understorey of pine (*Pinus*), birch (*Betula*) and mixed deciduous forests on mountains, up to tree-line; in Japan 1500–3000 m, mostly above 2000 m in Honshu; breeds in similar habitat but below 1000 m in Kuril Is. In winter, found in forest undergrowth, thickets and riverine scrub, also city parks.

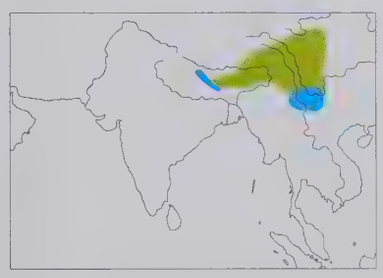
Food and Feeding. Invertebrates; also seeds, primarily in winter. Forages mainly on ground, often beneath bushes and in undergrowth, sometimes at edges of snow patches; occasionally above ground in trees and bushes.

Breeding. Season May–Aug; double-brooded. Female copulates with more than one male, and two males may assist female in feeding single brood; mating system probably similar to that of *P. modularis*, but details lacking. Nest a cup lined with hair, fur and feathers, placed in low bush or dwarf pine. Clutch 3–4 eggs; incubation period 12–13 days; nestling period 11–13 days.

Movements. N breeders migrate S to S parts of Honshu in Oct; mainly an altitudinal migrant in S, but some may winter in N Kyushu. Returns to breeding areas in Apr.

Status and Conservation. Not globally threatened. Fairly common in suitable habitat in Hokkaido, Honshu and Shikoku. No estimates of numbers or population trends available.

Bibliography. Anon. (1974, 2000a), Austin & Kuroda (1953), Brazil (1991), Dementiev *et al.* (1968), Flint *et al.* (1984), Furumaya (1983), Kiyosu (1965), Knystautas (1993), Konno & Fujimaki (2001), Matuzaki (1991), Sonobe (1982), Stepanyan (1990), Vaurie (1959), Yoshida (1998).



13. Maroon-backed Accentor

Prunella immaculata

French: Accenteur immaculé **German**: Waldbraunelle **Spanish**: Acentor Inmaculado

Taxonomy. *Acc.[entor] immaculatus* Hodgson, 1845, Nepal.
Forms a superspecies with *P. modularis* and *P. rubida*. Monotypic.

Distribution. E Himalayas (E from E Nepal) and S China (SE Xizang E to S Gansu, Sichuan and Yunnan).

Descriptive notes. 14·5 cm; 20 g. Distinctive dark, unstreaked accentor. Has predominantly dark grey head and upper mantle, black lores, some white scalloping on grey feathers of forehead; olive-grey to rich brown back and rump, slaty brown tail; scapulars and wings chestnut, greater wing-coverts grey; grey below, dark cinammon flanks, vent and undertail-coverts; iris pale yellow to whitish; bill blackish, base horn-coloured; legs pale greyish-brown to dull orange. Sexes alike. Juvenile resembles adult but lacks white on forehead, has olive back feathers tipped with black, paler throat spotted, buff breast streaked dark brown, belly and vent paler. VOICE. Song, from perch, described as monotonous, but details lacking; call weak, high-pitched and metallic "zieh-dzit" or "tzip".

Habitat. Humid coniferous and rhododendron (*Rhododendron*) forests, often near water; breeds from c. 2900 m to 5000 m. In winter, also in secondary forest, forest margins and edges of clearings at lower altitudes; 1700–3700 m in NE Indian Subcontinent, to 1500 m in Xizang.

Food and Feeding. Invertebrates and seeds, also some berries. Forages on ground, usually under thick vegetation, seldom in open. Secretive.

Breeding. Few records. Breeds May–Jul. No information on mating system. Nest well hidden, placed low down in bush, sometimes on ground. Clutch 3–4 eggs; no information on incubation and fledging periods.

Movements. Resident, with some altitudinal movement; post-breeding descent, often in parties, to lower elevations, resulting in expansion of range, e.g. into Nepal.

Status and Conservation. Not globally threatened. Generally uncommon to scarce, or rare; not uncommon in Nepal in non-breeding season. No information on density or estimate of abundance. The most secretive member of the family; probably overlooked to some extent. Status uncertain in some areas; possibly a non-breeding visitor in N Myanmar.

Bibliography. Ali & Ripley (1987a), Ali *et al.* (1996), Bangs (1932), Cheng Tsohsin (1987, 2002), Étchécopar & Hüe (1983), Grewal *et al.* (2002), Grimmett & Inskipp (2003), Grimmett *et al.* (1998, 2000), Inskipp & Inskipp (1991), Inskipp *et al.* (1999), MacKinnon & Phillipps (2000), Majumdar *et al.* (1992), Meyer de Schauensee (1984), Ripley (1982), Robson (2000), Shrestha (2000), Smythies (1986), Vaurie (1959, 1972), Zheng Guangmei & Zhang Cizu (2002).

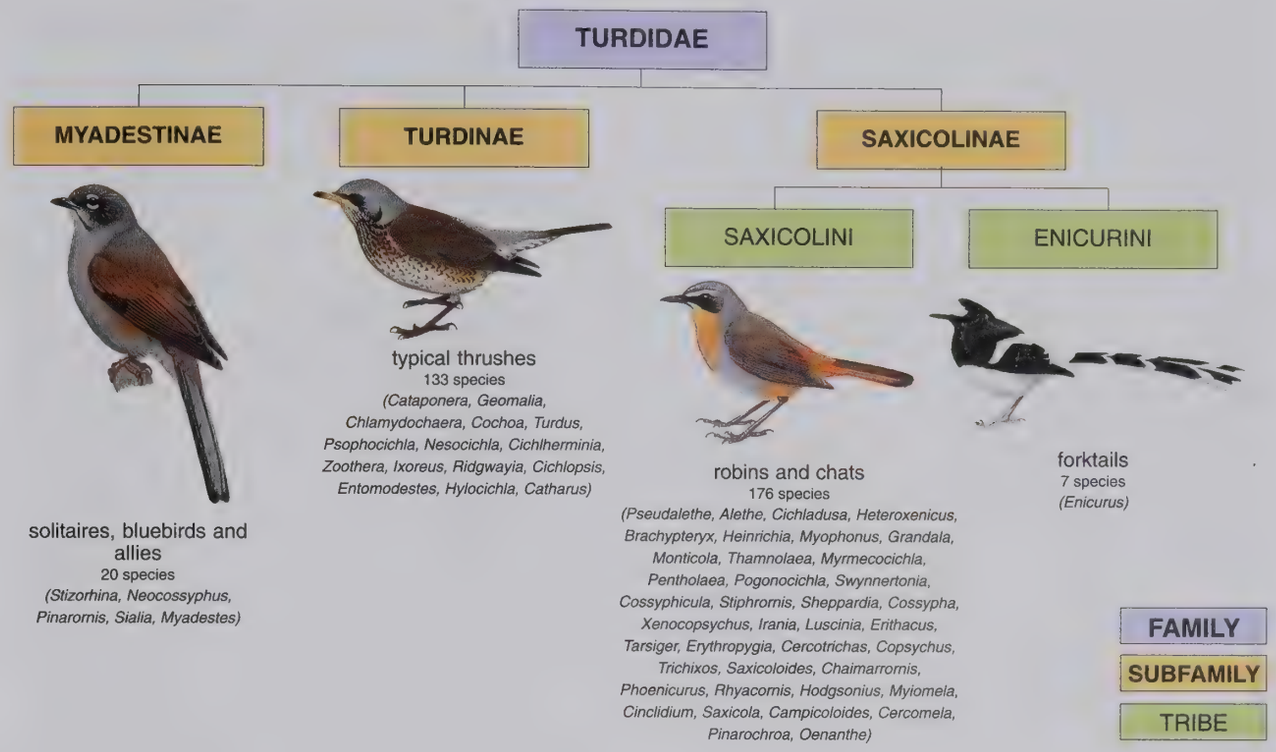
Class AVES
Order PASSERIFORMES
Suborder OSCINES
Family TURDIDAE (THRUSHES)

- Small to medium-sized passerines with fairly strong bill, usually medium-long tail, plumages varying from dull grey or brown to black, and from uniform to spotted and barred, some species with bright colours.
- 11–35 cm.

- Cosmopolitan.
- Most habitats, from dense forest to open country.
- 60 genera, 336 species, 953 taxa.
- 36 species threatened; 2 (possibly 4) extinct since 1600.

Systematics

There was a time in the mid-nineteenth century when the thrushes (Turdidae) were regarded as the most highly evolved of all birds, and they were placed at the beginning or the end of the oscine passerines, the position depending on how the sequence is interpreted. The basis for this arrangement was the combination of two features exhibited by these birds: an undivided planta, or sole of the foot, making them the "best" of perching birds, and highly developed vocal musculature. In 1896, in his great *Dictionary of Birds*, Alfred Newton described this conclusion as revealing "a woeful want of the logical apprehension of the facts", and he went on to argue that, on the contrary, the thrushes and chats are among the "lower members" of the oscines. Part of his evidence was that the turdid brain is small, the brain:body ratio of a Common Blackbird (*Turdus merula*) being 1:67 and that of a European Robin (*Erithacus rubecula*) 1:32, whereas those of the Eurasian Siskin (*Carduelis spinus*) and the Island Canary (*Serinus canaria*) are both 1:14. "The signification of these numbers", wrote Newton, "needs no comment to be understood." He apparently thought that brain:body mensural ratios would open up systematics in the way in which biomolecular studies are now believed to do.



Another century has passed, however, and, although brain:body ratios are very important in understanding the evolution of mammals, the possible significance of these numbers in avian systematics awaits more thorough research. Meanwhile, the placement of the thrushes has long since shifted towards the middle of the oscines.

So, what makes a thrush a thrush? It is not, at any rate, the vernacular name. The first thing to be said is that, because these birds were so familiar to early settlers, explorers, naturalists and systematists, the word "thrush" has been adopted for several look-alike groups which prove to have no true affinity with the family. Among such groups are the waterthrushes (*Seiurus*) of North America and the Wren-thrush (*Zeledonia coronata*) of Costa Rica and Panama, both actually New World warblers (Parulidae), the shrike-thrushes (*Colluricincla*) of Australasia, which probably constitute a family of their own, distantly related to the Turdidae, and the ant-thrushes of the genera *Formicarius* and *Chamaeza*, which are in fact Neotropical ground-antbirds (Formicariidae), not to be confused with the *Neocossyphus* ant-thrushes, which do belong in the Turdidae. Further examples include the laughingthrushes and jay-thrushes (*Garrulax*), which are Asian babblers (Timaliidae), the quail-thrushes (*Cinclosoma*) of Australasia, placed in their own monogeneric family (Cinclosomatidae), and the New Zealand Thrush (*Turnagra capensis*), perhaps more usually known as the Piopio, the systematic placement of which is uncertain. Among other such examples, it is worth mentioning that the Old World pittas (Pittidae) were often referred to as "jewel-thrushes" and the North American mockingbirds (Mimidae) as "mocking-thrushes". Even the name "thrasher", applied to four genera of mimids, is derived from the word "thrush", alluding to the often plain brown upperparts and speckled underparts of the species in question which, in one in-

Thrushes are arranged into three subfamilies. Allocating each genus to the right subfamily is often straightforward, but several less tractable forms are subject to unsettled treatment, with disputes over their true relationships, sometimes even at the family level. One such is Stizorhina, *which contains two thrush-sized but flycatcher-shaped African species, with short bills and legs, upright posture, and a habit of flicking the tail outwards. According to genetic analysis they fall well outside the typical thrushes, but cluster with New World solitaires* (Myadestes). *These data support the retention of the* ***Rufous Flycatcher-thrush*** *within Turdidae, and its placement in the subfamily Myadestinae.*

Subdivision of the Turdidae

[Figure: Douglas Pratt, Norman Arlott, Hilary Burn, Tim Worfolk]

terpretation of the name, made them appear "thrusher", or more thrush-like, than a true thrush.

In some cases, the appellations were clearly intended merely to signify resemblance, whereas, in other instances, they implied both resemblance and affinity to the thrushes. For example, some of the Australasian taxa mentioned above were for many years included in the thrush family, as were the scrub-robins (*Drymodes*) of that region. Over time, membership of the Turdidae has been pared back, but there are still many fuzzy edges which remain intriguing and problematic, although, in recent years, DNA analyses have started to produce important clarifications, as well as some new uncertainties.

The family as currently constituted is by no means the most recently supported arrangement, but it extends the life of the long-held view that the thrushes and the chats form two major subfamilies within a single family. The first of these subfamilies, the Turdinae, comprises for the most part relatively large, longish-tailed, forest passerines and is dominated by the genera *Zoothera*, *Turdus* and *Catharus*, while the second, the Saxicolinae, is made up mostly of small to medium-sized, bright-tailed, open-country passerines, dominated by the genera *Monticola*, *Sheppardia*, *Cossypha*, *Luscinia*, *Phoenicurus*, *Saxicola* and *Oenanthe*. This view remains attractive owing to the plumage and/or structural resemblances of certain species and genera across the subfamilial divide, as illustrated by, for example, the nightingales (*Luscinia*) and nightingale-thrushes (*Catharus*), or the Chestnut-capped Thrush (*Zoothera interpres*) and Chestnut-naped Forktail (*Enicurus ruficapillus*). Nevertheless, the results of biomolecular work carried out by C. G. Sibley and J. E. Ahlquist, E. Pasquet and co-workers, F. K. Barker and co-workers, and P. Beresford now suggest that the chats are, in fact, close enough to the Old World flycatchers (Muscicapidae) to be included either as a subfamily within or as a component of the latter, so that their supposed affinities with the true thrushes may be merely, or more of, a matter of convergent evolution. This finding is not entirely unexpected. It is worth remarking that R. A. C. Jensen and M. K. Jensen, in a 1970 study, reallocated the Herero Chat (*Namibornis herero*) to the flycatchers, a relationship reinforced by recent biomolecular work. These authors concluded that "separation of chats and flycatchers at the family level is unrealistic".

This is not to say, of course, that the thrushes and chats are not closely related. Both groups conform to certain characters which indicate a common ancestry, albeit often shared with the Old World flycatchers. Thrushes and chats are generally fairly slim and tapered, yet robust-bodied, and have a strong, sharp, straight bill which is often rather broad-based and usually just more than half the length of the head; they also possess rather large eyes, fairly sparse medium-length rictal bristles, a blade-tipped tongue, medium-length legs with strong toes, mainly rounded wings, and a squared-off or slightly rounded tail. Perhaps most crucially, they share with the Old World flycatchers two important features: a cryptic spotted juvenile plumage, although in some chat species this is reduced dramatically to slightly rusty edges of the wing-coverts, and a distinctive derived condition of the syrinx known as the "turdine thumb".

As with most oscines, there are ten primaries, of which P10 is often short, and twelve or, very rarely, ten or 14 rectrices. The legs are booted or "holothecal", in other words plain, without divisions on the surface, a feature not shared with the Old World flycatchers, and the feet are anisodactylic, with three toes pointing forwards and one to the rear, and acutiplantar, the hind toe angled sharply from the tarsus; in a few genera of chats, juveniles have scutellate tarsi. The flight is usually undulating, and almost all species are adapted to both terrestrial activity, involving running and/or hopping, and off-ground perching.They are thus capable of exploiting rather broad niches, foraging on the ground, in the soil and leaf litter, and in vegetation, and feeding predominantly on invertebrates but also, often for extended periods, on fruit (see Food and Feeding). This adaptive plasticity in behaviour is undoubtedly responsible for the family's almost unparalleled success.

Turdids are almost always territorial and monogamous, having songs that are commonly rich and melodious. The nests of turdine thrushes are typically tightly woven cups, often strengthened with mud, placed in a tree or bank, and the clutch size is of 2–6 eggs; chat nests are often rather untidy structures, built on or near the ground or placed in rock or tree crevices, in which clutches of 2–8 eggs are laid. In both subfamilies, it is almost always only the female that builds the nest and incubates the eggs. The eggs are mainly pale blue, greenish-blue or blue-green, sometimes plain but usually with reddish-brown speckling and mottling; egg coloration, however, is related largely to nest type, and is generally of little reliable taxonomic value. Turdid nestlings are typically covered in long scanty down, but those of a few species are naked; cup-nest youngsters commonly leave the nest a few days before they are able to fly. There is a single annual moult, following breeding; a small number of species have a partial pre-breeding body moult, but in the great majority breed-

The peculiarities of the ***Boulder Chat*** *once led to its inclusion in the babbler family, Timaliidae. On the basis of shared features it is now treated as a turdid allied to African ant-thrushes* (Neocossyphus) *and flycatcher-thrushes* (Stizorhina), *as well as the Nearctic bluebirds* (Sialis), *in the Myadestine clade. It has rather specialized habitat requirements, being restricted to granitic outcrops in south-central Africa, where it usually occurs on lower slopes with large boulders and trees. It shuns both open, rocky areas and dense vegetation, instead favouring boulder-strewn sites under a wooded canopy.*

[*Pinarornis plumosus*, Stone Hills Game Sanctuary, Matobo, Zimbabwe. Photo: J. R. Peek]

ing plumage is acquired by abrasion. Sexual dichromatism is common, possibly owing to the predominance of female attendance at the nest.

The most significant deviation from this generalized account of the family is found in a small, geographically diverse group of birds which are, except for two species, almost exclusively arboreal and which lack several key characters mentioned in the above list (no spotted juvenile plumage; typical oscine syringeal morphology). These are the ant-thrushes (*Neocossyphus*) and the flycatcher-thrushes (*Stizorhina*) of Africa, and the solitaires (*Myadestes*) of Hawaii, North and Central America and the Caribbean. *Myadestes*, a uniform genus of small, upright-perching birds with a short, rather wide bill, typically with predominantly grey plumage, with silvery or pale grey in the tail and an oblique dull wingbar, has long been a puzzle to systematists, who have sought to relocate it within the silky-flycatchers (Ptilogonatidae) or the waxwings (Bombycillidae). Nevertheless, field observations on the Black-faced Solitaire (*Myadestes melanops*) by P. Slud led him to remark perceptively that, "despite its different appearance and proportions, its behavior and attitudes suggest a semi-terrestrial thrush become adapted to arboreal life".

DNA analyses by Pasquet, A. Cibois and co-workers reveal that, despite superficial differences between the terrestrial *Neocossyphus* and the flycatcher-like *Stizorhina*, these two genera and *Myadestes* are all closely related and, moreover, group at some distance phylogenetically from the typical thrushes, supporting their separation in a third subfamily, the Myadestinae. Into this subfamily are added two further genera. The first contains the bizarre, little-studied Boulder Chat (*Pinarornis plumosus*) of southern Africa, which was once thought to be a babbler but which shows certain traits allying it compositely to *Neocossyphus* and *Stizorhina*; these traits are a stippled throat, a patch of colour in the primaries and on the distal outer tail, an elongate body and tail, an unspotted juvenile plumage, and absence of the turdine thumb. The second genus, *Sialia*, contains the North American bluebirds, another small, anomalous group of three flycatcher-like species which are evidently remote from the true thrushes. Although the bluebirds possess a spotted juvenile plumage, very recent biomolecular studies by J. Klicka and colleagues indicate that they are closer to *Myadestes* than the latter is to *Neocossyphus*. On the other hand, another genus bearing the English name of "solitaire", *Entomodestes*, appears, on behavioural and molecular evidence, to reflect convergence on, not true proximity to, *Myadestes*, and along with the monotypic *Cichlopsis*, also a "solitaire", is retained in the Turdinae.

Pinarornis and *Myadestes* share the habit of nesting on or very near the ground, but at present there is too little evidence to demonstrate the robustness of the current arrangement, whereby *Stizorhina*, *Neocossyphus*, *Pinarornis*, *Sialia* and *Myadestes* are united in their own "primitive" subfamily. This grouping of genera may prove to be paraphyletic, although it is, nevertheless, largely in line with the suggestion of S. L. Olson, with the exception that *Sialia* is added and *Modulatrix*, now judged to be related to the rockjumpers (*Chaetops*), a genus of uncertain affinities, removed.

The recent transfer of the thrushes of the Hawaiian Islands from their own genus, *Phaeornis*, to *Myadestes* has been widely corroborated by osteological and genetic studies, but it is intriguing that only one mainland species of *Myadestes*, Townsend's Solitaire (*Myadestes townsendi*), today undertakes migrations of a type which might have led to the colonization of so distant an oceanic archipelago. Two species in the Caribbean, however, indicate the over-water dispersal abilities of the genus. The songs of the Cuban Solitaire (*Myadestes elisabeth*) and the Rufous-throated Solitaire (*Myadestes genibarbis*) are similar to each other, and different from those of others in the genus, so that these two species are evidently closer to each other than they are to their congeners. They perhaps reached their homes as a result of two invasions of a single, now extinct continental species.

The Turdinae and the Saxicolinae represent two huge subfamilies to which most genera can be allocated on fairly straightforward evidence, commonly to do with their perceived relationships to certain "anchor" genera within the respective groups. Very recent investigations of nuclear and mitochondrial DNA sequences in many of the more obscure genera are now shedding light on the distribution of these genera within the subfamilies, and some new, albeit reassuring, alignments are resulting. Sibley and B. L. Monroe's surprising placement of *Alethe* and *Brachypteryx* in the true thrushes is now overturned, and these genera, along with those recently split from them, are regrouped under the saxicoline chats. The relationships only of *Geomalia* and *Cataponera* remain frankly indeterminate, but these two are, for the time being, treated as primitive thrushes and placed next to *Chlamydochaera* and *Cochoa*. It needs to be stressed that

One recurrent characteristic of turdids is a distinctly speckled juvenile plumage, as illustrated by this young ***Austral Thrush*** *standing close to its parent. This type of juvenile crypsis is reduced or absent in a few chats, but otherwise universal within the family. It might have helped to bind the family taxonomically as a single entity, were it not for its reappearance in an allied assemblage, the Old World flycatchers (Muscicapidae). Indeed, a growing body of evidence suggests that chats may be better grouped with the Muscicapidae, and only thrush-like by convergence. This is but one example of major shifts in avian systematics, driven by new genetic data, but far from resolved.*

[*Turdus falcklandii falcklandii*, Carcass Island, Falklands. Photo: Tui de Roy/ The Roving Tortoise]

none of these subfamilial allocations is set in stone, and the present sequence is governed mainly by the sharing of characters that may have little or no phylogenetic relevance but which, in the absence of more informed analysis, provide a degree of continuity. Thus, the fact that *Grandala*, *Myophonus* and *Monticola* are blue-plumaged species has in the past been judged as reflecting their close relationship; this potential link is retained, as there is no clear evidence to indicate where they may otherwise be placed.

Bearing in mind the above caveats, the Turdinae subfamily begins with two species, the Sulawesi Thrush (*Cataponera turdoides*) and the Geomalia (*Geomalia heinrichi*), which may not, in fact, be true thrushes. These two species are endemic on the island of Sulawesi, in Indonesia, and typify the peculiarity of that island as the intermediary between two great biogeographical regions. Both scientific names betray their describers' sense that these species were not thrushes. In the first instance, *turdoides* means "thrush-like" but, by implication, not "the genuine article", and repeats the generic name of a widespread group of babblers; in the second, *Geomalia* means "ground malia", the Malia (*Malia grata*) being another Sulawesi endemic most frequently placed in the Timaliidae, the babbler family. There is deep uncertainty about these two extraordinary animals, which exhibit both turdine and timaliine characters, giving rise to the notion that they may be primitive relations of both families. Their placement in the thrushes is based in part on the fact that juveniles of both possess a lightly spotted plumage, a feature not found among the babblers.

Until recently, the cochoas were regarded as oversized chats, but they have now been recognized as true thrushes on the basis of nuclear and mitochondrial DNA sequences. Their remarkable coloration and primitive songs, the latter merely long whistles, suggest a very isolated and probably ancient group, with relict populations scattered through the mountains of Asia from the Himalayas to eastern China and from Indochina to Sumatra and Java. In Borneo, there are no cochoas but, instead, the mysterious Black-breasted Fruithunter (*Chlamydochaera jefferyi*), which was for long thought to be a cuckoo-shrike (Campephagidae) related to the *Lalage* trillers, although it also demonstrates behavioural features suggesting a bulbul (Pycnonotidae), a laughingthrush (Timaliidae) and an oriole (Oriolidae). Recent separate anatomical and biochemical analyses, however, indicate that it is, in fact, a thrush, fairly close to *Cochoa* in genes, structure, appearance and ecology; the cochoas, too, are "fruithunters". The jigsaw-like fit of *Chlamydochaera* between *Cochoa*, in Sumatra and Java, and *Cataponera* and *Geomalia*, in Sulawesi, is convenient, and offers a plausible token of relationship among the four genera.

These intriguing cases from tropical Asia raise the question of the geographical origins of the thrushes and chats. The great majority of species and genera are found today in the Old World. Disallowing the boreal overlaps exhibited by a handful of species, only 68 of the 336 species, just 20%, and eleven, or 18%, of the 60 genera currently recognized are found in the Americas, the latter taken to include Hawaii and Tristan da Cunha. Of the remainder, the great majority are fairly evenly divided between Africa and Eurasia, but with Eurasia slightly ahead, although the scores are blurred by species shared between the two, either as migrants or as residents, and depending on whether north Africa is counted zoogeographically as "Asian". Africa has 101 endemic species and 18 endemic genera, compared with respective totals of 133 and 16 for Eurasia, leaving 26 species shared evenly between the two landmasses as widespread breeders, and five in Australasia. A further species occurs in both Asia and Australasia, another in those two continents and also the south-west Pacific, and one other in Eurasia, Africa and North America. The greatest geographical concentration of turdids appears to be in the Himalayas, where the radiations of *Turdus*, *Zoothera*, *Tarsiger* and *Phoenicurus* are striking. Radiations do not, however, give wholly reliable clues to origins, but in general the balance of likelihood may be that the family arose in Asia around the time of the formation of the Himalayas and rapidly spread through Eurasia and into Africa, making slower progress via what is now the boreal Siberia–Alaska (Bering bridge) connection to reach America.

Without question, *Turdus* is the most successful genus of the family, and indeed, in terms of natural geographical penetration and degree of speciation, perhaps the most successful of any passerine genus in the world. Now that the Varied Thrush (*Ixoreus naevius*) and the Aztec Thrush (*Ridgwayia pinicola*) are no longer treated in *Zoothera*, *Turdus* is the only thrush genus which has become established throughout Africa, Asia and the Americas, and the only one which breeds in the Oriental, Afrotropical, Palearctic, Nearctic and Neotropical Regions. Of its 70 species, eight are confined to Africa, 25 are essentially Asian, and 34 are restricted to the Americas. Despite the elevated number in the

last region, where all except one are in the Neotropics, a New World origin of *Turdus* is implausible. What seems to have happened is a north–south penetration of the American continents by two main turdine ancestors, one giving rise to the endemic New World genus *Catharus* mainly in North and Middle America, and one, *Turdus*, resulting in the widespread occupation of North American secondary habitats by a single species, the American Robin (*Turdus migratorius*), and an equally widespread occupation of South America involving a radiation into two main groups. The first of these two groups consists of large, relatively uniform-plumaged and mainly montane, Andean, species, including, incidentally, two that were previously separated, on the basis of the broader bill, in *Platycichla* but have very recently been shown by Klicka and colleagues to belong in *Turdus*. The second group comprises more typical, mainly lowland thrushes, brown above, and with a streaked throat and whitish vent. The Neotropical species exhibit a constant difference from Palearctic species in having rounder wingtips, reflecting their far more sedentary behaviour, and they have a wider bill than that of Palearctic and Oriental species, suggesting a greater frugivorous habit or, at least, a habit of eating larger fruit.

The Neotropical radiation of *Turdus* is notable for the contrast that it makes with the situation in the Australasian and western Pacific islands. South America is widely known as the "bird continent", yet there was ecological space enough for 33 species of *Turdus*. In Australasia and the Pacific, however, the family's most pioneering species, the Island Thrush (*Turdus poliocephalus*), is very patchily distributed both geographically and altitudinally. J. M. Diamond, who examined the situation on ten islands occupied by this species, observed that it is always confined to avian communities which contain around 30 or fewer species, the range being 23–36 species, with an average of 31, which suggests that it is unable to compete in richer communities. On large, species-rich islands, such as New Guinea, the decline in diversity with elevation yields forest communities of 30 species or fewer only above 2750 m, but the elevational boundary for such levels of diversity lowers progressively with size and remoteness of island. On tiny Tolokiwa, west of New Britain, for example, the Island Thrush appears at 750 m, where the complement has decreased from 40 at sea-level to 23. Inability to compete seems a strange condition for a genus which has proved so successful in South America.

It would be of interest to examine whether the extraordinary degree of plumage variation displayed by the Island Thrush correlates with such variables as elevation and species diversity. A striking feature of the genus *Turdus* is its apparent homogeneity, resulting in recurrent appearances of particular phenotypes: all-black plumages, dark brown plumages and brown-backed, grey-hooded and rufous-breasted plumages appear repeatedly in *Turdus* across its wide range. Even relatively anomalous species can find an unexpected image of themselves, such as West Africa's Gulf of Guinea Thrush (*Turdus olivaceofuscus*) and Peru's Maranon Thrush (*Turdus maranonicus*), or at least a striking homology, as in the case of the White-collared Thrush (*Turdus albocinctus*) of the Himalayas and Rufous-collared Robin (*Turdus rufitorques*) of Central America; and even when appearances may suggest a long isolation, voice can indicate a rather taut assemblage, as in the case of the Gulf of Guinea Thrush, which in some of its phrasings sings very much like the Olive Thrush (*Turdus olivaceus*). Songs of *Turdus* thrushes are not all inspirational, but in general song in this genus is as highly developed as it is in any other in the family and, indeed, in any family of birds; several species are commonly judged to produce what are among the finest songs known to human ears (see Voice, Relationship with Man).

Immediately following the *Turdus* sequence are several species whose outward appearance lays claim to individual generic recognition for each. These are the Tristan Thrush (*Nesocichla eremita*) of Tristan da Cunha, the Forest Thrush (*Cichlherminia lherminieri*) of the Lesser Antilles, and the Groundscraper Thrush (*Psophocichla litsitsirupa*) of mainland Africa. Of these, the least differentiated genetically, according to the findings of Klicka and colleagues, is the Tristan Thrush, which resembles the juvenile of the Austral Thrush (*Turdus falcklandii*), geographically its closest relative. The Tristan Thrush's tongue, however, has evolved a bristled tip to assist it in sucking the eggs of seabirds, and on this basis it seems appropriate to retain the species in its own genus. The same dataset indicates that both *Cichlherminia* and *Psophocichla* are close to *Turdus*, with *Psophocichla* at the same genetic distance from *Turdus* as are several *Zoothera* species; indeed, *Psophocichla* possesses plumage characters that ally it with both these genera.

The genus *Zoothera* is almost as successful as *Turdus* in its geographical spread, and is the only thrush or chat genus having a natural range in Australia, but it is unestablished in the Ameri-

With 70 species distributed in all continents bar Antarctica, Turdus *is the most successful genus in the family, outstripping virtually all other avian genera in its ability to reach far-flung scraps of land, and there diversify. This propensity is best illustrated by the* ***Island Thrush****, a "supertramp" with no less than 49 extant races spread from Sumatra to Samoa. These taxa thrive on islets and mountaintops with depauperate avifaunas, dropping out in more diverse habitats. The race endemic to Christmas Island is relatively dull, but morphological variation throughout the complex is extreme.*

[*Turdus poliocephalus erythropleurus*, Christmas Island, Indian Ocean. Photo: Jean-Paul Ferrero/ Auscape]

For much of their taxonomic history the ***Rufous-throated Thrush*** *and the* ***Black-throated Thrush*** *have been lumped as a single species, the "Dark-throated Thrush". Although they freely interbreed where their ranges meet, producing fertile offspring, they are retained as separate species on the grounds that the hybrid zone is relatively narrow, and either side of this zone the two forms are immediately identifiable by a range of vocal and phenotypic characters, not least the colour of their throats.*

Right: *Turdus atrogularis*, Sayh, Musandam, Oman. Photo: Hanne & Jens Eriksen]

cas. Klicka and colleagues' recent biomolecular evidence, however, suggests that the "scaly thrush species complex", comprising the Common Scaly Thrush (*Zoothera dauma*) and its close relatives, among which are the Long-tailed (*Zoothera dixoni*), Plain-backed (*Zoothera mollissima*) and Dark-sided Thrushes (*Zoothera marginata*) and all Australasian forms, is independently derived, rendering the genus as currently constituted polyphyletic and in need of revision. This is a surprising finding, given that a fairly robust character uniting species in the genus, including taxa in the "scaly thrush complex", is a broad underwing stripe. Moreover, this complex shares with many other *Zoothera* thrushes various traits which, taken together, would certainly seem to imply a single ancestor; these include highly reclusive behaviour, confinement to wet forest interiors, markedly terrestrial foraging habits, and usually simplified, minimized songs. Furthermore, the females and juveniles of the Pied Thrush (*Zoothera wardii*) and the Siberian Thrush (*Zoothera sibirica*), two species outside this complex, have patterned plumage which is strikingly similar to that of the "scaly thrushes".

A key feature of all African *Zoothera* and many Asian ones, present in reduced form in some "scaly thrushes", is a double row of wing spots formed by pale tips of the median and greater upperwing-coverts. Another frequent feature in this genus is a facial pattern that involves parallel dark vertical bars below the eye and along the rear ear-coverts; this, too, is seen in reduced or vestigial form in several "scaly thrushes". Six of the seven African *Zoothera* have orange underparts, as do three of the Asian species, suggesting a link between the continents, and this is reinforced by the remarkable homology of the seventh African species, the Spotted Ground-thrush (*Zoothera guttata*), and Sri Lanka's Spot-winged Thrush (*Zoothera spiloptera*). More distantly related, but by their wing spots clearly so, are the small, handsome *Zoothera* of the wider Sundaic region, which represent a distinct radiation. *Zoothera* thrushes are fairly strictly adapted to ground-foraging in thick forest, and this may explain their rather different body proportions from those of *Turdus*; they are on average shorter-tailed, the tail of most species being 60–74% of the wing length, compared with 70–90% in *Turdus*, and they have a longer bill, equivalent to 19–31% of the wing length as against 11–16% in *Turdus*. Most of the Sundaic species exhibit the same intensely secretive habits as their congeners, but on some islands their inhibitions have been lost. On Flores, for example, the Chestnut-capped Thrush sings from village-hut roofs. Indeed, the song of these red, black and white thrushes is remarkably well developed for *Zoothera*, leading to the heavy exploitation of these species in the bird trade (see Status and Conservation).

Until recently, the Varied Thrush and the Aztec Thrush, species which occupy the mountains of western North and Middle America, were treated in *Zoothera*, largely because they share the bold stripe on the underwing and possess relatively primitive songs. Recent biomolecular work does not closely ally these two taxa but, somewhat unexpectedly, links both to other North American thrushes. Each of these species, and particularly the Aztec Thrush, possesses distinctive plumage features which suggest that assignment to monotypic genera is appropriate; indeed, if they are not *Zoothera*, such treatment would seem essential, since it is clear that neither can be allocated to any current American genus. More detailed analysis may determine whether they relate more to Old World or to New World lineages, between which they are presently placed along with two genera of solitaires, *Cichlopsis* and *Entomodestes*. Several DNA studies have indicated that these last two are convergent on, but entirely unrelated to, "true" solitaires, a notable finding and one which bolsters the possibility that *Ixoreus* and *Ridgwayia* are similarly merely convergent on *Zoothera*.

The rather small, spot-breasted thrushes of America south to the northern Andes constitute a uniform group commonly treated under a single genus, *Catharus*, or divided between two genera, *Catharus* and *Hylocichla*. Debate has washed back and forth over the validity of *Hylocichla*, although it is now widely acknowledged that, if applicable at all, it delineates one species only, the Wood Thrush (*Hylocichla mustelina*). Arguments in favour of the retention of this genus include the Wood Thrush's fairly strong differences in plumage, skeletal structure and behavioural repertoire; arguments against its retention stress that other genera, such as *Turdus*, exhibit greater plumage and skeletal variations, and the fact the behavioural repertoire, sampled sufficiently, is widely shared among other members of this group.

Even so, biomolecular studies tend to indicate that *Hylocichla* is fairly well removed from *Catharus*, and on fine balance it seems better to retain the genus. S. D. Ripley thought that *Catharus* and *Hylocichla* evolved from a second wave of turdine invasions of the Americas, following the one that gave rise to *Cichlherminia* and prior to those involving, as he judged it, *Zoothera* and then *Turdus*. He speculated that *Catharus* thrushes were, in their behaviour and vocalizations, intermediate between the Old World nightingales (*Luscinia*) and true thrushes, but their physical resemblances to the former, which are probably more responsible for the epithet "nightingale-thrush" than are their not always arresting songs, are presumably due merely to convergence. Nevertheless, the painstaking R. Ridgway placed *Catharus* and *Hylocichla* close to the Old World *Erithacus* and *Luscinia*.

Zoothera thrushes are fairly strictly adapted to ground-foraging in thick forest, a specialization which seems to alter the optima for body proportions, resulting in shorter tails and longer bills than most Turdus *thrushes. They are also more dramatically patterned, with a higher incidence of bold scaling or barring. The* ***Common Scaly Thrush*** *seems to fit this general theme rather well, and it therefore comes as some surprise that recent genetic work shows it, and its allies, to be independently derived, rendering the genus polyphyletic and in need of revision. Nevertheless, the "scaly thrush complex" is best retained in* Zoothera *until corroboration of its true position is forthcoming.*

[*Zoothera dauma toratugumi*, Isekawa, Japan. Photo: Hirozo Maki]

The composition and sequence of the third subfamily, Saxicolinae, containing the chats and allies, have always been unstable, and the sequence is likely to remain so for many years yet. Recent independent biomolecular studies by Cibois and colleagues, G. Voelker and G. M. Spellman, and Beresford, much of these still unpublished, have helped to establish that genera such as *Myophonus* and *Monticola*, despite their respective vernacular names of "whistling-thrush" and "rock-thrush" — which are perhaps as much the product as the driver of their long-term classification as true thrushes — belong, in fact, with the chats, along with the shortwings (*Brachypteryx*).

Work on the alethes, carried out by Beresford, has tended to corroborate the notion of a monophyletic "African forest robin assemblage", including the alethes, as proposed 30 years ago by M. P. S. Irwin and P. A. Clancey and supported by, first, H. E. Wolters and, later, F. P. Jensen. Beresford also established the polyphyletic nature of *Alethe*, which she remedied by the erection of *Pseudalethe* for the four uncrested, shorter-legged, dull-patterned species. She further established that these two genera are not close to each other, and that *Alethe* is marginal to the main forest-robin assemblage; pending clarification of their relationships, however, they are currently treated side by side.

Apparently, no DNA research has been undertaken on the three African palm-thrushes in the genus *Cichladusa*, but the traditional view has been to group them with the chats, irrespective of their English name. They have been considered close to both *Alethe* and *Cossypha* but, unlike any African forest robin, they construct mud nests. This factor seems unlikely to be a strong guide to their phylogenetic relationships, but, in the absence of biomolecular analysis, it is a hint that the genus may be far removed from the forest robins. The close association of two species with palm trees is also suggestive of a very different ecological and evolutionary history. On this admittedly weak basis, they are in the present treatment removed to a position outside the main connective sequence of saxicolines.

In Asia, there are several highly discrete genera the status of which has been unclear. The shortwings (*Brachypteryx*) are notable curiosities, with their mouse-like terrestrial habits involving running, rather than hopping, their extreme reclusiveness, their powerful songs and their disclosable white loral spots or brows, the last-mentioned feature recalling the African genera *Pogonocichla* and *Sheppardia*. Early DNA studies apparently overturned the general opinion that they are primitive chats, but later ones have restored them to this position. The degree of uniformity within the genus is, however, now less certain. One species is so distinct in both plumage and voice from other *Brachypteryx* that P. C. Rasmussen has referred it to a monotypic genus; this is Gould's Shortwing (*Heteroxenicus stellatus*). Another taxon, hitherto known as *Brachypteryx major*, the "White-bellied Shortwing", has been judged by her to represent two species, both belonging in the chat genus *Myiomela*: these "new" species are the Nilgiri Blue Robin (*Myiomela major*) and the White-bellied Blue Robin (*Myiomela albiventris*). The Great Shortwing (*Heinrichia calligyna*) of Sulawesi, although often treated in *Brachypteryx*, merits retention in its own genus mainly for its striking size difference.

Two important genera, both of which are generally now judged to be chats despite their English names, are *Myophonus*, the whistling-thrushes, and *Monticola*, the rock-thrushes. These two, taken together with the anomalous Grandala (*Grandala coelicolor*), possibly represent, as *Brachypteryx*, early and heavily modified offshoots of the chats. The whistling-thrushes are particularly puzzling. Large, chunky, dense-plumaged and tough-skinned streamside birds with plush frontal feathering, an iridescent forehead and/or "shoulders" and sometimes other parts, powerful black legs, a hook-tipped bill and, in all except two species, unstreaked juveniles, they form a strongly homogeneous radiation with no obviously close relatives. Nevertheless, their dark blue coloration provides a weak basis on which to group them with other genera in which blue is dominant, such as *Grandala*, *Monticola* and the shortwings, notably *Heinrichia*, which J. Delacour judged to be their closest relative.

Superficially, the Grandala is so odd that it was once even placed in its own family, Grandalidae, and considered by some to be closer to the starlings (Sturnidae) than to the thrushes, or, if a thrush at all, to be most closely related to the bluebirds in the myadestine genus *Sialia*. Its most obviously distinguishing feature, however, is the pronounced elongation of the primaries and shortening of the secondaries, producing a highly aerodynamic wing for long-distance high-elevation nomadism; indeed, among passerine birds, only the swallows (Hirundinidae) surpass it in wing-tip length. This and other unusual features, such as its gregariousness, can now be seen as adaptations to an extreme environment, and not necessarily as signs of profound phylogenetic

*The **Varied Thrush** breeds in dense forests of the western seaboard of North America, from Alaska to California. It has some remarkable plumage features, not least of which is the existence of a rare grey and white morph. Until recently it was merged with* Zoothera*, but the results of biomolecular studies imply that it is more proximately allied to other New World thrushes, such as* Catharus*. As such, its resemblance to* Zoothera *is perhaps merely convergent, though why this convergence should extend as far as the dramatic underwing pattern is difficult to explain. Be that as it may, on the basis of these findings it is now placed in the monotypic genus* Ixoreus*.*

[*Ixoreus naevius*, Washington, USA. Photo: Dave Maslowski/ Maslowski Productions]

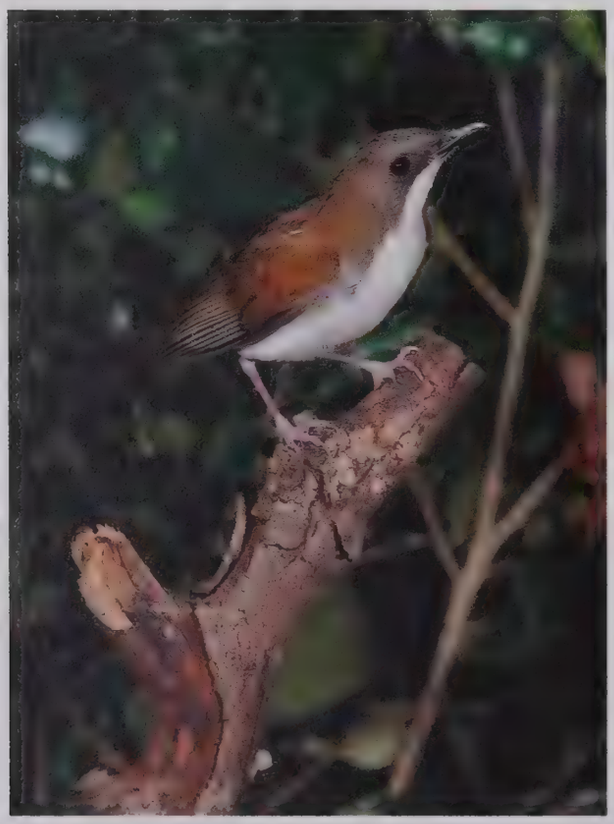
isolation. Recent DNA evidence that the Grandala belongs with the true thrushes in the subfamily Turdinae cannot be dismissed lightly. On the other hand, it exhibits such likeness in female plumage pattern to certain female saxicoline chats, such as the rock-thrushes and even *Rhyacornis*, that in the present treatment it is very provisionally retained as an anomalous chat with no very obvious relatives.

The plumage pattern of the rock-thrushes serves as a bridge to the various species and genera of chat which have a blue or bluish hood, rufous underparts and blue or rufous in the tail. R. Meinertzhagen argued that the genus arose in Asia and subsequently invaded Africa in several waves during glaciation cycles, leaving behind several speciating populations. He judged the Miombo Rock-thrush (*Monticola angolensis*) to be derived from the Blue-capped Rock-thrush (*Monticola cinclorhynchus*), and the Cape Rock-thrush (*Monticola rupestris*) from an early invasion of the Blue Rock-thrush (*Monticola solitarius*); all other African species he believed to be derived from the Common Rock-thrush (*Monticola saxatilis*), of which, indeed, he considered them to be still no more than subspecies. Meinertzhagen posited that, in later glaciations, the Blue Rock-thrush took refuge in south-eastern Asia and then reinvaded the continent northwards and westwards. He did not, however, consider the Malagasy species, which, owing partly to their size and partly to their more arboreal behaviour, have often been treated under a separate genus, *Pseudocossyphus*. Their existence does not undermine his hypothesis of an Asian origin, but it does complicate it: the four Malagasy species resemble the Little Rock-thrush (*Monticola rufocinereus*) in size and the Sentinel Rock-thrush (*Monticola explorator*) in pattern, and presumably radiated from an invasion of the latter.

Common and Little Rock-thrushes have the habit of quivering the tail, suggesting a link to the redstarts (*Phoenicurus*), and tending to validate Meinertzhagen's assessment of the origins of *Monticola*, even if his views of relationships are not reflected in the current species sequence. D. Lack also believed redstarts and rock-thrushes to be close relatives. In plumage, however, the rock-thrushes show some affinity, perhaps merely convergent, with Africa's two *Thamnolaea* cliff-chats, and they occupy the same rocky, hilly habitat as the latter. At least one of the cliff-chats is a typical, but not obligate, user of old mud nests of hirundines, and both are often considered congeneric with *Myrmecocichla*. The *Myrmecocichla* species, however, mostly dig their own holes for nesting, and they have a very upright stance, with a very short but often cocked tail, a curious low buzzing flight, and highly simplified songs. Closely related to both genera, and again often subsumed in *Myrmecocichla*, is *Pentholaea*, consisting of two relatively small, more arboreal "black-chats" which often nest in tree holes. They lack the white wingpanels of *Myrmecocichla*, are more "normal" in shape, and have more elaborate songs. There is a general consensus that these three open-country genera are fairly close to *Cossypha*, the dominant genus within the African assemblage of chats. Nevertheless, the resemblance of *Pentholaea* to certain species of *Oenanthe*, notably the close similarity of the

*The **White-eared Solitaire** is a beautifully marked, upright-perching bird with exclusively arboreal habits. It lives in montane forests of the southern Andes and shares the genus* Entomodestes *with a close relative from further north in the same range. These birds, and the sole member of another Neotropical genus,* Cichlopsis*, are named "solitaires", from which it might be concluded that they belong with their namesakes in the subfamily Myadestinae; an inaccurate deduction, as it happens, because biomolecular studies have shown them to be "true" thrushes, members of the subfamily Turdinae, and merely solitaire-like as a result of convergence.*

[*Entomodestes leucotis*, Manu National Park and Biosphere Reserve, Peru. Photo: Heinz Plenge]



The genus Catharus *contains twelve New World species collectively known as nightingale-thrushes. Their name derives from a supposed resemblance to true Old World nightingales* (Luscinia), *a comparison that applies more accurately to migratory Nearctic members of the genus than to resident Neotropical forms. The* ***Spotted Nightingale-thrush****, a shy terrestrial bird, belongs in the latter category. It is beautifully marked, but difficult to observe as it walks amongst the humid leaf litter of Andean foothill forests.*

[*Catharus dryas ovandensis*, El Triunfo Biosphere Reserve, Chiapas, Mexico. Photo: Patricio Robles Gil/ Sierra Madre]

White-headed Black-chat (*Pentholaea arnotti*) to the Mountain Wheatear (*Oenanthe monticola*), one race of which has an all-black tail, has been considered to indicate a close relationship between these two genera.

Also showing affinities to *Cossypha* is a cluster of species consisting of four monotypic genera, *Pogonocichla*, *Swynnertonia*, *Cossyphicula* and *Stiphrornis*, and a fifth, polytypic genus, the problematic *Sheppardia*. The four monotypic genera are all small, smart, often rather flycatcher-like species, each presenting its own puzzle. *Pogonocichla* is especially intriguing. It is one of two chats in Africa to show, in some subspecies, an unspotted subadult stage between the juvenile and adult plumages; in addition, it has different songs in different parts of its range and, more importantly, two types of piping call which have a patchwork distribution within subspecies, thereby disallowing any easy conclusion with regard to the taxonomic status of the forms. The bill is broad, with marked rictal bristles, evidence of its flycatching behaviour; it has erectile white loral tufts and a distinctive plumage pattern. In contrast, tiny *Swynnertonia*, although often placed adjacent to *Pogonocichla* owing to their similarities in habitat and plumage, has a long thin bill, no rictal bristles and no loral tufts, is sexually dimorphic and feeds on the ground. Curiously, however, it also has a subadult plumage, resembling that of an adult female, and biomolecular analysis indicates that the two genera are, in fact, as close as some past treatments had suggested. Close, too, in genetic terms is *Cossyphicula*. This species is nearest to *Swynnertonia*, despite its resemblance, as its name implies, to a diminutive *Cossypha*, despite the fact that it possesses, as does *Pogonocichla*, a broad-based bill and copious rictal bristles, and despite its song being very similar to that of *Stiphrornis*. The last-mentioned genus is like *Swynnertonia* in having a thin bill, no rictal bristles and an orange-yellow breast, and is like *Pogonocichla* in possessing a white loral spot, albeit an always visible one. In biomolecular analysis, however, it emerges as completely distinct, being closer to *Alethe* and *Cercotrichas* than it is to the great assemblage of "forest robins" focused on *Sheppardia* and *Cossypha*. Nevertheless, pending confirmatory evidence, *Stiphrornis* is retained next to the other monotypic genera with which it appears to have so much in common.

Until recently the genus Alethe *was considered to contain six African species of the humid forest understorey, but recent DNA analysis has shown this grouping to be polyphyletic, requiring the erection of* Pseudalethe *to accommodate four dull-coloured, uncrested, short-legged species, including the* ***White-chested Alethe****. Viewing the data at a higher taxonomic level, the same analysis indicates that all members of the "African forest robin assemblage", including* Alethe *and* Pseudalethe*, share a common ancestor, and thus form a monophyletic grouping which is not reflected in the current sequence.*

[*Pseudalethe fuelleborni*, Chiniziua forest, Mozambique. Photo: Hugh Chittenden]

Species in the genus *Sheppardia*, the radiation of which in Africa has been calibrated as having occurred some 5 million to 3 million years ago, near the Miocene/Pliocene transition, are rather flycatcher-like in appearance and behaviour, having a broad bill and well-developed rictal bristles, but they also feed on the ground and possess relatively long, thin tarsi. They share with *Pogonocichla* an erectile preocular spot, and possess a plain, fairly short tail. Even so, there is some debate about the generic status of certain species, as well as the specific status of others. Bocage's Akalat (*Sheppardia bocagei*) was for long treated in the genus *Cossypha*, largely owing to its dark-centred reddish tail, but it has an erectile preocular spot. Similarly, the Grey-winged Akalat (*Sheppardia polioptera*) has commonly been assigned to *Cossypha*, on the basis of its foraging habits, its skilful flight through the understorey, and its well-developed powers of mimicry, but it, too, has the diagnostic preocular spot, as well as an unpatterned tail, and recent biomolecular work supports its placement within *Sheppardia*. The Gabela Akalat (*Sheppardia gabela*) is a geographical outlier of the genus which lacks the typical orange-rufous coloration, and possesses longer and more pro-

fuse rictal bristles, giving it a very flycatcher-like appearance, from which Clancey judged that it merited recognition in the monotypic subgenus *Gabelatrix*.

DNA work also indicates that three closely related Tanzanian highland species, the Iringa Akalat (*Sheppardia lowei*), the Usambara Akalat (*Sheppardia montana*) and the Rubeho Akalat (*Sheppardia aurantiithorax*), are well separated from other *Sheppardia* and, indeed, from *Cossypha*. Although these comparatively large, dull akalats share the concealed preocular spot, they have relatively sparse rictal bristles and notably long tarsi, and they have previously been placed both in *Alethe* and in a separate genus, *Dryocichloides*. Beresford has demonstrated that *Alethe* is an inappropriate allocation, and pointed out that the type species of *Dryocichloides* was the Olive-flanked Robin-chat (*Cossypha anomala*). This means that, if *anomala* remains in *Cossypha*, a conclusion that her work supports, despite doubts by taxonomists working outside the field of molecular genetics, then the name *Dryocichloides* is unavailable for the three distinctive akalats, and a new genus will be needed in order to signal their lack of affinity with *Sheppardia*.

It is worth mentioning here that these shifting perceptions, of course, have inevitable impacts on the English nomenclature of problematic species. As an example, the Iringa Akalat was formerly known variously as the "Iringa Ground-robin", the "Iringa Alethe" and the "Iringa Robin-chat", and, with the erection of a new genus, yet another new English name for it may be coined. Moreover, and harking back to the first couple of paragraphs dealing with the subfamily Saxicolinae, can a species which has been removed from the genus *Alethe* still be called an alethe? Do we need a name such as "ant-robin" for the "false alethes", those four species now placed in *Pseudalethe*?

Because of its complement of species, a total of 13 in the present arrangement, its geographical spread, and the beauty of its songs and plumages, *Cossypha* is arguably the quintessential African chat genus, the core group against which other African chats and robins are gauged in terms of their degrees of relationship to it. *Cossypha* consists of medium-sized to large, sexually monochromatic chats with long tarsi, the larger species possessing a long graduated tail, and most of them combining dark brown upperparts, orange-rufous underparts and a white supercilium. The key diagnostic character is the rufous tail with dark central feathers. Even so, the group is by no means homogeneous and unproblematic. Archer's Robin-chat (*Cossypha archeri*) and the Mountain Robin-chat (*Cossypha isabellae*) resemble *Sheppardia* in size, dumpy shape, and wing, tail and leg proportions. The former also has a uniformly reddish tail, while the latter's appearance suggests a link to *Cossyphicula* such that Wolters erected for it the genus *Oreocossypha*, which Beresford, incidentally, finds to be tenable. On the other hand, Archer's is very close in appearance, behaviour and voice to the Olive-flanked Robin-chat, and the Mountain Robin-chat appears to form a species pair with Archer's. For the time being, therefore, the two remain in *Cossypha*.

The rocky outcrops of western Angola hold a prize oddity, the dramatic black-and-white Angola Cave-chat (*Xenocopsychus ansorgei*). Distinctive as it is in appearance and ecology, this species bears certain features, including a black head and neck, an elongate white eyebrow and wing-slash, and mostly white underparts, which ally it to one member of *Cossypha*, the White-throated Robin-chat (*Cossypha humeralis*) of neighbouring areas of southern Africa. *Xenocopsychus* has a song like this robin-chat's and makes a similar nest. Its behaviour is very like that of a robin-chat; and its tail pattern, with black central feathers and white, rather than rufous, outer feathers, is particularly telling. Thus, despite its scientific generic name, it is not a geographically misplaced *Copsychus*, a magpie-robin in a foreign land; in reality, it is a highly modified *Cossypha*.

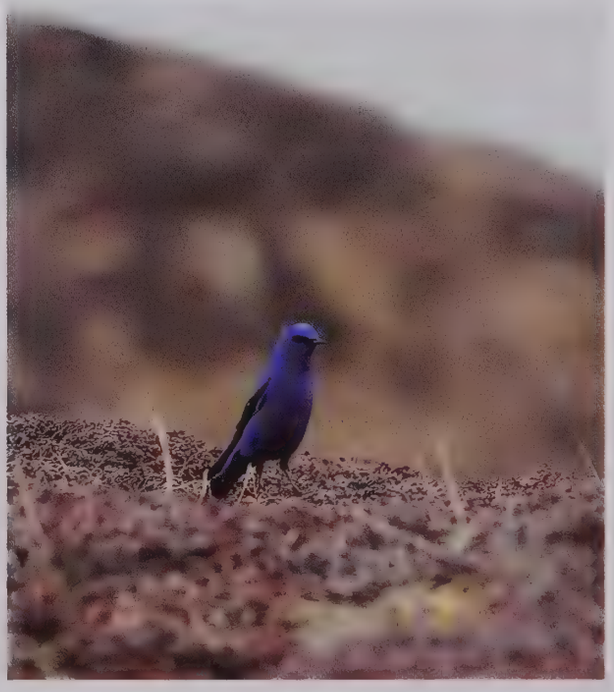
Placed, as is the previous species, in a monotypic genus, but having an Asian breeding distribution, the White-throated Robin (*Irania gutturalis*) bears a striking resemblance to certain species of *Cossypha*, although its all-black tail and its strong migratory behaviour suggest that a close link is unlikely. *Irania* is, however, an intriguing form which may have links to *Phoenicurus* or even *Cercotrichas*, but is probably closest to the robins and nightingales of the genus *Luscinia*. Many of the latter are characterized by having neat, bright underparts, including a distinctive throat coloration and pattern; the Indian Blue Robin (*Luscinia brunnea*) and *Irania* are notably alike in plumage.

The genus *Luscinia* itself is one in which many of the salient qualities of the saxicolines find their most extreme expression. These species are among the most skulking and the most nondescript, but also the most exuberantly coloured and the most exquisitely voiced, of all chats. They are all the size of a sparrow (*Passer*), with a slender bill, reduced rictal bristles, fairly long

The genus Cichladusa *contains an aberrant African trio with uncertain affinities. They have been considered close to some "African forest robins", but unlike any of these they construct mud nests. This is suggestive of a separate evolutionary history, as is the association with palms shown by two of the three species. The* ***Rufous-tailed Palm-thrush****, for example, is commonly found in ivory palm* (Hyphaene) *savanna, as well as oil-palm* (Elaeis) *groves, and it regularly roosts in palm trees. For these reasons, the genus is distanced from the main core sequence of saxicolines until its relationships are clarified by further research.*

[*Cichladusa ruficauda*, Epupa Falls, Kunene River, Namibia. Photo: Geoff McIlleron]

Phylogenies constructed on the basis of biomolecular analysis regularly throw up contradictory results. The Brachypteryx *shortwings, for instance, are traditionally treated as primitive chats, a view rejected by early DNA studies, but supported by more recent work. The shortwings form a discrete Asiatic assemblage of furtive terrestrial species, anomalous as much for their habit of running (not hopping), as for their semi-concealed white loral spots. The predominance of blue in the plumage of males, as shown by this* ***White-browed Shortwing****, prompts their placement alongside* Grandala *and* Myophonus.



[*Brachypteryx montana cruralis*, Doi Inthanon National Park, Thailand. Photo: Bernard Van Elegem]

wings, a medium-length tail and relatively long legs, most or all being adapted to mainly terrestrial foraging on damp ground under heavy vegetation cover. Except in the case of the two nightingales and the Rufous-tailed Robin (*Luscinia sibilans*), the sexes are markedly different, the males having strikingly contrasting underpart patterns, whereas the females are largely brown and cryptic. The "female-plumaged" Thrush Nightingale (*Luscinia luscinia*) and Common Nightingale (*Luscinia megarhynchos*) compensate for their unremarkable appearance by their songs (see Voice, Relationship with Man), but all 13 species, with the single exception of the male Bluethroat (*Luscinia svecica*) when singing, remain exceptionally secretive and difficult to see. Several species have a colourfully patterned tail involving bright lower halves of the outer feathers, a character which points towards *Phoenicurus*, *Oenanthe* and associated genera.

During the last half-century, species in the genera *Luscinia*, *Tarsiger*, *Sheppardia* and *Swynnertonia* were sometimes lumped in *Erithacus*, along with the type species of the latter, the European Robin, and various permutations of this treatment have continued since then, with one or more genera removed. Today, it is generally admitted that the European Robin is in many ways unique and is deserving of monotypic generic status. At the end of the *Luscinia* sequence, however, are two puzzling far eastern insular species, the Japanese Robin (*Luscinia akahige*) and the Ryukyu Robin (*Luscinia komadori*); the colour pattern, notably in the female Japanese Robin, and the demeanour of these two seem most closely to resemble those of the European Robin, and they are therefore frequently treated in *Erithacus*. Nevertheless, on both biogeographical and behavioural grounds, these species seem far more likely to belong with the Chinese radiation that produced the Firethroat (*Luscinia pectardens*), the Rufous-headed Robin (*Luscinia ruficeps*) and the Black-throated Blue Robin (*Luscinia obscura*); further, their blue or pinkish eggs are more typical of *Luscinia* than of *Erithacus*, which has white-based eggs.

Erithacus has softer, more copious plumage than that of *Luscinia*, as well as a less powerful song and structure, less migratory habit and less inhibited, more frenetic demeanour. Its former extension to include *Sheppardia* is best quietly forgotten, as the two genera have little in common beyond a superficially similar plumage coloration. Placement of *Erithacus* between *Luscinia* and *Tarsiger* does, however, reflect the stepped, if only slight, decreases in robustness and terrestrial behaviour shown by the three genera. *Tarsiger*, the bush-robins, are rather delicate, mainly arboreal chats with a fine bill, like that of an Old World warbler (Sylviidae), and striking male plumage patterns. They presumably arose in the Himalayas, where all except one of the five species are still to be found.

The scrub-robin genus *Erythropygia* is decidedly anomalous. Frontally scutellated tarsi, absence of sexual dichromatism, absence of a spotted juvenile plumage, and perhaps also a resemblance in tail posture and pattern to some prinias (*Prinia*), led to its being placed for many years with the Old World warblers, but the strong legs and terrestrial behaviour are robin-like. The long, graduated, white-tipped, steeply cocked tail is a characteristic feature of the scrub-robins. Like the palm-thrushes in *Cichladusa*, which Meinertzhagen thought congeneric, they are mainly brown-and-rufous birds of relatively open, dryland areas, although some species are highly reclusive and generally detectable only by their fine songs. Most species have bold facial patterns and wing mark-

The ***Grandala*** *is so peculiar that it was once classified as the sole occupant of a monotypic family, Grandalidae. Its most unusual features are its extreme primary projection and its gregariousness, but these are now thought to be adaptations to the extreme Himalayan environment, the former a tool for sustained nomadic flight and the latter a response to scarce and patchy resources. Genetic studies place it within the turdine cluster, but it shows enough chat-like features, such as female plumage pattern and habitual wing-flicking, that it is tentatively retained as an anomalous chat without clear origins.*

[*Grandala coelicolor*, Paro Valley, Bhutan. Photo: Roland Seitre]

The whistling-thrushes are large, dense-plumaged, tough-skinned birds. Their bills are stout and hook-tipped, and their plumage is often blue with patches of iridescence. Despite being similar in size to Turdus, *they are probably an early offshoot of the chats. Each of the Greater Sunda islands of Sumatra, Borneo and Java is home to at least one resident form of* Myophonus. *One montane representative in each case was treated as a race of the "Sunda Whistling-thrush", which on the balance of evidence is now thought better split into three separate island species. That on Java thus becomes the* ***Javan Whistling-thrush****, largest and bluest of the trio.*

[*Myophonus glaucinus*, Gunung Gede, Java. Photo: Bernard Van Elegem]

ings. The Black Scrub-robin (*Cercotrichas podobe*) is usually considered congeneric with the other scrub-robins, all then being placed in *Cercotrichas*. It shares with them white spots on the tail tips, but is exceptional for its larger size and almost all-black plumage, and for various reasons seems best isolated in its own separate genus. Further generic splitting of the scrub-robins may be in order: T. B. Oatley has already taken the step of assigning the Brown Scrub-robin (*Erythropygia signata*) and its three supposedly closest relatives in the discarded genus *Tychaedon*, albeit without offering a clear diagnosis, and other changes may be proposed in due course. Song and reclusiveness are both highly developed in these last four species, and their tail movements are less pronounced.

Although there is unlikely to be a strong link between these primarily Afrotropical scrub-robin genera and the predominantly Asian genus *Copsychus*, the association of good song quality with obtrusiveness is also demonstrated well by the White-rumped Shama (*Copsychus malabaricus*). In addition, the Black Scrub-robin finds in the Oriental Magpie-robin (*Copsychus saularis*) an ecologically, behaviourally and visually rather similar counterpart. *Copsychus* are medium-sized, robust, long-tailed, mainly black-and-white chats, some with semi-terrestrial habits. The two species mentioned are the sole representatives of the genus in mainland Asia, the arboreal shama in the south-east and the semi-terrestrial, and very familiar, magpie-robin throughout. Like several other Asian bird genera, however, *Copsychus* has successfully spread through the western Indian Ocean to the Seychelles and Madagascar, and there is a small radiation in the Philippines. A close relative, the monotypic *Trichixos* of the Sundaic forests, resembles the White-rumped Shama but is stouter-billed, with a concealable white supraocular line and a dark-tipped orange-rufous tail.

The genus *Saxicoloides* holds a single species, the Indian Robin (*Saxicoloides fulicatus*), which is superficially sufficiently akin to *Copsychus* in appearance and behaviour to have been mistakenly treated in that genus in the past. The degree of their relatedness is unknown but, most unusually among the chats, the well-developed tarsi of *Saxicoloides* are scutellated, and it has therefore been supposed that the genus represents some form of link to the accentors (Prunellidae), the scutellate tarsi of which have repeatedly been viewed as a key factor disqualifying them from membership of the chats. The bill of *Saxicoloides* is also unusual, being slightly downcurved, the wings are notably pointed, and the tail is long and is rather languorously dipped as the bird hops about on the ground. This species has a merely vestigial song, it nests in holes, and its juveniles possess vague bars and streaks. The true affinities of the Indian Robin are very unclear; the great chronicler of Sri Lankan ornithology, V. Legge, thought them almost timaliine.

The two water-redstart genera, *Chaimarrornis* and *Rhyacornis*, present a simpler problem, albeit one not entirely resolved. There have been various treatments and recommendations, including one that suggests that *Chaimarrornis* belongs in the African cliff-chat genus *Thamnolaea* and, more prosaically but probably more accurately, one that merges both genera in *Phoenicurus*. The water-redstarts are clearly very close to "true" redstarts and have tail coloration and movements which are similar to those of certain *Phoenicurus*. The plumage patterns in both water-redstart genera are, however, highly distinctive, as also, of course, are their ecologies. Whether they are more closely related to each other than to other redstarts, as some authorities have suggested, is unresolved. In the present treatment they are placed one on each side of the major genus *Phoenicurus*, which contains eleven species. This genus is characterized by the rather slender bill, distinct rictal bristles and soft plumage, with the rump and outer tail chestnut in almost all species, and by the distinctive tail actions exhibited by most of its members. *Phoenicurus* is also distinguished by having two species, the Common Redstart (*Phoenicurus phoenicurus*) and the Black Redstart (*Phoenicurus ochruros*), which not infrequently hybridize and produce fertile offspring, and which are maintained as separate species chiefly by their ecological preferences and the greater adaptation of the latter for a terrestrial life.

The monotypic *Hodgsonius* was once considered a shortwing, presumably owing to its largely terrestrial and reclusive habits, but Ripley considered it to provide a likely link between *Phoenicurus* and *Myiomela*, bearing, as it does, characters of both genera. The orange-red sides of the dark, rather long tail recall *Phoenicurus*, while the slaty-blue coloration and skulking habits suggest *Myiomela*. The most widely distributed species of *Myiomela*, the White-tailed Blue Robin (*Myiomela leucura*), substitutes white basal sides of the tail, and, like the two preceding genera, shows a similar pattern of sexual dimorphism. The present composition of the genus *Myiomela* is, however, novel. As noted earlier, and representing another instance of what might be considered shortwing convergence, the bird that is usually called the

"White-bellied Shortwing" and placed in the genus *Brachypteryx* is now believed to consist, in fact, of two *Myiomela* species, the Nilgiri Blue Robin and the White-bellied Blue Robin. Further analysis of the generic placement of these two "new" species is needed, as also is an examination of the differences between *Myiomela* and *Cinclidium*. These two genera have often been united owing to their general conformity of colour, shape and size, and it is notable also that they share with *Myophonus* the shining grey-blue forehead and "shoulder", but the monotypic *Cinclidium* has a long, graduated tail, pale-scaled underparts, and white primary coverts on the underwing. All species in *Hodgsonius*, *Myiomela* and *Cinclidium* are remarkably poorly studied.

In complete contrast, the genus *Saxicola* is among the best known of all the chats, owing in particular to the astonishing success of the Common Stonechat (*Saxicola torquatus*), the only member of the family to breed throughout Africa, Europe and Asia. In terms of plumage, *Saxicola* is a rather disparate assemblage, its eleven species united chiefly by their foraging behaviour. All are compact and upright; all but one, Hodgson's Bushchat (*Saxicola insignis*), are small, with a short, broad-based bill, and, with the sole exception of Jerdon's Bushchat (*Saxicola jerdoni*), all have a short square tail. They feed by flights to the ground or into the air from low to medium-height lookout perches, but, again, there is a single exception, the White-bellied Bushchat (*Saxicola gutturalis*). This last species, from Timor, is sufficiently anomalous to pose the question of whether it belongs in *Saxicola* at all; Timor is an Endemic Bird Area with some great avian curiosities, many deserving renewed taxonomic study. On the other hand, *Saxicola* is the only chat genus other than the *Brachypteryx* and *Heinrichia* shortwings that penetrates east of Wallace's Line and, furthermore, it is the only one, in the form of the Pied Bushchat (*Saxicola caprata*), that breaks across Weber's Line, the median point in the transition zone between the Oriental and Australasian Regions. This latter phenomenon seems, however, to be a very recent development, as the Pied Bushchat has no recorded brood parasites in New Guinea, despite the abundance there of the Brush Cuckoo (*Cacomantis variolosus*), a known parasite of *Saxicola*; moreover, its clutch size in New Guinea, where it lays almost as many eggs as it does in its Palearctic range, is remarkably large for a tropical cup-nester.

It is possible that some Oriental bushchats not obviously derived from the Common Stonechat are more closely allied to *Cercomela* chats than to other *Saxicola*, although *Cercomela* exhibits little or no sexual dichromatism. These are the Pied Bushchat, Jerdon's Bushchat, the Grey Bushchat (*Saxicola ferreus*) and perhaps even the White-bellied Bushchat. Although the males of these species are rather distinctive and certainly different from any *Cercomela*, the females, with a black tail and rufous-buff rump, some with rufous-buff continuing onto the basal outer tail, are very reminiscent of such *Cercomela* as, for example, the Familiar Chat (*Cercomela familiaris*).

Southern Africa's Buff-streaked Chat (*Campicoloides bifasciatus*) is commonly treated as an aberrant *Saxicola*, having much the same pattern, colour and sexual dimorphism as the Common Stonechat, or as an aberrant *Oenanthe*, vaguely resembling the Black-eared Wheatear (*Oenanthe hispanica*) or the Somali Wheatear (*Oenanthe phillipsi*), while its black tail recalls some *Cercomela* chats. A. Tye strongly favoured *Saxicola* as its closest relative and proposed its placement there, but this judgement minimized the significance of the species' unusual egg colour, creamy or buff with heavy reddish-brown freckles. This and its more terrestrial behaviour combine to suggest that treatment of the Buff-streaked Chat in its own monotypic genus remains appropriate, possibly reflecting an ancient lineage within the African chat assemblage, but perhaps indicating a bridge between *Saxicola* and *Oenanthe*.

Similarly, *Cercomela* chats are regarded as a link between *Saxicola* and *Oenanthe*, being more terrestrial than the former and somewhat less so than the latter; one species also suggests a link back to *Phoenicurus*. These chats are small and dull-plumaged, albeit with a rather more distinctive tail. Three of the species have a black tail, hence the name "*Cercomela*". Two have a rufous rump and rufous tail sides with an otherwise black tail, and four have a black tail with white outer feathers in various patterns. Three species from south-western Africa, differing in rump and tail patterns, have the distal part of the inner vane of the outermost primary P9 emarginated, giving rise to the epithet "sickle-winged" and the generic name *Emarginata*, last used by Ripley for the two species in which the feature is most pronounced. One chat commonly treated in *Cercomela* is now returned to its own monotypic genus, *Pinarochroa*, on the basis of its somewhat longer legs and considerably shorter, wheatear-like tail. This is the Moorland Chat (*Pinarochroa sordida*), often referred to as the Sombre Chat.

Oenanthe itself is the largest genus in the chat subfamily, with 21 species recognized in the present, relatively conservative arrangement. Wheatears form a rather homogeneous group of stocky, medium-sized terrestrial chats of open, mainly arid

Thrush-like in shape and hence in name, the members of the genus Monticola *are now generally viewed as saxicoline chats, rather than part of the main thrush lineage. The plumage of most species largely consists of ashy blues, dull chestnut-orange and white. The* ***White-throated Rock-thrush*** *is no exception. It is also fairly typical of Palearctic forms in its migratory nature, breeding in the forests of north-east Asia from Lake Baikal to the Russian Far East, North Korea, and north-east China, then migrating to South-east Asia for the winter. Some individuals, like this one, turn up from time to time as vagrants in Japan.*

[*Monticola gularis*, Isekawa, Japan. Photo: Hirozo Maki]

Monticola *is speciose in both Asia and Africa, which presents complications when trying to determine its origins. One theory holds that an ancestral rock-thrush first appeared in Asia and diversified, followed by repeated invasions of Africa during glaciation cycles, each influx leaving behind a newly speciating population. In this way, the* ***Cape Rock-thrush*** *of southern Africa is supposedly the result of an early invasion by the Blue Rock-thrush* (M. solitarius). *This view has not attracted much support, and certainly is not reflected in the traditional sequence. However it arose, the Cape Rock-thrush exemplifies the African members of the genus, and indeed open-country* Monticola *in general, in being a rotund bird, colourful in a washed-out kind of way, as if bleached by too much sun. Likewise, it is fond of mountainous terrain, and prone to perching prominently on vantage points, such as buildings, boulders and the tops of crags. In some regions it frequents burnt karoo or grassland, and visits seashores down to the intertidal zone.*

[*Monticola rupestris*, northern KwaZulu-Natal near Wakkerstroom (Mpumalanga), South Africa. Photo: Andy & Gill Swash]

The Malagasy rock-thrush radiation was once placed in a separate genus, Pseudocossyphus. *However, despite their small size, and forest-dwelling or scrub-dwelling habits, its members match certain continental* Monticola *species closely in colour pattern, not to mention foraging behaviour, suggesting that the two genera are best merged. The* ***Amber Mountain Rock-thrush****, pictured here, is often treated as a subspecies of the Forest Rock-thrush* (M. sharpei)*, and this may yet prove to be the most appropriate arrangement.*

[*Monticola erythronota*, Montagne d'Ambre National Park, Madagascar. Photo: Roland Seitre]

environments. They have a slender black bill and stout black legs, reduced rictal bristles and a short tail, and almost all are characterized by the possession of neatly delineated, brilliant white on the rump and basal tail sides, "white arse" being the origin of the modern English appellation, although sometimes the white is replaced by buff or rufous. Otherwise, the plumage is commonly sandy, with black ear-coverts or face and wings, or else black and white throughout. Some wheatear species are dimorphic or polymorphic, and the interplay between polymorphism and speciation in this genus is of considerable interest with regard to evolutionary theory. In particular, work led by E. N. Panov has sought to explain the extraordinary circumstance in the Variable Wheatear (*Oenanthe picata*), where it has for years been unclear whether the semi-assortative groupings of its variably appearing populations involve morphs, subspecies or even species. The considerable number of "morphs" exhibited by wheatears appears to be related to the surprising degree of speciation within the genus, which is, in turn, related to the delicate and not necessarily inflexible ecological divisions that have served to divide them. There is much hostile interaction among these species where they overlap geographically. A degree of miscegenation may be inevitable if the barriers between species are basically far more behavioural than they are ecological.

Enicurus, the forktails, seem to remain entirely outside the preceding group of chats. Several characters distinguish them, most notably the deeply bifurcate tail and the remarkable pied plumage. All have pale-coloured legs, greatly reduced songs and streamside-haunting habits. They have not always been regarded as close to the thrushes and chats, and in the past they have been placed in a separate family or subfamily; because the form of their wings is "essentially Timeliine [*sic*]", R. B. Sharpe, in volume four of the *Catalogue of Birds in the British Museum*, published in 1883, classified them as aberrant babblers. In the absence of evidence of a close relationship to any other chats, the seven forktails are deemed to represent a separate tribe.

The problem of species limits in the Turdidae is considerable. Even a cursory review of the species as admitted in the present account suggests that well over 10% have unresolved questions relating to their taxonomic status; merely on the basis of the lists below, which are by no means complete, the family could number as few as 313 species or as many as 381, a startlingly wide margin. These questions fall into two categories. First, there is the issue of whether accepted species merit their taxonomic ranking or should be relegated to the status of subspecies. This is much the less common type of problem, but it still affects many taxa. Second, there is the increasingly frequent tendency to elevate well-differentiated subspecies to species status, decisions based sometimes on traditional arguments relating to biological incompatibility, sometimes on newly determined genetic distances, sometimes on principles derived from a species concept other than the biological, and sometimes on mistaken assumptions over the relevance of large geographical disjunctions.

In the first category, from the standpoint of the arrangement currently adopted, there are a good many species over which real uncertainties or differences of judgement appear to persist, or where arguments in favour of splitting have not been formally set out. In the subfamily Myadestinae, these involve Rufous (*Stizorhina fraseri*) and Finsch's Flycatcher-thrushes (*Stizorhina finschi*), and Black-faced, Varied (*Myadestes coloratus*) and Andean Solitaires (*Myadestes ralloides*). In Turdinae, the same problems relate to the following pairs or groups: Naumann's (*Turdus naumanni*) and Dusky Thrushes (*Turdus eunomus*); Rufous-throated (*Turdus ruficollis*) and Black-throated Thrushes (*Turdus atrogularis*); Common, Tibetan (*Turdus maximus*) and Indian Blackbirds (*Turdus simillimus*); Olive, Taita (*Turdus helleri*) and Somali Thrushes (*Turdus ludoviciae*); Pale-vented (*Turdus obsoletus*), Cocoa (*Turdus fumigatus*) and Hauxwell's Thrushes (*Turdus hauxwelli*); Spectacled (*Turdus nudigenis*) and Ecuadorian Thrushes (*Turdus maculirostris*); Grey-cheeked (*Catharus minimus*) and Bicknell's Thrushes (*Catharus bicknelli*); and in the western Pacific, New Britain (*Zoothera talaseae*), San Cristobal (*Zoothera margaretae*) and Guadalcanal Thrushes (*Zoothera turipavae*). Not surprisingly, the Saxicolinae are afflicted with similar uncertainties over species limits, as illustrated by the following examples: White-tailed (*Alethe diademata*) and Fire-crested Alethes (*Alethe castanea*); Forest (*Monticola sharpei*) and Benson's Rock-thrushes (*Monticola bensoni*); Lowland (*Sheppardia cyornithopsis*) and Equatorial Akalats (*Sheppardia aequatorialis*); Siberian (*Luscinia calliope*) and White-tailed Rubythroats (*Luscinia pectoralis*); Miombo (*Erythropygia barbata*) and Bearded Scrub-robins (*Erythropygia quadrivirgata*); Przevalski's (*Phoenicurus alaschanicus*) and Eversmann's Redstarts (*Phoenicurus erythronotus*); Common and White-tailed Stonechats (*Saxicola leucurus*); Pied (*Oenanthe pleschanka*) and Black-eared Wheatears; Chestnut-rumped (*Oenanthe xanthoprymna*) and Rusty-tailed Wheatears (*Oenanthe chrysopygia*);

and Buff-breasted (*Oenanthe bottae*) and Heuglin's Wheatears (*Oenanthe heuglini*). This yields a total of 44 currently accepted species that might be collapsed into 20.

In the second category, candidates for separation as distinct species are as follows: race *niveiceps* of the Island Thrush, race *smithi* of the Olive Thrush, the nominate race of the Comoro Thrush (*Turdus bewsheri*), race *xanthorhynchus* of the Gulf of Guinea Thrush, race *anthracinus* of the Chiguanco Thrush (*Turdus chiguanco*), race *caucae* of the Black-hooded Thrush (*Turdus olivater*), race *confinis* of the American Robin, races *daguae* and *assimilis* of the White-throated Thrush (*Turdus albicollis*), race *graysoni* of the Rufous-backed Thrush (*Turdus rufopalliatus*), race *subalaris* of the Slaty Thrush (*Turdus nigriceps*), races *ardosiaceus* and *albiventris* of the Red-legged Thrush (*Turdus plumbeus*), race *tanganjicae* of the Abyssinian Ground-thrush (*Zoothera piaggiae*), races *aurea*, *major*, *horsfieldi* and *neilgherriensis* of the Common Scaly Thrush, race *cuneata* of the Bassian Thrush (*Zoothera lunulata*), race *atrigena* of the New Britain Thrush, race *griseiceps* and grey-headed allies of the Orange-billed Nightingale-thrush (*Catharus aurantiirostris*), at least races *goodfellowi* and *floris* of the White-browed Shortwing (*Brachypteryx montana*), races *picta* and *simplex* of the Great Shortwing, race *harterti* of the White-headed Black-chat, race *bensoni* of the East Coast Akalat (*Sheppardia gunningi*), the "northern *poensis* group" of Bocage's Akalat, races *macclounii*, *grotei* and *mbuluensis* of the Olive-flanked Robin-chat, race *tschebaiewi* of the White-tailed Rubythroat, race *superbus* of the European Robin, race *rufilatus* of the Orange-flanked Bush-robin (*Tarsiger cyanurus*), race *formosanus* of the White-browed Bush-robin (*Tarsiger indicus*), race *tongensis* of the Brown Scrub-robin, race *albiventris* of the White-rumped Shama, race *superciliaris* of the White-browed Shama (*Copsychus luzoniensis*), races *spectatrix* and *validior* of the Brown-tailed Chat (*Cercomela scotocerca*), race *seebohmi* of the Northern Wheatear (*Oenanthe oenanthe*) and, finally, subspecies groups *lugentoides*, *lugubris* and *schalowi* of the Mourning Wheatear (*Oenanthe lugens*). This extensive list yields a total of 32 species that might be split into 76 species.

It should be made clear that the species limits adopted in the present arrangement are regarded as appropriate. Relatively few of the possible "lumpings" and "splittings" listed in the preceding paragraphs are, on present evidence, compelling propositions; if they were, they would have been implemented. Even so, judgements may not always appear to be founded on constancy of criteria. For example, the two pairs of Palearctic thrushes *Turdus naumanni–eunomus* and *Turdus ruficollis–atrogularis* are maintained as four species because each is so distinct from its "sibling", despite the two broad areas of intergradation; yet the highly distinctive red-breasted race *philippensis* of the Blue Rock-thrush, which also has a broad area of intergradation with other populations, is retained as a subspecies. The reasons for such seeming contradictions are often too elaborate to detail, yet simply to follow established precedent, if inappropriate, is often a rather unpalatable alternative.

The number of "splittable" species is potentially much larger than is listed above, owing to an increasing preference among some biologists for the delineation of species on the basis of constant clear-cut diagnostic characters, however minor, thereby tending to render subspecies obsolete. On this basis, the Island Thrush alone, given the geographical isolation of each of its races, putatively represents 51 different species. To most authorities such a rearrangement appears implausible, but the Island Thrush is crying out for a detailed evaluation of its characters and distribution in order to enable taxonomists to gauge, at least, whether a single species is involved.

Several other chronic species-level problems exist in the taxonomy of the thrushes and chats which field, museum and laboratory biologists are still far from resolving satisfactorily. The issue of whether the Common Stonechat is one or three species has recently arisen, following biomolecular evidence that the European, Asian and African populations have each been separated for something like a million years. While the three-way split has been adopted with alacrity in some quarters, it is notable that variation *within* each new "species" can be greater than that measured *between* them, rendering diagnosis without DNA analysis highly problematic. In other words, if the Common Stonechat is deemed to represent three species, it is difficult to see why it should not be six, or eight, or more; its retention as one species seems the better option, at least until the variation within the new postulated "species" is properly explored and understood. A problem that has to be faced with this course of action, however, is that, on current genetic evidence, the Fuerteventura Stonechat (*Saxicola dacotiae*) is closer to the European populations of

The genus Thamnolaea *contains two exclusively Afrotropical species of crags and kopjes, inselbergs and gorges, and whatever partially vegetated rocky ground they can find. Their favoured habitats, and their general colour pattern, suggest a relationship with* Monticola, *although this may result from convergence rather than any true affinity. The* ***Mocking Cliff-chat*** *is the more familiar of the duo, occurring extensively through East Africa, and often becoming tame at car-parks and camp-sites. The bird pictured here is accustomed to tourists visiting a famous vantage point over Lake Nakuru.*

[*Thamnolaea cinnamomeiventris subrufipennis*, Lake Nakuru, Kenya. Photo: Stephen Dalton/ NHPA]

The African genus Myrmecocichla, *sometimes collectively known as the anteater-chats, is sometimes broadened to include the* Thamnolaea *cliff-chats too. The catalogue of dissimilarities between them is extensive, however, supporting their separation. The members of* Myrmecocichla *are mostly blackish in plumage, as illustrated by this* **Sooty Chat**, *and they tend to have a much more obviously upright stance, and a shorter tail, sometimes held cocked. Unlike cliff-chats they sing weakly, and prefer level landscapes with scattered shrubs, stumps and termitaria, especially favouring short-sward grassland, across which they travel with an odd buzzing flight, revealing conspicuous white wing-flashes as they go. Moreover, they usually excavate their own nests, while cliff-chats often appropriate the mud-nests of swallows (Hirundinidae).*

[*Myrmecocichla nigra*, Masai Mara National Park, Kenya. Photo: Luiz Claudio Marigo]

the Common Stonechat, and the Reunion Stonechat (*Saxicola tectes*) is closer to the African populations of the latter, than these two populations of the Common Stonechat are to each other. This makes it relatively difficult to continue to regard the island taxa as full species, although there are other ways of looking at the situation.

Other cases in which there is pressure to break down one "large" species into several "smaller" ones are the Common Scaly Thrush and the White-browed Shortwing of eastern Asia. Both the thrush and, at least among its males, the shortwing are rather homogeneous in plumage over their wide ranges, but subtle morphological variations are often backed up by other characters such as song and egg colour. On Mindanao in the Philippines, there are several mountains on which White-browed Shortwings radically alter their songs at a certain elevation, yet ornithologists have so far failed to find any morphological character distinguishing populations at different altitudes. Shortwings are to some degree comparable to the *Scytalopus* tapaculos (Rhinocryptidae) of South America in terms of their reduced wing size and mouse-like habits, factors which imply minimal genetic interchange between isolated populations; it is not impossible that, as with *Scytalopus*, vocalizations and biomolecular studies may reveal that some *Brachypteryx* taxa currently ranked as subspecies will prove to be distinctive enough to merit species status. In Africa there is intractable confusion over the dividing line between the African (*Turdus pelios*) and the Olive Thrushes, and the assignment of some subspecies to one or the other of these two species is still highly unstable. In South America, the Great Thrush (*Turdus fuscater*) and the Chiguanco Thrush approach each other closely in size and appearance, differing where they meet in that the former possesses an eyering; but the Chiguanco Thrush's acquisition of an eyering, in addition to darker coloration, south of the range of the Great Thrush raises the question of whether the subspecies involved, *anthracinus*, belongs in reality with the latter species.

The difficulty with all these cases is in ensuring a sufficiency of material for the evaluator. Such material needs to be of several types: specimens, including eggs and nests, in museum trays and tissue samples in laboratory refrigerators are the most obvious, but recordings in institutional sound archives, photographs on websites, and published field notes, preferably quantified, on behaviour and ecology are also of great use. With species having very large geographical ranges, it is often difficult to obtain or to find adequate samples, and sometimes any at all, from crucial areas where two taxa are thought to be in contact, and in the modern era the situation is compounded by national laws, international treaties and, not infrequently, security problems that render such sampling ever more expensive and logistically challenging. All this indicates the need for ever-increasing levels of co-operation and collaboration among workers in various disciplines, and including the more adventurous birdwatchers, in order to begin to resolve the many outstanding issues in turdid systematics.

Morphological Aspects

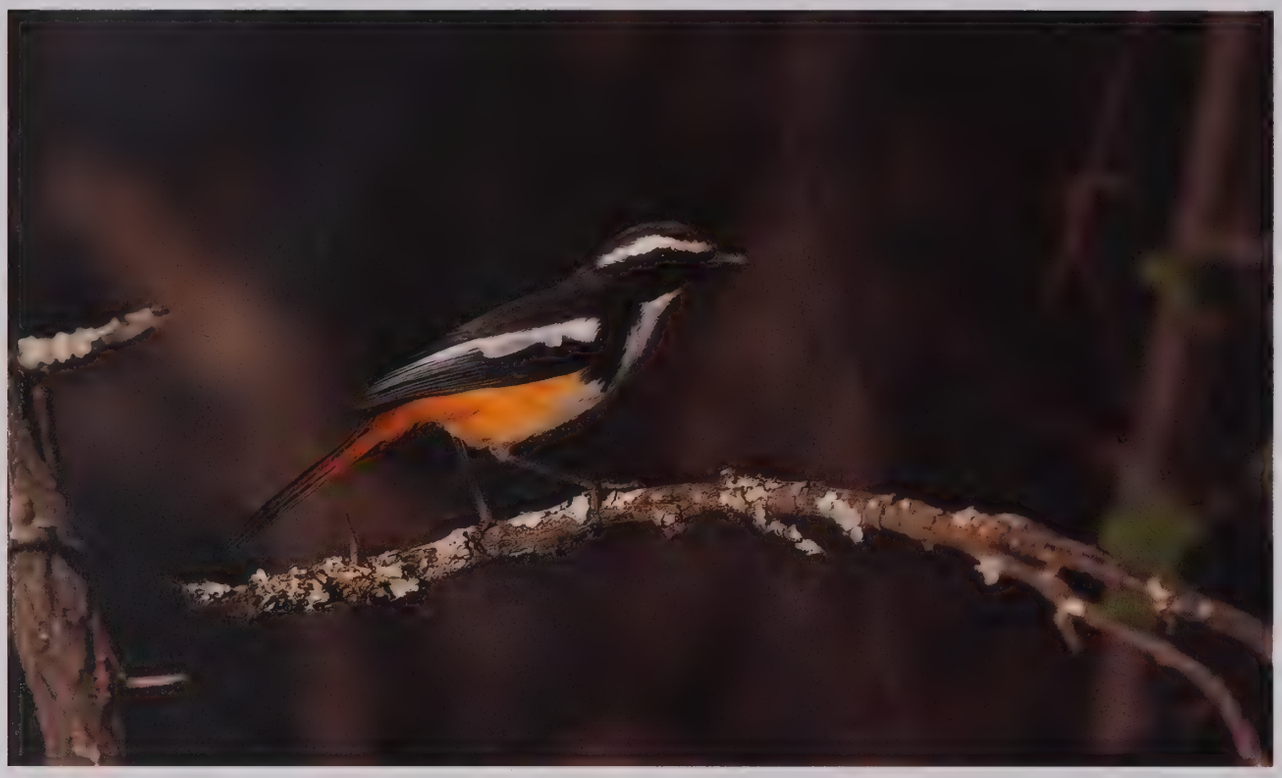
The success of the thrushes and chats in terms of global distribution and habitat occupancy is directly related to their use of the ground and lower vegetation strata and to an associated ecological flexibility that enables them to exploit both invertebrates and fruit. These factors are reflected in the morphology of the family. The species in both main subfamilies are remarkable mainly for their generalized condition, adapted as they are for both terrestrial and arboreal life, for both invertebrate and vegetarian diets; nor are there any elaborate plumage structures or extremes of differentiation between the sexes, suggesting that the standard avian social mating system of "monogamy" and pairwise territoriality applies throughout. Only a single species is highly modified, this being the Grandala, which has swallow-shaped wings (see Systematics), while two, the sicklewing chats of the genus *Cercomela*, have curious structural deviations of one primary. What variations exist in body size, and in the lengths and shapes of the bill, wing, tail and tarsus, reflect the flexible yet strongly consolidated behavioural and ecological adaptations for feeding and breeding to be found throughout the family. As an example, chats inhabiting patches of shrubby thickets and foraging mainly on foot have short rounded wings with high wing-loading, and strong legs and feet, whereas species foraging mainly by aerial hawking or perch-and-pounce techniques in more open areas have longer wings, shorter tarsi and longer rictal bristles.

The myadestine thrushes range in size from 16 cm to 27 cm, and in weight from 24 g to 72 g. These are mainly medium-sized species with relatively short tarsi, a relatively short, broad-based bill with mostly short sparse rictal bristles, and relatively long wings and tail, and they typically adopt more upright postures than those of the true thrushes or chats. They feed mainly by aerial sallying, perch-to-ground flights, or hover-gleaning movements in foliage, taking insects by the first and second techniques and fruit by the third. The long wings and tail provide the necessary manoeuvrability and power; the bill gives the capacity to seize and pluck; and the short legs are responsible for the upright stance and the ability to launch into flight strongly in any direction. In all these aspects a convergence on flycatchers is appar-

The African akalat radiation contains ten species of the humid forest understorey. They are dainty and flycatcher-like in appearance, with broad-based bills and well-developed rictal bristles, but their tarsi are relatively long. Evolutionarily, they seem close to robin-chats (Cossypha)*, differing mainly in shape, as well as in their erectile pre-ocular spots, and shorter, plainer tails. Predicatably, the generic allocation of some forms is debated.* ***Bocage's Akalat****, for instance, is sometimes included in* Cossypha *owing to its dark-centred reddish tail, but its posture and pre-ocular spot argue for inclusion in* Sheppardia.

[*Sheppardia bocagei*, Mutinondo, north-east Zambia. Photo: Johann Grobbelaar]

ent. An interesting phenomenon is recorded for Townsend's Solitaire. This species, when bringing food to its young, carries the items in the upper part of the digestive tract or in a sublingual pouch, the anatomical details of which have not yet been determined. It had been noticed that this species is a relatively infrequent provisioner of food at nests, and this storage mechanism explains why, since it evidently permits a relatively large number of prey items to be delivered in one visit. It is possible that this adaptation, found so far in just this one species, has evolved as a means of avoiding nest predation; nests of *Myadestes* are commonly placed on the ground, where the risks may be correspondingly higher.



Turdine thrushes range in size from 14·5 cm to 33 cm and in weight from 21 g to 175 g. The great majority fall in the respective ranges 20–25 cm and 50–100 g. Only a single species, the Great Thrush is, in some of its races, longer than 30 cm and heavier than 150 g, the next largest species being the Mistle Thrush (*Turdus viscivorus*). These are mainly smallish-medium to medium-large passerines with well-developed tarsi, and with a strong but relatively unspecialized bill, moderately long, deep and broad at the base, and with undeveloped rictal bristles. They have medium-length, fairly rounded wings, which are longer and more pointed in migratory species or populations, increasingly so with length of migration, and a medium-long tail, which is associated with balance during low-carriage terrestrial foraging and with manoeuvrability in escape flight. The smallest species, those in the genus *Catharus*, have proportionately the shortest tail, and the largest ones have the longest tail. Turdine thrushes forage mainly on the ground, for invertebrates, and in low trees, for fruit. Development of the bill as a blade for digging in soft earth is generally countered by its second use in plucking fruit, but two or three members of the "scaly thrush complex", namely the Sri Lanka Scaly Thrush (*Zoothera imbricata*), the Dark-sided Thrush and, in particular, the Long-billed Thrush (*Zoothera monticola*), have a bill that is considerably extended in length and depth, as an adaptation for feeding entirely or almost entirely on soil-living invertebrates. In these species, an accompanying shortening of the tail perhaps reflects the dampness of the conditions in which they operate. At the other end of the scale are the cochoas, which have a relatively short but laterally very broad-based bill, resembling that of the specialized fruit-eating cotingas (Cotingidae), and which are known to subsist on fruits of various sizes.

Subtle differences between ecologically grouped members of the genus *Turdus* illustrate various ways in which evolutionary pressures influence morphology. Forest *Turdus* are on average smaller than non-forest *Turdus*, and tropical lowland species are on average the smallest, while all the very large species are montane. Females are on average slightly smaller than males, but the variation among species is considerable. There is a fairly clear tendency for species which are dimorphic in plumage to be dimorphic also in size, and in this respect there is a relationship with migratory behaviour, as resident species, in which the pair-bond may be long-lasting, exhibit less dimorphism than do migrant species, the males of which commonly acquire new mates each year. Of over 30 species in which the sexes are alike, only

Visually, the ***Forest Robin*** *seems likely to belong alongside* Swynnertonia *and* Pogonocichla*, with which it shares the lower strata of tall African forests. Nevertheless, this impression, imparted by its orange breast, lack of rictal bristles, and permanently visible white loral spot, seems to be inaccurate. When the results of biomolecular analysis are plotted, it clusters closer to* Alethe *and* Cercotrichas *than to the main assemblage of forest robins with which it seems to have so much in common. Pending confirmation of this novel result, the traditional placement of* Stiphrornis *is maintained.*

[*Stiphrornis erythrothorax gabonensis*, near Limbe, Dikolo, Cameroon. Photo: Doug Wechsler/ VIREO]

The thirteen species of robin-chat include some of the most familiar and beautiful of African chats. Some are highly visible forms of semi-open woodlands, gardens and savanna-edge habitats, and all are grouped in the genus Cossypha, *membership of which is somewhat unstable. Quintessentially, they are characterized by a long, graduated, rufous tail with dark central feathers, often coupled with brown upperparts, orange-rufous underparts, a blackish head and a white supercilium. In these regards, the* ***White-throated Robin-chat*** *is fairly typical. Like others, it is sexually monochromatic, and its tarsi are relatively long and slender.*

[*Cossypha humeralis*, Nylsvley, Limpopo, South Africa. Photo: Warwick Tarboton]

four are long-distance migrants, whereas, of around 40 species in which the sexes are slightly or markedly different in plumage, twelve are long-distance migrants. In the Neotropics, all lowland *Turdus* species are alike in plumage, but 75% of the montane ones are slightly to markedly different in plumage, and black tends to occur in the males of dimorphic species. In the Old World, the Somali Thrush and the Yemen Thrush (*Turdus menachensis*) are very long-tailed for the size of the bird, and the Comoro Thrush and the Gulf of Guinea Thrush are very long-legged by comparison with African mainland species.

Saxicoline chats range in size from 11 cm to 35 cm and in weight from 10 g to 231 g, the great majority falling within the ranges 15–20 cm and 20–65 g. A single species, the Blue Whistling-thrush (*Myophonus caeruleus*), emerges as the largest and heaviest of all species in the family, but the figure of 231 g is an exceptionally high weight even for this hulking bird. At the other end of the scale, the Lesser Shortwing (*Brachypteryx leucophris*) is the smallest chat and the Orange-flanked Bush-robin the lightest, but the 10 g recorded for the latter represents another exceptional value and, in reality, several species, such as the smaller shortwings, akalats and stonechats, notably the Gabela Akalat and the Reunion Stonechat, are likely to have lower mean weights. This heterogeneous subfamily demonstrates a much greater span of morphological adaptations than is found in the other two. It includes some very stubby, upright-posturing, short-tailed forms, typified by *Myrmecocichla*, *Cercomela*, *Pinarochroa* and some *Saxicola*, and some svelte, low-carriaged and long-tailed ones, illustrated by some *Cossypha* species, some *Monticola* and the seven *Enicurus* forktails. Some, such as, for instance, the genera *Pogonocichla*, *Cossyphicula* and *Sheppardia*, have a broad-based bill and copious rictal bristles, designed for aerial flycatching, and others, of which *Swynnertonia*, *Cossypha* and *Luscinia* are examples, have a narrow bill and reduced rictal bristles, for gleaning from adjacent substrates. The *Brachypteryx* shortwings are well named for the particular reduction in wing length associated with their highly terrestrial existence, and the concomitant development of their legs, involving both the tarsometatarsus and the tibiotarsus, is striking. The tribally distinct forktails have strongly curved and very pointed claws for gripping surfaces of rocks adjacent to turbulent waters. These and the *Myophonus* whistling-thrushes have dense plumage to counter the cold spray of the streams by which they live.

Turdid plumages cover the entire spectrum of colours, green being supplied by a single species, the Green Cochoa (*Cochoa viridis*). Except for bright breast patches and/or underparts exhibited by a few chat genera, and discounting the opposition of black and white in several others, the colours are, however, rather muted and subtle, as befits birds of understorey habitats (see Habitat).

With the exception of the bluebirds, which are rich blue to powder-blue above, and the Boulder Chat, which is mainly black, the myadestine thrushes present a mixture of black, dark grey to silvery grey, olive-greens and olive-browns, buff and foxy-rufous to chestnut, with white occasionally appearing in the outer tail, wing and face. Again with the exception of the bluebirds, they are sexually uniform in plumage; in the case of the bluebirds, even the juveniles can be sexed by plumage, an unusual condition. Many of them show wingpanels, formed by light bases of the primaries or the primaries and secondaries, which are visible on the upperwing and underwing or, in the case of at least some *Myadestes*, on the underwing only, this latter condition suggesting a link to the turdine genera *Catharus*, such as the Russet Nightingale-thrush (*Catharus occidentalis*), and *Zoothera*.

The true thrushes, the Turdinae, for the most part make use of the same colour palette as the myadestines, but add salmon-pinks and grey-blues, and draw on an immense range of patterns based on key topographical features, including supercilia, ear-covert patches, eyerings, throat stripes, hoods, ventral spotting and scaling, flank colour and spotting, wingbars and wing spots, wingpanels and tail spots. Ventral spotting is a character displayed by most juveniles in this family, and is also a feature of the adults of various species, among them the Song (*Turdus philomelos*) and Mistle Thrushes, the "scaly thrush complex", several other *Zoothera* and *Psophocichla* in the Old World, and *Hylocichla* and most *Catharus* species in the New World. This retention of spotting in adult plumage has been considered evidence of primitive status within the relevant genus and within the family, on the basis that spotted plumage must have been the original pattern of all early thrushes and that any species showing spotted plumage today must be more directly descended from that original stock than are any unspotted species. On the other hand, it seems far more likely that such species are equally directly descended from the ancestral stock but have, presumably for adaptive reasons, retained the original spotting. Certainly, it is implausible that such a plumage would be reacquired by a species after it had evolved a different adult pattern, but it is, of course, important to understand that "primitive" in this context in no way implies maladaptation.

Albinism, which *is* maladaptive, seems to be relatively frequent in the Turdidae, and especially in the genus *Turdus*, as evidenced by the many reports of albinistic and partially albinistic Common Blackbirds from urban areas. These reports may reflect greater observer bias and interest, but more probably indicate a real circumstance, since towns are likely to be relatively safe havens against aerial predators for miscoloured birds, and perhaps are richer in the mutagens that may drive such aberration.

Among the most cryptic of the true thrushes are the twelve species of the "scaly thrush complex". These are the Plain-backed, Long-tailed, Common Scaly, Sri Lanka Scaly, Olive-tailed, Russet-tailed (*Zoothera heinei*), Fawn-breasted (*Zoothera machiki*), New Britain, San Cristobal, Guadalcanal, Long-billed and Dark-sided Thrushes. It is difficult not to think of them as among the most primitive species, given their lack of salient plumage features and their undeveloped vocal qualities. The exaggerated mud-digging bill possessed by the last two species, seen to a lesser degree also in the fairly closely related Sunda Thrush (*Zoothera andromedae*), is, however, evidence of specialization within the group, and it is noteworthy that Common Scaly Thrushes in the Himalayas, where they are sympatric with the Long-billed and Dark-sided Thrushes, have a smaller bill than that of individuals elsewhere in the species' range, evidence of modification through competition with its close relatives.

One of these close relatives, the Bassian Thrush of Australia, appears to have another, considerably more remarkable adaptation. Apart from a regular trembling of the body, thought to stimulate worms, its staple diet, to move towards the surface, J. S. L. Edington reported hearing "a noise similar to a jet of air", coincident with a downward dipping of the vent, whenever a foraging bird stopped and before it probed the earth; and each tremble was accompanied by a "very soft sound somewhat similar to an inhalational gasp". The tentative conclusion was:

> "The louder of the two noises described (that accompanied by a downward movement of the vent) may well be a 'scare tactic' to induce earthworms to contract reflexly (or other prey to move away) and so betray their presence... If the source of the louder noise is assumed to be from the quick passage of air through the vent, then the softer, antecedent noise (each accompanied by a body shiver) might be explained as aerophagia—the gulping of air. Air swallowing would naturally occur more frequently when air was passed more frequently. Such a system would be possible for a bird with a short gut."

A short-gut condition would, in turn, be possible only in a species having an exclusive or virtually exclusive dependence on earthworms, a water-rich, high-protein food resource. The result is easily the most bizarre foraging technique reported for any thrush and, arguably, for any species of bird (see Food and Feeding). This report may also be an indication of the dietary conservatism of the earliest thrushes.

Plumage differences between the sexes of the true thrushes are a common but by no means constant condition. Such dimorphism is most prevalent among species in which the males are strongly marked; this is to be expected, since females undertake more nesting duties than do males and need to remain more cryptic. Thus, in the genus *Catharus* and the African and American branches of the genus *Turdus*, in both of which the males are for the most part relatively plain and cryptic, sexual dichromatism is notably reduced. It is undoubtedly in the Himalayas and adjacent upland areas of China and Tibet that the genus *Turdus* produces its most colourful or strikingly patterned representatives, including the Grey-winged Blackbird (*Turdus boulboul*) and the White-collared, Black-breasted (*Turdus dissimilis*), White-backed (*Turdus kessleri*) and Chestnut Thrushes (*Turdus rubrocanus*), but in all cases the females are considerably less brightly coloured than the males. Rather the same applies in *Zoothera*. African and most Asian species in this genus exhibit little or no difference between the sexes, even though some are exquisitely coloured, but the Pied Thrush in the Himalayas and the Siberian Thrush in north-east Asia show startling contrasts, the males of both being dramatically black and white, whereas females of the two are almost identically brown and buff. Occasional aberrations in female thrush plumage can cause confusion, as was the case with the female Common Blackbird with boldly dappled underparts observed in Switzerland: this was identified as, and for long accepted as, that country's first Naumann's Thrush.

The saxicoline chats are, for many people, among the most attractive species of bird, and this undoubtedly reflects, in the first instance, the quality of their coloration, in terms of both tones and pattern. It is the neatness and smoothness of the plumage, and the elegantly understated way in which patches of brightness are incorporated into, and offset by, the refined shades of

Although the genus Luscinia *contains the dull-plumaged, sexually monomorphic but vocally spectacular nightingales, not all of its members are unreservedly brown. In eastern Asia, in particular, the genus has radiated into a variety of forest-dwelling forms, males of which are characterized by gorgeous plumage. Some are emblazoned with vivid patches of rufous or black, particularly on the gorget, while others possess a blue that is almost glossy in its brilliance. One such is the* ***Siberian Blue Robin****, a relatively slim, terrestrial chat of dense, damp undergrowth. It breeds in northern taiga forests and migrates south to South-east Asia in winter.*

[*Luscinia cyane bochaiensis*, Yamanasi, Japan. Photo: Hirozo Maki]

brown on so much of the upperbody feathering, that make these birds so compelling. Taking males as standard, these species are typically dark brown and rufous, dark and light brown and rufous, grey and rufous, or slate-blue and rufous, all commonly with some black and white, usually on the head or tail; or they are simply black and white. The tail pattern is often distinctive. Major genera, such as *Monticola*, *Cossypha*, *Luscinia*, *Tarsiger*, *Erythropygia*, *Copsychus*, *Phoenicurus* and its close allies, *Saxicola*, *Cercomela*, *Oenanthe* and *Enicurus*, which together account for about 65% of all chats, have well-marked tail patterns involving, in most cases, dark brown and rufous or black and white.

Such tail patterns are used in intraspecific and, perhaps, sometimes interspecific signalling, often being displayed only when the bird flies a short distance. Species in the genera listed above, however, commonly make rapid "involuntary" tail movements such as quivering, wagging, cocking or fanning, sometimes in combination, which serve to emphasize the features of the tail. Some of them, usually the more terrestrial species of semi-open country, such as *Erythropygia*, *Phoenicurus*, *Copsychus* and *Enicurus*, along with *Xenocopsychus* but including also *Saxicola*, add white markings in the wing to complement or reinforce the tail pattern.

Species having an unpatterned tail have other signalling strategies. Two long-tailed ground-haunting taxa, the monotypic *Saxicoloides* and *Cinclidium*, make exaggerated tail movements, including flipping, twisting and cocking, which simply emphasize the length of the tail, but they also have, as do *Myophonus* and *Myiomela*, bright "shoulder" patches which convey information. Other saxicolines may at least partly replace tail movements with wing movements. Examples are open-country species such as those in the genera *Thamnolaea*, *Myrmecocichla* and *Pentholaea*, which have white marks on the head and, especially, the wings, the latter marks often being displayed best as a panel when the bird is in flight or when its flicks open the wings. On the other hand, species frequenting deep-shaded undergrowth, such as the shortwings, share with several other plain-tailed genera, including *Pogonocichla* and *Sheppardia*, a disclosable area of white above the eye which is evidently used as a short-distance signal in certain social contexts, presumably mainly aggression and attraction in connection with, respectively, territorial conflict and breeding. The striking and generically anomalous black-and-white plumage configuration of the Blue-capped Redstart (*Phoenicurus caeruleocephala*) appears to be an appropriate signalling device in the shadowed understorey of the open forest in which it lives. Several other chat species which dwell on or near the ground in heavy cover show similar use of dark blue and white. These are the White-bellied Redstart (*Hodgsonius phaenicuroides*), the Siberian Blue Robin (*Luscinia cyane*) and, as noted, three species of shortwing, including the Great Shortwing.

In this regard, the whistling-thrushes are of particular interest owing to the recent discovery of their apparent or probable ability to signal through ultraviolet (UV) reflectance. Their shiny blue patches are mostly confined to the forehead and "shoulder", although some species possess spangling on the body plumage, too. It seems likely that several other chat genera also use UV reflectance as a signalling mechanism. For example, both *Cinclidium* and *Myiomela* have the same glistening violet-blue forehead and "shoulder" as those of *Myophonus*. Such adaptations are presumably associated with territorial or dominance behaviour in deep shade.

Ultraviolet reflectance is not, however, confined to deep-shade taxa. In the genus *Luscinia*, there are several species which are arguably the most widely appreciated of all the chats, united by their incorporation of bright red into the throat and/or breast patterns of males. These are the Siberian and White-tailed Rubythroats, the Firethroat, the Indian Blue Robin and, most notably, the Bluethroat. This last species complements its chestnut-red throat spot and/or breastband with a bright metallic blue chin and breast which has been found to be UV-reflectant, and which demonstrates the kind of uses to which colour patches of chats are put. In experiments, males with this UV reflectance reduced by sunblock chemicals, but to human eyes appearing

The genus Erithacus *has fluctuated in its limits as much as any over the last few decades. At times it embraces the nightingales and robins in the genus* Luscinia, *or expands still further to include an assortment of vaguely related Asiatic and African genera, such as* Tarsiger *and* Swynnertonia. *Nevertheless, the original "robin", the* ***European Robin****, differs significantly in the quality of its voice, the texture of its plumage, and its overall structure and stance, as well as the colour pattern of its eggs. Nowadays, it is generally reckoned to deserve isolation in a monotypic genus.*

[*Erithacus rubecula*. Photo: F. Rauschenbach/ CD-Gallery]

The taxonomic sequence leading from Luscinia, *through* Erithacus, *to* Tarsiger, *is designed to follow a subtle stepwise progression in behaviour and body structure. Thus, the quintet of species placed in* Tarsiger *occupies the most slender, least terrestrial end of the continuum. The form with the widest distribution, breeding from the Finnish highlands to the mountains of Japan, is the* ***Orange-flanked Bush-robin****. Like its congeners it is a delicately proportioned, mainly arboreal chat with a fine, warbler-like bill. The stunning males are often unobtrusive, except in the breeding season when they rise to prominent song-perches, showing off their colours to good effect.*

[*Tarsiger cyanurus cyanurus*, Kuusamo, Finland. Photo: Markus Varesvuo]

identical to "normal" males, were largely avoided by females, indicating that the females of this species use UV colour vision in mate choice. Moreover, UV reflectance was found to be lower in first-year males than in older ones, indicating that greater sexual status is enjoyed by older males compared with younger males. The spectral purity of the blue feathering is associated not only with age, but also with greater levels of paternity in males' own nests, and with greater fertilization success with females other than the mate. Indeed, the extra-pair offspring in a nest have been found to be more "immunocompetent", which is thought to be an indicator of better health, than are within-pair offspring in the same nest. This suggests that a male's blue breast signals his overall physical and genetic condition and is the basis for a female's mate selection either through forming a pair-bond or, failing this, by surreptitious extra-pair copulation. Almost certainly the same considerations apply to the bluebirds in the subfamily Myadestinae. It has been found that Eastern Bluebird (*Sialia sialis*) males having larger breast patches and brighter plumage provision the nestlings more often, fledge heavier offspring, and pair with females that nest earlier, and that males with more UV hues in their plumage fledge more offspring. These results point to plumage coloration as being a reliable indicator of a male's mate quality and of his potential reproductive success.

Choice of sexual partner by the female may be more critical in temperate climates, perhaps because food is seasonally so abundant that the provisioning of nestlings is something that she can accomplish largely, albeit not typically, on her own. Hence, females of temperate-zone species may be more free to pursue the benefits of extra-pair copulations, because they are less dependent on the paternal care that they might forfeit. In such species in which female choice is strong, one might expect strong sexual differences in plumage. The pattern of sexual plumage dimorphism is not, however, clear-cut. Among the saxicoline genera, the sexes are the same in 16 (*Pseudalethe*, *Alethe*, *Cichladusa*, *Heteroxenicus*, *Pogonocichla*, *Cossyphicula*, *Stiphrornis*, *Sheppardia*, *Cossypha*, *Xenocopsychus*, *Erithacus*, *Erythropygia*, *Cercotrichas*, *Chaimarrornis*, *Cercomela*, *Pinarochroa*); the sexes are different in 17 (*Brachypteryx*, *Heinrichia*, *Grandala*, *Monticola*, *Thamnolaea*, *Pentholaea*, *Swynnertonia*, *Irania*, *Tarsiger*, *Trichixos*, *Saxicoloides*, *Phoenicurus*, *Rhyacornis*, *Hodgsonius*, *Cinclidium*, *Saxicola*, *Campicoloides*); and the situation is mixed in seven (*Myophonus*, *Myrmecocichla*, *Luscinia*, *Copsychus*, *Myiomela*, *Oenanthe*, *Enicurus*). Interestingly, of the 16 sexually undifferentiated genera, as many as 13, or 81%, are almost exclusively African, while twelve (71%) of the 17 sexually differentiated ones are largely or wholly Asian. The explanation for this is probably phylogenetic. At least, there is no obvious correlate of these biases in terms of ecology, including habitat, foraging stratum and technique, and breeding pattern, but only one of the first group, *Erithacus*, is a temperate genus, whereas eight of the second (*Grandala*, *Monticola*, *Irania*, *Tarsiger*, *Phoenicurus*, *Hodgsonius*, *Saxicola* and *Campicoloides*) are at least partially temperate in distribution. Species in which brown and rufous tones are dominant tend to be sexually uniform, while those with black or blue in the plumage, at least that of the male, tend not to be.

Of course, whether the problem of sexual differentiation is as great for the birds themselves as it can be for human eyes is by no means certain. Subtle plumage cues may be perfectly sufficient, irrespective of behavioural ones, but, in the avian world in general, greater explicit monogamy prevails among species showing little or no obvious sexual difference in plumage.

One subtle cue, involving neither plumage nor a sexually monochromatic species, but still evidence of an interesting discriminatory capacity, concerns the bill coloration of the Common Blackbird. Again, this appears to be an important but involuntary, and therefore honest, signal of individual health. Male Common Blackbirds possessing a more orange bill are chosen by females in better body condition, and enjoy higher reproductive success than do yellower-billed individuals. Males with a brighter bill also seem to pose a more objectionable threat as rivals, since mounted male blackbirds having a more deeply orange bill are more heavily attacked by neighbouring males than are those with a merely yellow bill. The explanation is neat. Carotenoids that colour the male's bill also perform an important function in the immune system, notably as free-radical scavengers that reduce oxidative stress on cells. Hence, a male with a deep yellow or orange-tinged bill is honestly signalling his physical and genetic quality as a prospective mate, since he has sufficient carotenoids to produce a bright signal over and above his requirements for immune defence. In feathers, such colours reflect state of health at the previous moult, but carotenoids circu-

At its most inclusive, the genus Cercotrichas *contains ten species of scrub-robin, most of which are largely terrestrial birds with long, steeply cocked tails and frontally scutellated tarsi. These features, plus the absence of a spotted juvenile plumage, led to them being placed with the sylviid warblers for many years. Although relatively homogeneous, the group is now broken into two, with all but one species removed to* Erythropygia. *This could potentially be further subdivided into four long-billed tall-forest species and five shorter-billed scrubland species, the latter typified by the* ***Red-backed Scrub-robin****, a common bird in drier habitats of East Africa.*

[*Erythopygia leucophrys*, Kenya.

lating in bare parts may change in concentration over short time periods, thus giving accurate, up-to-date information about a male's condition. In the case of the yellow bill of male Common Blackbirds, the yellow or orange colour has been found to decrease rapidly in intensity following the experimental activation of their immune systems.

In carotenoid-based coloration, males cannot "bluff" at being of superior quality than they really are, since they do not have the resources at their disposal. This is a situation shared with the male Black Wheatear (*Oenanthe leucura*), the extravagant behavioural display of which involves the collecting of stones and the placing of them in the vicinity of the nest, while the female is present. This display is energetically costly, and only the healthiest males can collect large stones, which may weigh a quarter of the male's own body mass; as many as 10 kg of stones may be accumulated in a season. Calculations suggest that individual stone-carrying trips involve a muscular power output of 400 W per kg, the largest expected for any species of bird. The male's wing morphology is specially adapted for carrying heavy loads, with a low wing-loading compared with that of the female. Males carrying the greatest loads have the lowest wing-loading and appear to be in better health, since they were shown to be better able to defend themselves against an experimentally simulated infection than were males with lighter piles of stones to their credit.

This does not necessarily mean, however, that male turdids are always larger, heavier and more powerful than the females. In the case of some South American *Turdus* thrushes and the Andean Solitaire, at least, there seems to be a trend for females to be marginally heavier than males, although this needs to be formally evaluated. Weights of all species can change dramatically with circumstance, and on a daily basis as much as a seasonal one, as the following examples demonstrate. The White-chested Alethe (*Pseudalethe fuelleborni*) is heavy at the start of the breeding season, light while feeding young, and heavy again when moulting; the weight loss during the brood-feeding stage is due to the necessary diversion of limited resources by the parents. The current lowest and highest known weights of Swainson's Thrush (*Catharus ustulatus*), 25 g and 31 g, respectively, were taken from the same individual six days apart, before it resumed its spring migration. As a final example, the usual weight range for a healthy adult Fieldfare (*Turdus pilaris*), at least during the winter, is 105–115 g, but individuals weighing up to 140 g and more have been recorded. A weight of around 65 g, approaching 55% of the upper limit of its normal body mass, is regarded as a critical threshold for this species; below this level, Fieldfares have relatively little chance of survival without an immediate improvement in condition.

High weight almost invariably correlates with good body condition, and heavier individuals in a population are likely to be socially dominant and more capable of surviving adverse short-term conditions. Nevertheless, a study of fat levels in Common Blackbirds wintering in Italy did not reveal greater survival, ei-

Like the Hypsipetes *bulbuls, the genus* Copsychus *is largely Asiatic but representatives have colonized Indian Ocean islands as far afield as Madagascar. Although treated as a single entity, the genus is subdivided by English name, the shorter-tailed species being called "magpie-robins", and the longer-tailed species "shamas". The* ***White-rumped Shama*** *is typical of the latter in being less brazen and terrestrial, and more a reclusive songster of the humid forest understorey. So beautiful and powerful is its voice, in fact, that it is one of the most popular cage-birds in South-east Asia.*

[*Copsychus malabaricus interpositus*, Khao Yai National Park, Thailand.
Photo: Bernard Van Elegem]

*The **Indian Robin** has often been included within* Copsychus *on account of similarities in stance and plumage. Its well-developed and scutellate tarsi are unique, however, as are the slight decurvature of the bill and the oddly pointed wings. In addition, the tail is differently employed, being dipped in a leisurely manner when hopping about on the ground, rather than cocked more jauntily. These anomalies justify its placement in a monotypic genus and hint at a phylogenetic background perhaps rather remote from the magpie-robins; they are also responsible for the suggestion that it is actually a babbler (Timaliidae), or a bridge towards the accentors (Prunellidae).*

[*Saxicoloides fulicatus*, India. Photo: Konrad Wothe]

ther within or between years, among those with higher reserves; this was either because the environment in Italy is not harsh enough to test the blackbirds' endurance or because heavy, and hence presumably slower, individuals run greater risks of predation. Such persistent environmental checks and balances lie behind the subtle differences in body size that can evolve over long periods in widespread species. American Robins, for example, are smallest in the warm, humid eastern USA, and largest in the high, cool and dry Rocky Mountains, northern Great Plains and northern deserts, and individuals in these latter regions have more pointed wings. This species' bill length varies concomitantly with general size, except that, for whatever reason, the longest bills are found in the isolated population in the mountains of southern Baja California, in west Mexico. The legs are relatively short and the plumage pale in Mexico, whereas these morphological characters are, respectively, long and dark in the cool maritime forests of Newfoundland, in east Canada. Thus, despite Gloger's Rule, the darkest plumages of the American Robin are not in the most humid regions, the south-eastern USA, but, rather, in cool areas where air saturation is high.

Size and coloration of thrushes also vary slightly with age. Adult Fieldfares tend to be marginally larger than first-year birds, the difference between old and young males being more pronounced than that between old and young females. The same is true of Common Blackbirds, using wing length as an indicator. In some species of chat, first-year males are much like females, and they often breed in this plumage. The same has been observed for an increasing number of species in the genus *Turdus*, but for these, although it is not so rare a phenomenon as was once thought, it is still very uncommon. In contrast, it is the norm for Black Redstarts, but there is as yet no explanation of why up to 90% of first-year males of this species retain female-type plumage even though they enter the breeding population. Most such birds are marginalized in suboptimal habitats and achieve poor reproductive success, whereas first-year birds with male-like plumage fare much better. As with yearling Bluethroats and their lower levels of UV reflectance, there may be ineluctable physiological constraints on these young redstarts which inhibit the rapid acquisition of full male characteristics.

Adult thrushes and chats, at least in temperate climates, undergo one complete moult annually, involving the replacement of all feathers in the weeks following the conclusion of breeding. In some species of apparently only two genera, *Monticola* and *Luscinia*, this moult produces a moderately distinct non-breeding plumage, in which the bold colours of the underparts are partly obscured by buff feather tips. Details of this moult process are fundamentally the same as those for all passerines. The replacement of the body feathers proceeds rather protractedly in tandem with that of the flight-feathers. The flight-feathers are moulted individually or in groups of two or three, beginning with the innermost primary, P1, and continuing outwards symmetrically to the wingtip, with P10 last. Replacement of the tertials and median wing-coverts is slightly staggered behind the primary moult, and is followed by the shedding of the outer greater coverts and then the inner coverts. Moult of the secondaries begins only when the primary moult is well advanced, and proceeds in the opposite direction, from the outermost secondary inwards towards the already replaced tertials. Replacement of the tail feathers and the tail-coverts commences soon after the start of the primary moult, the feathers being replaced from the central ones outwards, not always symmetrically, and is completed, at least in temperate species, in about 3–4 weeks. Altogether, however, the duration of the post-breeding moult is around twice as long, the contour feathers of the body often taking 7–8 weeks to be fully replaced. In the case of the Northern Wheatear, females may sometimes be two weeks later than males in the timing of the moult, and doubtless certain other species show similar variations.

In the tropics, the process may be much more staggered and protracted. The mean duration of individual moult of 17 White-chested Alethes was 176 days. Moreover, it commonly overlaps partly with the reproductive cycle. In South Africa, for example, about 4% of adult Cape Robin-chats (*Cossypha caffra*) in the south-western Cape, a winter-rainfall region, begin to moult as early as late September, and another 20% in October, but the majority start in November and have completed the primary moult by early February. In summer-rainfall areas, the moult probably commences at least two months later and is often not completed until April.

The juvenile moult, from typically spotted plumage into first-year dress, begins slightly later than that of adults. It is normally only partial, involving a proportion of body feathers and wing-coverts and not extending to the flight-feathers or tail feathers, although juveniles of some tropical species can undergo a complete moult. Early and more southerly broods of some species

The typical redstarts belong in Phoenicurus, *a genus containing eleven species with Palearctic breeding ranges. When foraging, they employ sit-and-wait tactics, and for this reason they tend to perch with an upright stance, like flycatchers (Muscicapidae), and their slender bills are surrounded by distinct rictal bristles. Another recurrent feature, and that which gave rise to their name, is a fiery orange rump and outertail. In most species the tail itself is shivered diagnostically. Some redstarts breed in deep forests, others in scrub, and a few, including* ***Güldenstädt's Redstart****, restrict themselves to bare terrain above the tree-line.*

[*Phoenicurus erythrogastrus grandis*, Yoye-Tso, Ladakh, India. Photo: Otto Pfister]

often replace a larger number of greater coverts than do later or more northerly ones. In the Northern Wheatear, this moult commences at about the sixth week and lasts until the eleventh week, and is thus completed in approximately 4–5 weeks. Similarly, the White-throated Robin-chat acquires an adult plumage pattern in the tenth to eleventh week of life. By way of contrast, the moult of the juvenile Rufous-capped Robin-chat (*Cossypha natalensis*) extends over three months. Juveniles generally leave the natal territory before commencing moult, which is undertaken in silence and seclusion. Following this moult, age determination of first-year and adult birds is often dependent on the colour and degree of abrasion of the fringes of the wing-coverts. In the genus *Turdus*, at least, adults and first-years can be distinguished by the appearance of the secondary coverts, the immature forms of which are, in almost all cases, retained for the year from the post-juvenile until the first post-breeding moult.

Most passerines have no pre-breeding moult, and any increases in the intensity of coloration of breeding individuals are due to abrasion. There are, however, some exceptions. Some temperate species, both as adults and as first-years, have a partial moult prior to the onset of breeding during which they replace some of the body feathers and wing-coverts. This moult, which is much less obvious or intensive than the post-breeding moult, can commence in January and continue into early April, and for several *Turdus* thrushes it proceeds gradually throughout the winter months. In the case of the Siberian Blue Robin, the wings and tail are not moulted in winter, but a complete moult of the body plumage takes place from November, proceeding gradually until February and then becoming intensive in March–April. Migrant species usually have to divert energy first into the growth of feathers and then into fat deposition, although experiments with Bluethroats demonstrate that, if constrained, they can achieve both. Tropical species such as the White-chested Alethe can, as noted above, regain weight during the moult, since the requirement for strong new feathers prior to migration is not present and the whole process can therefore be extended.

Habitat

The span of habitats utilized by the thrush family is reflected in the vastness of its geographical spread. What other family of birds has representatives billeted in the depths of many of the world's tropical and temperate forests, in the harshest deserts of the Old World, in the heart of many industrialized cities, on some of the remotest islands of the three main oceans, above 5000 m in African and Asian mountains, and in the high-Arctic tundra? Only in wetlands can the thrushes and chats be said to have failed, not having the lightness of body and the flexibility of feet to perch in perpendicular vegetation, for they are, emphatically, birds with strong terrestrial habits and thus, for the most part, unadapted for life in wetlands. Even so, streamsides are used by whistling-thrushes, water-redstarts and forktails, damp fringes by the genus *Luscinia*, and intertidal shorelines by the Familiar Chat, the Tristan Thrush and, more occasionally, others, including various European *Turdus* species.

Very possibly the thrushes arose as forest birds, living dual lives, as many still do today, on the shaded forest floor, seeking invertebrate food, and in the higher parts of trees, where they sing, nest, take fruit and find refuge. This duality of terrestrial and arboreal existence is the key to the family's success, for with it came the capacity to move into ever more open, disturbed habitats, and eventually, in the case of some species and genera, to replace the shelter provided by trees with that offered by rocks and cliffs. Indeed, many of the commonest and most successful thrushes on earth today are adapted to the interface between wooded and open country, and have probably greatly profited from the anthropogenic fragmentation of continuous landscapes, mainly by forest incursions but also by the planting of copses, orchards and hedgerows in extensive grassland areas. Examples are, in the Turdinae, the Common Blackbird, the American Robin, the Mistle Thrush, the Redwing (*Turdus iliacus*), the Fieldfare, the Clay-coloured Thrush (*Turdus grayi*), the Great Thrush, the Rufous-bellied Thrush (*Turdus rufiventris*), the Austral Thrush, the Olive Thrush, Naumann's and Dusky Thrushes, and Rufous-throated and Black-throated Thrushes; in the Saxicolinae, one could mention such species as the White-browed Robin-chat (*Cossypha heuglini*) and the Oriental Magpie-robin. The modern adjustments of the Oriental Magpie-robin, which probably originated in the light forest of the subtropical belt, were wryly remarked upon by H. R. Caldwell and J. C. Caldwell in China: "It is one of the inconsistencies of nature, being beautiful and trim, graceful and proud to extremes, yet given to visit every dung pit and place of filth in the community". Some of these changes have taken place

Tacked on to the end of the "true" redstarts in the taxonomic sequence are the water-redstarts in the genus Rhyacornis. *These two species seem closely related to* Phoenicurus, *judging by their similar structure and behaviour, although their tail is habitually waved or flashed open, rather than briefly shivered. As their name suggests, both species are strictly tied to watercourses: the* ***Plumbeous Water-redstart*** *is rarely seen away from the banks of narrow clear-water streams or broader torrents, where it sallies from low perches, walks along banks, and even wades in the shallows in search of water-borne prey.*

[*Rhyacornis fuliginosa fuliginosa*, Corbett National Park, India. Photo: Konrad Wothe]

very recently: the Common Blackbird did not begin to invade cities until the mid-nineteenth century, and there are areas in the south-east of its range where this process is still in train.

When the Anglo-Saxons called the Fieldfare *feldefare* they meant "field-traveller", which is a good description of the bird's habits, so often seeming to be on the move over the open ground that the early farmers of Britain had created in the island's then extensive forests. The name does, however, miss an important point: that the species is no less dependent on the forest adjacent to the fields for shelter at night and for cover from predators by day. Indeed, trees and bushes, although not necessarily many or large, are crucial components of the habitat of the great majority of thrushes and chats. The family occupies the spectrum of wooded habitats from tall primary forest down to the lowest scrub, and most turdids exploiting open fields and grassland almost always stay within a minute or two's flying distance of cover. The distribution of the family through this spectrum is not one of greatest abundance in primary forest and least abundance in low scrub. The proportion of species in primary forest is not particularly high, but increases substantially with secondary and edge habitats. This is because of the high seasonal use made of berries and fruit, which are temporarily much more abundant in regenerating areas. Primary forest holds various species of understorey-haunting chat, but the proportion of chats surpasses that of true thrushes as the canopy diminishes in height and breaks into patchy scrub and shrubbery, until eventually, when only scattered bushes remain, only saxicolines are left.

The myadestine thrushes, being the least terrestrial, are the most strongly bound to trees, and all of them, even the Boulder Chat, require forest, forest edge, woodland or parkland. Whether such habitat selection enhances the view that they are the most primitive turdids is a matter of debate. Certainly, the true thrushes, those in the subfamily Turdinae, are far more flexible and extend from forest into open lands with adjacent tree cover, and a very few species, or populations of species, have ventured farther. The Ring Ouzel (*Turdus torquatus*) can survive on heathland and moorland entirely without trees, although this is unusual and, in any case, applies only in Britain and only in the summer; equally, the Island Thrush in the Snow Mountains of New Guinea has substituted rock and cliff cover for trees, but this switch applies only to this single population. Similarly, the Austral Thrush substitutes tussac grass for tree cover on some islands in the Falkands, and the Tristan Thrush apparently does likewise in some parts of Tristan da Cunha. The saxicoline chats, however, have achieved far greater emancipation in a number of taxa, namely *Grandala*, several species of *Monticola*, *Myrmecocichla*, *Chaimarrornis*, some species or populations of *Saxicola*, *Campicoloides*, most *Cercomela* species, *Pinarochroa* and most of the *Oenanthe* species. Of all the saxicolines, perhaps as many as 40 species, or 22%, of which about half are wheatears, are not dependent on trees, although the Grandala will, perhaps facultatively, visit orchard trees in autumn.

Habitat selection in birds is driven by several factors intrinsic to the birds themselves, principally the need for appropriate

The genus Cinclidium *has recently been disrupted because the type species, the Long-tailed Blue Robin* (C. frontale), *is now deemed sufficiently distinctive to warrant its own private genus. This leaves two erstwhile members, plus two new recruits, to populate the resurrected genus* Myiomela. *The Javan and Sumatran form, the* ***Sunda Blue Robin****, is typical of this quartet in its dark blue plumage with paler highlights, and its fondness for hiding away in the gloomy understorey of humid submontane forests. It is usually seen on pathside perches, a metre or so up, but it sometimes forages on the ground.*

[*Myiomela diana*. Photo: Roland Seitre]

space in which to feed, to breed, to sing and to shelter, and by several extrinsic factors, including interspecific competition, predation pressure and disturbance levels. A species' niche width, the degree of its ecological flexibility, is a measure of the stability and predictability of its habitat, but is very difficult to assess. For the Turdidae, the combined use of ground and perch has, as indicated, been highly liberating in terms of ecological radiation and niche occupancy, and their levels of specialization, in terms of year-round dependency on one or a few key resources, are, for the most part, not acute. There are a few examples of the latter. Bicknell's Thrush appears to select high-density stands of balsam fir (*Abies balsamea*), leaving other areas of forest within its small range empty, even though they are also empty of its close congeners; and two of the three *Cichladusa* palm-thrushes have a particular but not obligate association with various African palm trees. In Africa, the White-chested Alethe, in order to breed successfully, must have access to army ants, preferably with an ant colony on its territory or else in adjacent areas; similarly, the Northern Anteater-chat (*Myrmecocichla aethiops*) normally requires termitaria as a component of its habitat. It may well be, however, that the most specialized species of all are the least tree-dependent group, the wheatears, since habitat selection and foraging niche in this genus seem to be determined by extraordinarily subtle differences. These are discussed further at the end of this section.

Among forest-dwelling thrushes, specialization is in part definable by sensitivity to habitat alteration. For several species, such alteration is primarily and simply a matter of habitat fragmentation. The Varied Thrush, for example, responds poorly to discontinuity in old-growth stands, and is almost invariably absent from patches less than 16 hectares in extent, even if conditions are apparently suitable in all other respects. The reasons for this are not clear, but a similar phenomenon in another North American turdine, the Wood Thrush, is explicable in terms of increased mammalian and avian predation pressure. In one study of this species, 86% of nests in continuous forest were successful, compared with 72% in large fragments of more than 100 hectares, and 43% in fragments smaller than 80 hectares; rates of predation were only 10% within the continuous forest and 22% in large fragments, but as much as 56% in small fragments. Higher predation levels in forest fragments suggest that most predators are species of the forest edge and/or that many benefit from anthropogenic conditions on the periphery of fragments. In the case of the Varied Thrush, predation may have no relevance, and the problem may relate, instead, to home-range size and foraging-substrate availability; even though "territories" may be as small as 7 hectares, it is possible that this species requires far larger areas over which to collect food.

Even when forest cover is continuous, however, Wood Thrushes do not escape the risks of predation, and distinct changes in use of forest habitat occur with changes in this risk. Of 61 radio-tagged adults in one forest in northern Virginia, 30 remained for the full two months after breeding, during which time they underwent the complete post-breeding moult (see Morphological Aspects). Of these 30, eleven remained on their territories, while 19 moved to stands of deciduous saplings adjacent to or up to 7 km from their territories. From this, it appeared that the thrushes were selecting vegetation the structural attributes of which, such as density of the understorey, gave them greater protection against predation, presumably by raptors. Wing and tail moult inevitably result in slightly impaired flight efficiency, so the use at this time of screening vegetation, even if possibly less suitable in terms of foraging opportunities, would help to compensate for the birds' temporarily increased vulnerability. Meanwhile, the juvenile Wood Thrushes also moved to patches with a dense understorey, dividing their time before later August among (a) second-growth scrub/deciduous sapling sites located along forest borders and abandoned farms, (b) deciduous forest damaged by gypsy moth (*Lymantria dispar*) infestation, and (c) Virginia pine (*Pinus virginianus*) forest with a heavy deciduous understorey. Such cover is doubtless valuable to juveniles, which are inevitably less experienced than are the adults, but, in contrast to the latter, their flight-feathers are new and complete at this stage, so that, in their case, the greater benefit of using such habitat probably lies in the high density of fruit then to be found in it. Either way, it is instructive to conservationists that simply to focus all effort on preserving open-understorey forest, the Wood Thrush's main breeding habitat, would clearly be a mistake. Gratifyingly, a parallel, independent study of Wood Thrushes in southern Missouri reached the same conclusion: in large tracts of mature deciduous forest, a mosaic of early-successional and mid-successional forest stands, along with mature riparian forest, is essential in providing both breeding and post-dispersal habitat.

Multiple use of habitat over the breeding season is also important in the breeding success of the White-throated Thrush. Recent work in Costa Rica, again using radiotelemetry, found

*The **Common Stonechat** has successfully colonized the Palearctic from the British Isles to Japan, and Africa south to the Cape of Good Hope. It (or a close relative) has reached islands such as the Canaries, Madagascar and Reunion. As a corollary of this success, it has diversified into a plethora of forms, some of which are treated here as separate species. The recent tendency has been to split this stonechat into an African, a European and an Asian species, a proposition that seems attractive when viewing the resultant nominates, but virtually untenable when assessing variation within each group. All continental forms are retained here as a single polytypic taxon.*

that most fledglings of this species, whether raised in cattle pastures or in coffee plantations, move into forest when they leave their nesting habitat, and that fledglings remaining in agricultural habitats, namely coffee or pasture, are less likely to survive until brood dispersal than are those that move into forested areas. Thus, although White-throated Thrushes can nest successfully in agricultural habitats, the utilization of forest positively influences the survivorship of young during the period of post-fledging dependence. For the European Robin, too, breeding success is correlated not with territory size but, instead, with vegetation density, the speculation being that thicker cover may provide more food and/or more protected nest-sites and/or better refuge from predators.

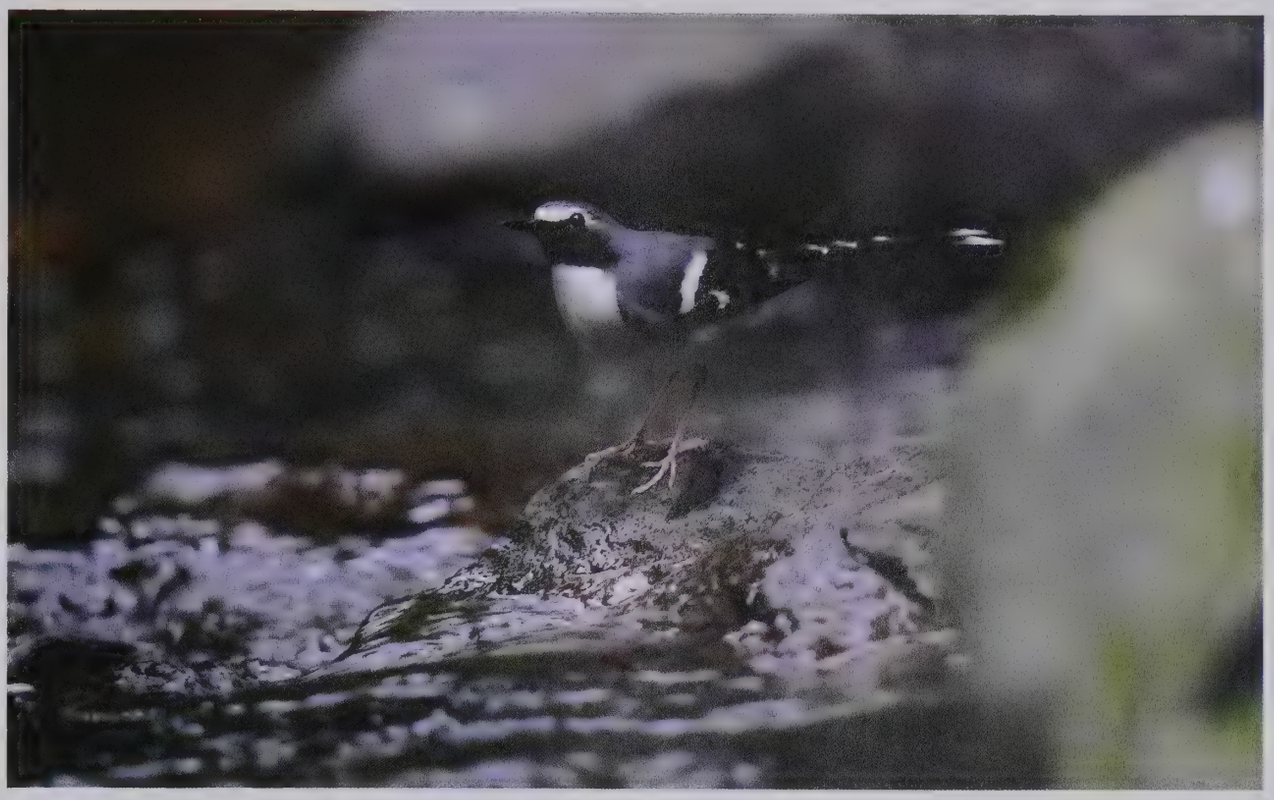
Work on Common Blackbirds and Song Thrushes in Britain and elsewhere has tended to produce similar kinds of evidence, but is less conclusive with regard to the factors influencing success or failure up to the point of fledging. In one study, it was found that Common Blackbirds make uneven use of woodland, leaving some areas empty, occupying others at low density, and clustering in others in "hotspots". The hotspots were characterized by having the greatest habitat complexity, and blackbirds nesting in them tended to achieve better breeding success than did those in sparsely occupied woodland or in adjacent farmland. Song Thrushes, too, fare poorly as landscapes become more simplified. In the 25 years from 1970 to 1995, this species' populations in lowland rural Britain declined by approximately 70%, most severely so on intensively managed arable farmland. Comparison between a stable population on mixed farmland and a rapidly declining population on arable farmland demonstrated that lack of woodland and grassland, and the faster drying of surface soils in the arable landscape, combined to limit the availability to thrushes of earthworms, the species' key summer invertebrate prey. The steady loss of hedgerows, scrub and permanent grassland with livestock, together with the widespread installation of under-field drainage systems, has reduced the complexity and viability of modern farmland as an ecosystem that can support Song Thrushes (see Status and Conservation).

Of course, individuals that fail to select optimal habitat, habitat covering all of their various biological needs over the year, are very possibly excluded from that habitat by other members of the same species. The habitat of the European Robin in the non-breeding season is influenced by the sex, age and body size of individuals. In northern Europe, adult males tend to occupy the habitats in which winter survival is most probable, while many females and juveniles migrate. In Spain, winter immigrants, many of them therefore females and first-years, tend to inhabit scrublands, such immigrants making up 60% of the robins present in scrubland, but only 30% of those in woodland. Individuals spending the winter months in woodlands achieve better condition than do those wintering in scrubland, even though food is more abundant in the latter, indicating that other features of woodland, for example shelter, must count in its favour. Because of this difference, it has been assumed that the partitioning of habitats approximately between males, on the one side, and females and young, on the other, is not driven by specialization but, rather, simply by social dominance. Over time, however, this circumstance of dominant male in one habitat and subordinate female in another would inevitably select for individuals best able to survive in the latter, and hence would lead to specialization. Interestingly, evidence of this has been found in southern Italy, where European Robins occurring in different habitats differed from one another not only in body size, measured in terms of wing, tail and tarsus lengths, but also in bill length and volume. Subordination is, in any case, no reason for scrubland-wintering robins not to be highly defensive of what little they have. Several studies have shown that, in the non-breeding season, European Robins occupy territories encompassing a number of key features between which the individual moves and to which it mainly sticks, making a core area as small as 0·037 hectares, or a perimeter of only 74 m, used for feeding, shelter, roosting and vigilance. Utilization of territory space is thus non-uniform and multi-nuclear, the robin spending up to 78% of its time in one or more resource patches, chiefly bushes, that may represent only 1% of its whole territory.

Bicknell's Thrush exhibits a similar division of non-breeding habitat by the sexes, males appearing to predominate in primary montane forest and females in mid-elevation, moderately disturbed forest. In Austria, female Common Blackbirds in countryside adjacent to urban areas appear to be forced into the urban areas in winter. Conflict between males and females over resources appears to be common among thrushes and chats, resulting either in habitat-partitioning or, alternatively, in longer-distance migration by females to what are likely to be somewhat different and, arguably, suboptimal habitats. This is not, however, always the rule. In the USA, Hermit Thrushes (*Catharus*

The African radiation of Cercomela *chats includes eight species, all of which are dull greyish birds with black or patterned tails. They are more terrestrial than* Saxicola*, but less so than* Oenanthe*, and are thus postulated to provide a bridge between the two. The* ***Tractrac Chat*** *is representative in its sombre dress, its modest song, its residence in deserts or semi-deserts, and its love of the wires and fences that criss-cross the Karoo and Namib plains; these last provide useful vantage in stark, treeless country, and are often used by foraging* Cercomela *chats. The common call of this species is the gravelly disyllable celebrated in its onomatopoeic name.*

[*Cercomela tractrac*, 60 km east of Swakopmund, Skeleton Coast, Namibia. Photo: Christophe Courteau/Bios]

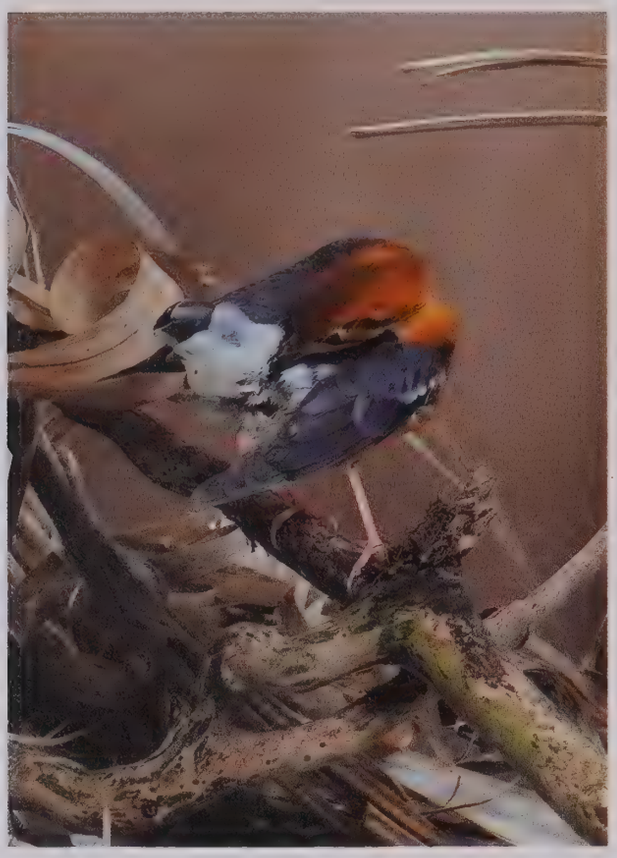


Wheatears are stocky mid-sized terrestrial chats with a slender black bill and stout black legs. Some, like the ***Desert Wheatear****, are predominantly sandy in colour with darker wings or masks, while others, such as the* ***White-crowned Wheatear****, are more dramatically pied, but almost all are characterized by a conspicuous patch of white on the rump and tail-sides; indeed this "white arse" gives rise, in refined form, to their English name. Most of the 21 species of* Oenanthe *live in open, rocky or arid landscapes, and none has much patience with trees. A recurrent theme in the genus is that of polymorphism, wherein different phenotypes regularly interbreed, producing offspring that match one morph or another, rather than intermediate hybrids. In some cases breeding is more or less assortative, and it is difficult to judge whether each particular phenotype is a morph, a subspecies, or indeed an incipient species.*

[Above: *Oenanthe deserti*, Khawr Sawli, Oman. Photo: Hanne & Jens Eriksen.

Below: *Oenanthe leucopyga leucopyga*, Tassili Najer, Djanet, Algeria. Photo: David Vilasís]

The Enicurus *forktails defy comfortable placement in any taxonomic sequence. They have sometimes been grouped with babblers (Timaliidae), or isolated in their own family (Enicuridae), and while they are now generally thought to be thrushes, they are so clearly divergent that they are provisionally allocated to a separate tribe alongside the saxicoline chat radiation, amongst which no obvious relatives can be found. Like all forktails, the* ***Slaty-backed Forktail*** *is a beautiful, elegant bird with a deeply bifurcate tail, strikingly pied plumage and delicate pinkish-white legs. Its life is spent exclusively in the vicinity of noisy streams, where its voice is reduced to a shrill whistle.*



[*Enicurus schistaceus*, Guangdong, China. Photo: John Holmes]

guttatus) wintering in Louisiana establish and maintain territories or wander among occupied territories, but territorial behaviour and the frequency of non-territorial individuals are not governed by age and sex, suggesting the absence in this species of a sex-based or age-based dominance hierarchy.

A critical factor in habitat selection for any species is interspecific competition, which inevitably comes from species that are structurally, and often, therefore, also phylogenetically, closest to the species in question. When migrants arrive on their non-breeding grounds, structurally similar species are most commonly involved as competitors, but thrushes migrating to the Neotropics and chats visiting the Afrotropics obviate this challenge by exploiting locally abundant resources. On both continents they fit into the available habitats, forest in South America and seasonal savanna and dry woodland in Africa, as niche specialists more than as outright competitors. The problem of competition is more acute when the species, whether migrants or residents, are closely related. For example, where Ruddy-capped (*Catharus frantzii*) and Russet Nightingale-thrushes meet, in parts of Mexico, the former is squeezed into dense broadleaf riparian forests in deep canyons, and its bill becomes longer, whereas the latter occupies many kinds of habitat, from open oak (*Quercus*) woodland to dense closed fir–pine–oak (*Abies–Pinus–Quercus*) forest. Where the Ruddy-capped Nightingale-thrush occurs alone, however, it occupies a niche more akin to, and has a bill of the same length as, that of its close congener. In the Old World, in areas where Black and Common Redstarts meet, typically in mosaic urban environments, the former always dominates in aggressive interactions, but it keeps itself to places in which the proportion of trees is less than 26%, leaving areas with higher tree proportions to its rival. Towards 5000 m in the Himalayas, where very few other passerines are to be found, the Black Redstart vies with the Blue-fronted Redstart (*Phoenicurus frontalis*), the former dominating in drier terrain and the latter in wetter localities.

Similar narrow partitioning of habitat occurs wherever there is intrageneric or interspecific competition. It is very apparent among sympatric North American thrushes, ecological separation of which is achieved by a combination of foraging tactics, differential use of micro-habitats, and often altitudinal and even temporal segregation, the last involving differences in timing of breeding. Reports of these distinctions make sometimes dizzying reading, in part because the combinations of species, and the combinations of the solutions that they find, are not fixed. Thus, with regard to the last point, Swainson's Thrush in north-eastern North America reaches its greatest abundance at elevations higher than those for all other turdids except Bicknell's Thrush; in the west, on Vancouver Island, it is, conversely, most abundant at the *lowest* elevations, with, for example, the Hermit Thrush much higher up, while on islands off the coast of Maine, in extreme north-east USA, Swainson's is subordinate to the Hermit Thrush, the latter is subordinate to the Wood Thrush, and the Hermit Thrush and the Veery (*Catharus fuscescens*) are separated by habitat. In the Appalachian Mountains the Hermit Thrush is displaced by the Veery at lower elevations, and in both the Appalachians and the Adirondacks it is displaced by Swainson's Thrush at higher elevations. In Vermont, in north-east USA, sites occupied by Swainson's Thrush have larger, maturer trees than do those in which Bicknell's Thrush is found.

In one study in New York State, Hermit and Wood Thrushes were found to forage primarily on the ground near forest edges, the Veery and Swainson's Thrush low in trees in the forest interior, and Bicknell's Thrush on the ground in the forest interior. In another study, the Hermit Thrush foraged on bark and in the air more frequently, but in the leaf litter less often, than did the Veery or Swainson's and Wood Thrushes; it foraged in foliage more frequently than did the last species, but less often than the Veery and Swainson's Thrush. It spent 46% of its time at 0–0·2 m, 27% at 0·3–2 m and 26% from 2 m up to the canopy, whereas the Veery spent 70% of its time and the Wood Thrush 87% in feeding at 0–0·2 m; the corresponding figures for Swainson's Thrush were similar to those for the Hermit Thrush. In mixed second-growth forest in Wisconsin, the habitats exploited by both the Hermit Thrush and the Veery are similar, but the former forages primarily below 6 m in conifers and the Veery primarily below 3 m in hardwoods. Where these two species and the Wood Thrush meet, the Veery generally chooses the wetter, younger woodlands, with less canopy cover, more shrubs and less leaf litter, while Hermit Thrushes occupy younger forest with denser stands of medium-sized trees and greater canopy cover. Finally, in areas where Swainson's, Hermit and Grey-cheeked Thrushes co-occur in the Alaskan taiga, Swainson's Thrush utilizes the ground layer more than does the Grey-cheeked and the tree-height layer more than the Hermit Thrush, in addition to which it exploits the low and medium shrub layers to a greater extent than does the Varied Thrush.

*The **Orange-headed Thrush** preens its body feathers with rapid head movements, as is the case for all passerines. In similarly conventional style, it grooms the longer feathers of the wings and tail rather differently, pulling them gradually lengthwise through the bill to re-engage loose hooklets, thereby ensuring a smooth, unbroken surface area for efficient flight. While preening, oily secretions are gathered from the uropygial gland, near the base of the tail, and liberally distributed so as to maintain the quality and resilience of feathers.*

[*Zoothera citrina rubecula*, Lake Bratan, Bali. Photo: Tony Tilford]

Responses of closely related species to situations in which habitats become "one-dimensional" or "two-dimensional" reveal how subtle ecological niches can be. In linear, or one-dimensional, habitats such as streams, the community of streamside chats segregates by body size and weight, micro-habitat, foraging behaviour and diet. Along a Nepali river in winter, White-capped Water-redstarts (*Chaimarrornis leucocephalus*), Plumbeous Water-redstarts (*Rhyacornis fuliginosa*) and Little Forktails (*Enicurus scouleri*) largely occupied rocks in the river itself, whereas Spotted (*Enicurus maculatus*), Slaty-backed (*Enicurus schistaceus*) and Black-backed Forktails (*Enicurus immaculatus*) kept mainly to marginal rocks or shoals. When foraging, Plumbeous Water-redstarts used aerial sallying in 75% of feeding actions, compared with 20% for White-capped Water-redstarts, the latter dividing its other feeding actions equally between picking prey from rocks and picking prey from the streamside. The Little Forktail devotes almost 100% of its foraging time to picking from rocks, specializing on the hygropetric (wetted) zone and, therefore, frequenting mainly the vicinity of waterfalls and splashing rapids. The Spotted Forktail focuses mainly on picking items from shoals or mud, which accounts for 60% of its foraging, and otherwise on catching prey in or on the water or on the riverbed. Slaty-backed and Black-backed Forktails spend roughly equal amounts of effort in picking prey from shoals or mud, but the former invests more heavily in catching prey in or on water or on the riverbed, to which it devotes 50% of its effort, whereas the latter picks prey from rocks (30%) and from streamsides (20%). By these adjustments, albeit not without occasional conflicts, in which the White-capped Water-redstart is constantly dominant, this assemblage of saxicoline chats, along with other riverine passerines, forges a tightly fitting ecological community.

It is, however, with the wheatears that the most notable and, perhaps, the most unexpected ecological segregation occurs, and all within a single genus. Very largely treeless, or two-dimensional, semi-desert habitats would scarcely seem fertile ground for an ecological radiation among birds, yet north Africa and the Middle East host no fewer than 18 species of wheatear, most as breeding species and a few as non-breeding visitors. Eleven of them have been recorded in just one country, Iran, where they were the subject of a pioneering but still unpublished ecological study by L. Cornwallis. Cornwallis found that spatial segregation of Iranian wheatears is achieved largely by interspecific differences in altitudinal range, geographical distribution and/or habitat. Minor differences in bill, wing and leg morphology correlate with subtle differences in foraging behaviour and substrate, giving competitive advantages in particular habitats; these are reinforced in some cases by plumage coloration, dun for wheatears of more open country, where hiding places are few, and black and white for those in more broken country, where shadow is usually available. Even so, the overlap between species in morphology and in prey type and size indicates a great potential for habitat elasticity in the absence of competitors. Where different species occur syntopically, spatial separation is achieved by interspecific territoriality, with a hierarchy of dominance. Thus, of the eight common breeders studied by Cornwallis, the Northern and Chest-

*Other aspects of feather maintenance and grooming in thrushes are virtually identical to the comfort behaviour found throughout the vast passerine assemblage, including indirect (or "overwing") head scratching, as illustrated by this **Tractrac Chat**. This species, along with a range of relatives in the semi-arid regions of Africa, is also a keen dust-bather, perhaps because water is so scarce in its favoured habitat. Conversely, dust-bathing either does not occur in typical turdine thrushes, or occurs so rarely that it has never been reported.*

[*Cercomela tractrac*, Namib-Naukluft National Park, Namibia. Photo: Rolf Kunz]

nut-rumped Wheatears co-occur in the montane zone above 2500 m, the former occupying more level terrain and the latter inhabiting sloping, rocky ground. At intermediate elevations five species co-occur; of these five, Finsch's (*Oenanthe finschii*), Isabelline (*Oenanthe isabellina*) and Desert Wheatears (*Oenanthe deserti*) occupy flatter areas, but with the larger Isabelline excluding the Desert Wheatear and confining Finsch's Wheatear to more barren and stonier substrates, while the marginally smaller Mourning and Black-eared Wheatears are limited to more sloping areas. In the rocky gullies at lower elevations, the eighth species, Hume's Wheatear (*Oenanthe albonigra*), appears.

If habitats of wheatears are determined in part by competitive exclusion, habitat occupancy may vary with regional species compositions. In parts of its range, the Hooded Wheatear (*Oenanthe monacha*) occupies the most desolate habitats, and its ecological isolation appears to be related to its tolerance of the highest desert temperatures and to the fact that, being relatively light in weight, it does much of its hunting on the wing, in rocky areas where terrestrial foraging would be highly inefficient. In Israel, however, it inhabits more open and better-vegetated areas than those occupied by the White-crowned Wheatear (*Oenanthe leucopyga*), which prefers rather sheltered but sparsely vegetated rocky and cliff-like areas, while the Mourning Wheatear occurs in more open areas such as mouths of wadis and stony plateaux and hills. The White-crowned Wheatear, however, emerges as the ultimate desert wheatear and, indeed, the ultimate desert bird, being the only one found throughout the year in the most extreme Sahara. It is, for example, the only resident avian species on the Gilf Kebir plateau, in the Libyan Desert.

General Habits

The diversity of thrushes and chats, as observed in their sizes, shapes and coloration, is repeated in their characters. All have the alertness, the bright-eyed vigilance, of the hunter; the more cryptic species, and the larger ones, have the alertness, and the still-bodied silence, of the hunted, while the more colourful species, and the smaller ones, live by their wits and their bravado, their nervous, electric energy visible in their sharp body movements and sudden flights.

On the ground, the smaller turdids mostly hop, but they sometimes walk, too; the larger thrushes either walk or hop, unless needing to move fast. The saxicoline Brown Scrub-robin usually hops but, when venturing out into tracks and clearings at dusk, it runs, taking short steps, with the head, body and tail held in line, and assuming an upright stance only when it stops. Perhaps surprisingly, its close relative the Bearded Scrub-robin, which has interbred with it, has never been recorded as walking or running, but only as hopping. The *Catharus* and *Hylocichla* thrushes are obligate hoppers. Eastern Bluebirds hop and walk sideways, moving with short sidling steps. Flight styles of turdids vary, from the intermittent oaring and deep undulations of the Mistle Thrush to the skilful high-speed twisting and weaving of the robin-chats and to the straight, low whirring flight of the shortwings.

The great majority of the Turdidae are solitary, rather than sociable. The wits by which they live are individual, and not collective. The strongly sociable species are the high-altitude Grandala and the high-latitude *Turdus* thrushes, which forage gregariously outside the breeding season for spatially and temporally patchy food resources; during this season they also roost together, probably for the same reason of unevenly distributed resources, seeking to derive from their neighbours information on the best directions for the following day's foray after food. Some other members of the family form collective roosts or loose foraging groups, but usually for only short periods within a year. Most, however, remain fiercely independent, unwilling even to join mixed-species foraging flocks, although some army-ant followers may give the opposite impression when they gather at a swarm of ants.

Perhaps the most fiercely independent of them all are the wheatears, which are truly remarkable for their powers of endurance. The Northern Wheatear, despite its strangely short-tailed and hence rather unaerodynamic appearance, undertakes the longest habitual over-water flight known for any passerine, intrepidly braving the Atlantic in spring and autumn to reach and, after breeding, to leave Greenland and the New World (see Movements). Many of its congeners populate some of the most arid lands in the world, and by their presence bring a particular grace to seemingly the most unforgiving and hostile of terrain (see Habitat). The secrets of their survival in such adverse circumstances will one day be explained in terms of their physiological attributes, including metabolic rates, air-sac capacity, water retention, and so on, but for the present these birds are simply a source of biological marvel and astonishment.

The key needs for survival are good health, adequate food and effective predator avoidance, and each of these factors has exerted an influence over the evolution of avian habits. Among

Sunbathing has been reported from members of all three turdid subfamilies, and involves the typical procedure of crouching on warm sunlit ground, spreading out one or both wings, fanning the tail, and erecting the contour feathers of the back and rump, as demonstrated by this ***American Robin****. The body is orientated so that the back faces the sun, or it is rolled at a slight angle so that the flank and the sides of the neck are illuminated. Whatever posture is adopted, the behaviour seems to induce a period of heedless rapture during which birds can be approached far more closely than usual.*

[*Turdus migratorius*, Freeville, New York, USA. Photo: Marie Read]

the thrushes and chats, various interesting adaptations have arisen, but there are many avian norms to which the family conforms. Feather maintenance is undertaken in typical passerine fashion, including indirect head-scratching, whereby one leg is brought over the wing. Thrushes and chats are equally enthusiastic water-bathers, and when water is available and secure they may visit it to bathe several times a day. Many African robin-chats have been recorded as "bathing" in dew-laden or rain-laden foliage if no puddles or water-retaining tree holes are at their disposal, and the White-throated Robin-chat has been seen to bathe by flying through a garden spray. At small pools, including birdbaths, some of these species are so aggressive in defence of the resource that they will not allow even their mates access; when individuals water-bathe at places outside their territories, however, they do so without aggression, even though often in close proximity to conspecifics. Preening, the stretching of limbs and the shaking of the body and tail are typically then undertaken on the edge of the pool or on a nearby branch. Preening, involving the use of uropygial secretions, is carried out in the usual fashion, the body feathers being groomed with rapid head movements, and the wing and tail feathers being pulled through the bill in the direction of the feather barbs in order to re-engage loose hooklets.

African robin-chats and scrub-robins also dust-bathe and sand-bathe. Bearded Scrub-robins appear to do so much more frequently than do other robins, perhaps because surface water is rare on the sandy soils that characterize their habitat. At a spot with loose, deep sand, commonly on an open track, the bird may first mould a hollow by making rapid sideways whisks of its beak, or, more often, it will just squat and half-roll on its side, flapping the free wing and rubbing the outstretched head and neck in the sand. Curiously, however, true thrushes appear not to dust-bathe, or to do so only with extreme rarity. Only one published report appears to exist, and its singularity is compounded by the improbability of the species in question: in August 1986, J. del Hoyo, an observer of impeccable credentials, encountered a Green Cochoa dust-bathing by a track in a forest in Thailand. Given that it is usually dry-country species that dust-bathe, that this action took place during a short break in light rain in a rainforest, that it involved a normally highly arboreal rainforest species, and that no other species of true thrush has ever been reported as indulging in such behaviour, the nature of this record speaks for itself.

Sun-bathing, in contrast, has been witnessed for all three subfamilies, and involves the typical procedure of crouching on ground or rock with the back or flank to the sun, spreading one or both wings, fanning the tail, and erecting the contour feathers of the back and rump to expose as large a feather surface as possible. Anting, thought to be a method of inhibiting ectoparasites, is also common to all turdid subfamilies, members of which use both the direct and the indirect methods. The first method involves the application of ants (Hymenoptera) to the body by the bird, and the second the passive exposure of the body to ants. A Wood Thrush was once witnessed to "ant" with a large snail, the shell of which it was hammering on the ground; it thrust and dabbed the snail under its wings, along its flanks and beneath its undertail-coverts. Similarly, captive *Turdus* thrushes of two different Neotropical species were seen to rub, respectively, garlic and red pepper under their wings. The observer, H. Sick, assumed that these substances were next-best substitutes for ants and were being used for the purpose of controlling ectoparasites.

All birds suffer to some degree from disease and infestations, but these are normally held in check by immune responses and routine comfort behaviour. Outward signs of the problem are usually hard to spot, unless death occurs and the body remains somewhere where it can be recovered. Such was the case with some Western Bluebirds (*Sialia mexicana*), afflicted with enteritis, which were found dead in a nestbox in the late 1990s. Swainson's Thrush is a host for foot pox (*Poxvirus avium*), which can result in growths on the feet and at the base of the bill, deformities and foot loss; cases are relatively few and mild, but may be linked with a higher incidence of leg loss in this species compared with others, as recorded in ringing programmes. Owing in part to their abundance and accessibility as study animals, several species of thrush are currently being used in investigations to determine levels and types of disease and infestation in wild populations. "Immunocompetence", measured as the degree to which an individual can defend itself against disease and parasites, is increasingly a subject of behavioural ecology (see Breeding). Of more immediate human interest, however, is the fact that some thrushes, the Common Blackbird and the Brown-headed Thrush (*Turdus chrysolaus*) among them, are thought to be implicated in the spread of Lyme disease, both by carrying the ticks that are the vector and by hosting the pathogen itself, and thus acting as a reservoir from which the disease can spread.

Thrushes and chats are amongst the most ardent aficionados of water-bathing. Many species will flutter on dewy or rain-sodden grass and foliage in order to bathe, and one has been noted flying deliberately through the mist of garden sprinklers. Usually, a more secluded site is favoured, be it a shallow secluded pool, a slow-moving stream, or a puddle retained in the crotch of a tree. Having found an ideal location, this ***Siberian Thrush*** *may visit it daily, or even several times a day, to bathe.*

[*Zoothera sibirica davisoni*, Yamanasi, Japan. Photo: Hirozo Maki]

*Investigators have found that when a **European Robin** is freed after being held captive for anything from a day to several days, its first impulse is not to forage, or to sing, but to bathe. This fact gives some idea of the importance of bathing to thrushes and chats in general. Bathing sites are aggressively defended in some cases, even against mates, but more usually they produce a relaxation of territorial behaviour. Being pugnacious animals, a trio of adult robins is a rare sight in resident populations, but small numbers do sometimes gather at favoured bathing pools, especially when non-breeding or non-territorial birds abound.*

[*Erithacus rubecula*, Sierra de la Paramera, Ávila, Spain. Photo: José Luis Rodríguez]

Comfort behaviour such as preening, dusting and bathing occupy a very small proportion of the daily routine of thrushes and chats. Two far more time-consuming activities, or, rather, inactivities, are loafing and roosting. Loafing, or "quiet wakefulness", refers to the period or periods in the day when a bird remains perched and immobile, resting without sleeping or with only very brief sleeps. For many of the Turdidae, this takes place mainly in one period, over midday, and for some species it can be protracted. The Omao (*Myadestes obscurus*) in Hawaii, for example, spends many hours during the day perched motionless in a tree. Loafing takes its most extreme form, however, in desert-adapted wheatears such as the White-crowned Wheatear, which in the heat of summer retires to the shade at around 08:30 hours and does not resume feeding until 16:30, a span of inactivity lasting for eight hours, and which, even in winter, typically loafs during the six hours between 09:30 and 15:30. Metabolic processes in these species must be greatly slowed, while the energy extraction from their food must be extremely efficient. In fact, Mourning Wheatears have been observed deeply asleep over a period of 1·5 hours in the hottest period of the day, and this may be normal for all desert-adapted members of this genus. Common Stonechats exhibit different resting metabolic rates at different latitudes, these being lowest among residents in Kenya, higher for partial migrants in Ireland, and highest for fully migratory Austrian and Kazakh individuals. These rates prove to be genetically based, and are evidently associated with the relatively slow development and high longevity of birds in tropical and subtropical regions.

Roosting, in the case of the Turdidae, is typically preceded by a period of restless, nervous activity, often with much alarm-calling. The adaptive significance of this strange behaviour pattern is unexplained, although it may be a type of self-advertisement, or possibly even a means of shedding excess calories. It is well established that a diurnal bird must build up its fat reserves towards dusk in order to avoid starvation during the night, when it cannot feed. The storing of fat, however, also imposes burdens such as increased predation risk and higher flight and metabolic costs. All European Robins provided with an *ad libitum* food supply reach almost exactly the same body mass at dusk, thereafter ceasing to forage, indicating that there is, indeed, an optimal level of fat reserves which a bird of this species, and presumably of any other, needs to reach by dusk.

Once in the roost-site, the individual first enters a state of quiet wakefulness, as when loafing. Postures adopted by turdids are rather upright, on a surface that can be gripped strongly in the feet. For the Common Blackbird, at least, eye closure is a reliable indication of sleep. Head postures during sleep are of two types: retraction of the head, with the bill pointing forwards and the head sometimes nodding, and turning of the head so that the bill points backwards into the upperpart plumage, this latter being used only in full darkness. Common Blackbirds sleep for about 38% of a 24-hour period. Roosting lasts from after sunset to before sunrise, typically between points when the light levels are too low for clear human vision, but of course the duration of the roosting period itself is directly influenced by latitude.

The roosting perch is usually in thick cover and fairly low down. Common Blackbirds frequently pass the night in bushes or small trees, often against walls, while Song Thrushes in Finland use the lower parts of thick spruce trees (*Picea*) and, in open parts of Scotland, heather (*Calluna/Erica*). Mistle Thrushes roost in evergreen trees, thick hedges, brambles (*Rubus fruticosus*) and even clumps of mistletoe (Loranthaceae), and Western Bluebirds in America also use mistletoe when not roosting in holes. In Hawaii, four Omaos fitted with radios were tracked to roosting locations about 3–6 m above ground in ohia trees (*Metrosideros collina*), all within the boundaries of their core activity areas. Rock-haunting turdids such as the Blue Rock-thrush and the Variable Wheatear withdraw to sheltered sites in cliffs, sometimes substituting holes under roofs of buildings; in the case of White-crowned Wheatears, pair-members roost separately, and this is probably true for most, if not all, rock-haunting species. Red-backed Scrub-robins (*Erythropygia leucophrys*) normally choose a perch 1·5–2 m above ground in thorny branches, Pied Bushchats and their fledglings in New Guinea roost in tall cane-grass about 2 m in height, and certain other species will make use of reedbeds for night-time shelter. Some hole-nesting wheatears and their closest relatives presumably also use mammal burrows for roosting. The Southern Anteater-chat (*Myrmecocichla formicivora*), a co-operative-breeder, does so throughout the year, each group, of up to five individuals, using as many as ten burrows on its territory for the purpose.

During the breeding season, pair-members other than those of rock-haunting species will often roost together, or fairly close to each other. In Costa Rica, for instance, A. F. Skutch found a

After bathing, thrushes usually retreat to a nearby perch where they dry themselves by fluffing out the feathers, fluttering the wings, shaking the body and preening. The bird pictured here is a ***Groundscraper Thrush****, a boldly speckled resident of southern African woodlands and gardens. According to biomolecular studies it is very close to* Turdus*, but just divergent enough to justify continued separation in a monotypic genus.*

[*Psophocichla litsitsirupa litsitsirupa*, Nylsvley, Limpopo, South Africa. Photo: Warwick Tarboton]

mated pair of Clay-coloured Thrushes, at the start of the breeding season, roosting in a small orange tree in a coffee plantation. The two were perched about 1 m apart on slender, rather exposed branches 2 m and 2·8 m, respectively, above the ground.

Outside the breeding season, some members of the family roost communally. Such behaviour, being more obvious to human eyes, has been relatively widely reported, but is not yet known to be widely practised. Most reports concern true thrushes in the higher latitudes. Nevertheless, there is at least some evidence that the phenomenon occurs among other taxa and/or in other regions. For example, up to twenty or so bluebirds will pack into tree holes at night as a means of conserving body heat, and Pale-breasted Thrushes (*Turdus leucomelas*) have been watched as they gathered at dusk and disappeared one by one into a densely leafed tree in a street in Paramaribo, Suriname. Clay-coloured Thrushes have been seen to roost together in small groups in tall bamboo clumps in Costa Rica, and, in Mexico, thirty or so went to roost in a forest in Veracruz, making so much non-vocal noise that "the bushes… resounded with a dull roar", each new arrival startling the entire flock, causing each individual to fly, with much fluttering, to another low perch. Non-territorial, thus mainly first-year, European Robins roost communally in the period July–February, possibly chiefly as a mechanism enabling the individuals involved to assess the local population density; it is speculated that, by judging the number of other non-territorial robins in the area, they are better able to decide whether, in the quest for a territory, they should disperse or stay put. Even male Sri Lanka Whistling-thrushes (*Myophonus blighi*), from a genus that is typically highly solitary, have been observed to form roosts of up to four individuals at points where their territories adjoin.

It is, however, the turdine thrushes breeding at higher latitudes that produce the largest roosts, and among these species the phenomenon may be commoner than is generally observed or believed. In July of each year, more than 10,000 wintering Creamy-bellied Thrushes (*Turdus amaurochalinus*) form a roost in the bamboo understorey of *terra firme* forest in Noel Kempff Mercado National Park, Bolivia. American Robins habitually form large roosts outside the breeding season, and they roost in groups even in the spring and summer months. These roosts are attended by individuals of both sexes and all ages during the winter, by adult males during the breeding season, by adult females once nesting is completed, and by them and their offspring as soon as the latter reach independence. This pattern is followed in some areas by Common Blackbirds. Communal American Robin roosts typically comprise 20–200 individuals, but some have been estimated to hold as many as 250,000. Roosts in New Jersey in the period June–November are made up of individuals that generally forage within a 3-km radius of the site, and, although these sometimes switch roosts, they rarely move farther than 2 km from the previous roost-site. Communal winter roosting is probably used by this species not for thermoregulation, but for the exchange of information on foraging sites and for anti-predator security.

The same is true of the Fieldfare in the Old World. At any time from July to April, this thrush forms large roosts in conifers,

Given that tails are so strikingly patterned in many species of chat, it comes as no surprise that they are regularly flaunted. By cocking them, shivering them, pumping them downwards or flirting them open, chats employ their tails in various simple displays, probably as a form of self-advertisement. This ***White-tailed Rubythroat****, captured in stunning pose, with eye-catching rectrices raised and fanned, leaves little doubt as to the value of a prominent tail-pattern as an instantly controllable, species-specific, long-distance visual signal.*

[*Luscinia pectoralis ballioni*, Almatyskoje, Tien Shan mountains, Kazakhstan. Photo: Lionel Maumary]

The use of wings in visual signalling systems seems much less important than that of tails in thrushes and chats. A good number of species, however, particularly within the saxicoline clade, flick their wings habitually, sometimes revealing patches of white. Others flash their wings outward momentarily when foraging, or after landing on exposed perches, as demonstrated by this ***Chestnut-rumped Wheatear****. These modest displays using wings and tails are probably analogous in function, serving to draw attention towards the bird, or away from a nest.*

[*Oenanthe xanthoprymna*, Yesilce, near Gaziantep, Turkey. Photo: Robin Chittenden]

preferably young plantations, in deciduous woodland with a dense understorey, in tall hedgerows, osier (*Salix*) stands and reedbeds and, in some areas, on the ground in open fields. In 1788, in his famed book *The Natural History of Selborne*, Gilbert White recorded that, in the gathering dusk, Fieldfares flew in to settle for the night on the ground on his local heath in Hampshire, in southern England. Fieldfare roosts are generally modest in size, with individuals numbering in the hundreds, but they occasionally reach tens of thousands and, in January 1975, some 200,000 were recorded as roosting with Common Blackbirds at a site in France. As the flying birds reach the roost-site, in small flocks, they plummet sharply down into it. The time of arrival is probably determined by several factors, including the time of year, foraging success and/or distance travelled. The shorter the day, the longer the birds need to forage, and early arrival indicates high foraging success. Dusky Thrushes in Japan indicate their intentions to move to the roost by sitting in trees and calling for 5–30 minutes, before setting off for the site; groups tend to arrive 50–60 minutes before sunset, whereas lone individuals arrive 10–20 minutes before sunset. Fieldfares roosting in woods often work their way down the trees, finally selecting a perch a metre or two off the ground; they are not known ever to huddle together as smaller-bodied birds sometimes do, but always leave a certain individual distance to their nearest neighbour. In the morning, as with most birds, they are commonly out long before daybreak, with a general clamour as they disperse towards their destinations for the day.

Immediately before or after roosting, many forest and woodland species make use of deep twilight in order to forage quietly on the ground in slightly more open areas than those exploited during the daytime. Indeed, some of the most reclusive species, such as the *Zoothera* thrushes and some scrub-robins, are likely to be seen only before sunrise or after sunset, although they may then appear to be fairly common; yet in daylight hours it can be difficult to credit that the species are present at all in the local environment. Ground-foraging forest-dwelling thrushes and chats tend to have large dark eyes, and the twilight activity of various invertebrates on the forest floor means that many turdids, as, for example, the Rufous-capped Robin-chat, emerge from cover after sunset to forage in clearings and along narrow roads, and are often still active when most other diurnal birds have already retired to roost. It is difficult to know the extent to which such behaviour involves predator avoidance, rather than niche exploitation.

Many forest-inhabiting chats and thrushes are among the world's supreme avian skulkers. In Asia, the Indian Blue Robin is, according to the widespread frequency with which its song is heard, an extremely common bird in the Himalayas, but it is very seldom seen, as it perches openly to sing only in the few days before nesting commences. Likewise, in Africa, the Blue-shouldered Robin-chat (*Cossypha cyanocampter*) can scarcely be seen even in twilight, and it sings in complete darkness. J. P. Chapin found the Forest Scrub-robin (*Erythropygia leucosticta*) extraordinarily shy and, even when singing, "more than elusive—almost ghostly". Similarly, every birdwatcher in Europe knows how difficult it can sometimes be to catch sight of a Common Nightingale or Thrush Nightingale even while it is singing, and how impossible the task becomes after the middle of June, when singing ceases.

On the other hand, many of the Turdidae have distinctive and obvious body movements that are used both intraspecifically and interspecifically to signal the individual's presence and to declare its intentions. These are as much signatures as they are signals, and are fundamental components of the all-year display repertoires of the family, and, indeed, of all three of its subfamilies. They are part of the behaviour of even some of the most reclusive species, such as the Common Scaly Thrush, with its curious shivering and bobbing. Common and Black Redstarts sporadically shiver or flicker the tail, most frequently after alighting. Güldenstädt's (*Phoenicurus erythrogastrus*) and Blue-capped Redstarts also do so, but less often, the latter, at least, compensating by frequently flicking its wings, exposing the rump, and, when feeding on the ground, by raising and lowering its tail slowly in the manner of some *Tarsiger* chats. Eversmann's Redstart not only shivers its tail but also flirts and flicks it, and the Plumbeous Water-redstart, whenever it lands, dips and flirts its tail in a rapid scissors-motion that makes a prominent visual signal. Both the Siberian Blue Robin and the Rufous-tailed Robin in the genus *Luscinia* shiver the tail. Somewhat unexpectedly, perhaps, the habit re-emerges in certain Neotropical turdine thrushes. In central South America, the tail-quivering of the Creamy-bellied Thrush as it perches at once distinguishes it, even at a distance, from the Pale-breasted Thrush, and the Rufous-bellied, Cocoa

Thrushes and chats are famed for the strength and versatility of their songs, some of which are listless or repetitive, and others are simply magnificent. Amongst the acoustic signals of all birds, and indeed all living creatures, theirs perhaps most closely approach (and some say surpass) the human aesthetic we call music. Being oscines, they learn their songs and their repertoires are often impressive. Many, including the ***Siberian Rubythroat****, amass or bolster these vocabularies by imitating other species of birds: the most accomplished and prolific avian mimic is not a mockingbird (Mimidae), or a lyrebird (Menuridae), but a thrush.*

[*Luscinia calliope*, near Nome, Alaska, USA. Photo: Arthur Morris/ VIREO]

and Black-billed Thrushes (*Turdus ignobilis*) also dip or quiver the tail on alighting.

More exaggerated tail movements are common throughout the family. When landing on or above the ground, many species in the genera *Turdus*, *Catharus*, *Copsychus* and *Erythropygia*, as well as the Black Scrub-robin, cock the tail high over the back and lower it slowly, often with slight flicks and drooping of the wings. These gestures grow more pronounced as the birds become more proprietorial in the breeding season, but they are demonstrated throughout the year. The Brown-backed Scrub-robin (*Erythropygia hartlaubi*), for example, moves the tail so incessantly that it continues to do so even while preening. Whistling-thrushes make deliberate gestures whenever they alight, first raising the tail and then depressing and fanning it several times. Some of the rock-thrushes, including the Chestnut-bellied (*Monticola rufiventris*) and Blue-capped Rock-thrushes, have a habit of pumping the tail slowly up and down, and males also fan it. Similarly, the Indian Blue Robin waves its tail up and down rather slowly, like a pitta (*Pitta*), when perched, and its near-namesake the Indian Robin does likewise when on the ground, frequently raising the tail vertically or even farther forward to expose the chestnut undertail-coverts. *Myrmecocichla* chats constantly wag the tail upwards and downwards, holding it fanned when up and closed when down, and, when the individual is excited, these movements cause the tail to travel through a 180-degree arc. Wheatears typically bob the head and flirt the tail in a single movement. *Enicurus* species, the forktails, not only repeatedly wag the tail up and down but also simultaneously open and shut it scissorswise, in an action identical to that of the *Rhyacornis* water-redstarts. They perform this signal in bouts, with 2–5 such actions in a sequence, the visual effect being enhanced by the flashing-open of the wings at the carpal, thereby exposing the white in the wings.

Wing-flicking movements are probably no less widespread than are tail movements. Many of the above-mentioned species and genera also use wing-flicking actions of some kind, even if these are less conspicuous or less emphatic than the tail movements. Some taxa, however, make wing movements that are stronger than the tail movements. The Hawaiian *Myadestes* species have a habit of wing-fluttering when perched, the bird drooping the wings slightly and shivering the primaries lightly or vigorously. The function of this behaviour, which has not been documented for other myadestine thrushes, is as yet unexplained, but it is exhibited as much by recently fledged individuals as by adults, and as much by calm birds as by stressed ones. Similar behaviour by the Varied Thrush appears to be a submissive display. Common Stonechats flick their wings most frequently on alighting, drawing attention to themselves through the flashing of the white wing-coverts, this suggesting a strong element of self-advertisement. *Cercomela* chats, when alighting, flick open their wings several times, the movement involving mainly just the primaries, but with the tail also partly fanned, and the Familiar Chat and the Blackstart (*Cercomela melanura*) do so at every stop after hopping a distance across the ground. These rather deliberate, measured wing-flicks or wing-flashing actions, which

The song of the ***White-throated Robin*** *is a sustained and vigorous outpouring, including warbles, fluty whistles and scratchy chattering notes. Morphologically, the species bears a striking resemblance to certain robin-chats* (Cossypha)*, but its black tail and migratory behaviour suggest that its origins lie elsewhere. Where, exactly, remains a mystery, but it is probably most closely allied to the robins and nightingales in the genus* Luscinia*. Like them, it is known to vocalize strongly in its winter quarters, at least from January onwards, and it may use song to defend two territories each year, one in Asia Minor, and another in Africa.*

[*Irania gutturalis*, Lesbos, Greece. Photo: Richard Brooks]

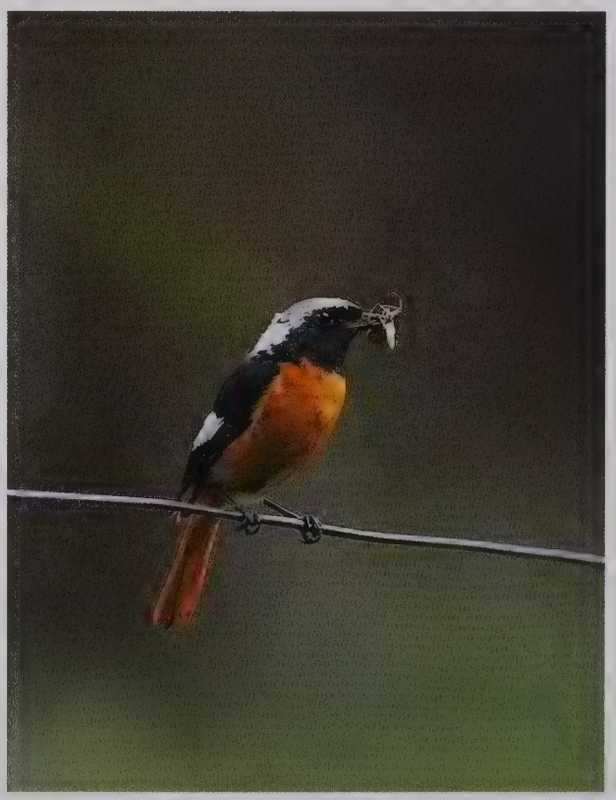
In many turdids the sexes are dichromatic, and females are silent, but this generalization does not apply to a large subset of chats and solitaires in which the sexes are alike and females sing. One such species is the ***Southern Anteater-chat****, a dull-coloured denizen of southern African savannas. Its song is a series of snippets sustained for prolonged periods, each phrase a medley of strong fluty whistles and sharper chirps. The male is usually responsible for this, but the female sometimes produces the same refrain, especially when excited.*

[*Myrmecocichla formicivora*, Nieuwoudtville, Northern Province, South Africa. Photo: Peter Steyn/Ardea]

As with many other species of open landscapes, such as pipits (Motacillidae) and larks (Alaudidae), some turdids have adopted the technique of song-flighting. This practice seems absent in true thrushes, but prevalent in myadestine solitaires and saxicoline chats. Open-country wheatears, for example, address the lack of vantage points from which to project their songs by launching themselves into the air. In the ***Isabelline Wheatear*** *the song begins with an accelerating series of downslurred notes during the ascent phase and shifts abruptly, as soon as the descent begins, into a manic jumble of crackling, buzzing and twanging.*

[*Oenanthe isabellina*, Lesbos, Greece. Photo: Richard Brooks/ FLPA]

are also made by certain desert-adapted wheatears, have been thought to help in the locating of invertebrate prey, by causing the latter to react with sharp movements of their own.



Several species of ant-following chat, including those in the genera *Stiphrornis*, *Sheppardia*, *Alethe* and *Pseudalethe*, make agitated wing-flicking and tail-flicking movements when working an ant column, and react with similar movements to imitations of their calls. This suggests that, for these species, the behaviour is associated more with aggression and self-advertisement than with foraging itself. Similarly, Fieldfares and Mistle Thrushes, when guarding a fruit resource, perch conspicuously on or next to the food plant and, at the approach of a potential rival, loosen and slightly lower their wings so as to reveal the white underwing-coverts as a warning of impending attack.

Although self-advertising wing and tail movements appear essentially involuntary, they are much more obvious when the bird is mature and confident of itself and of its ground. A fascinating piece of observation by R. Leverton, studying migrant Ring Ouzels at a stopover site, demonstrated the importance of familiarity with a particular terrain. Newly arrived Ring Ouzels were always "visibly unsure and naïve"; when he flushed them, their flight was aimless and erratic. By the end of the third day, however, those individuals that had stayed had learnt the geography of the area within a radius of 1 km, and they had established an alternative feeding ground up to 700 m away from their preferred site; whenever danger arose, they would make off, low, silently and accurately, to this alternative foraging area. They had also selected a roost-site and several loafing sites, and knew the position of a small concealed dewpond at which to drink and bathe.

This anecdote explains perfectly why so many species of thrush and chat are site-faithful. In Africa, for example, a given pair of Blue-shouldered Robin-chats may almost invariably be found in its own particular part of the forest. Ringed individuals from a population of Rufous-capped Robin-chats at Kagoro, in Nigeria, were found to be still in exactly the same place more than eight years later, and a Brown-chested Alethe (*Pseudalethe poliocephala*) was controlled just 100 m from where it had been ringed nine years earlier. Similarly, in Panama, a Clay-coloured Thrush ringed in 1964 in the Canal Zone was found dying ten years later less than 1 km from the initial site of capture. The whistling-thrushes of Asia are among the most predictable of thrushes and chats in terms of both routine and site usage. The fixed routine means that they are generally hard to find at any time other than dawn and dusk, but the habitual site usage means that they are almost certain to be present at particular spots at those hours of the day.

Migrant species are no different. For example, adult Whinchats (*Saxicola rubetra*), particularly males, return from their African winter quarters to the territories that they previously occupied in Europe, and the Blue Rock-thrush keeps to the same neighbourhood day after day, even in successive seasons. In China, a first-year male Bluethroat ringed in November 1991 at Mai Po, in Hong Kong, was retrapped there in the springs of 1992, 1993 and 1995, while a male Orange-headed Thrush (*Zoothera citrina*), reasonably assumed to be the same individual, was present for seven successive winters at the bottom of the access road to the Tai Po Kau Nature Reserve. In the New World, Townsend's Solitaires return to defend the same set of trees each year on their non-breeding grounds, and, on the basis of limited data, Varied Thrushes are strongly site-faithful in winter and appear to be so also when breeding. Philopatry among Eastern Bluebirds seems to be partly a function of breeding success: pairs that failed to breed in one year were less likely than were successful breeders to return to the same area in the following year.

Various studies of turdine thrushes in America have produced some interesting results. In a colour-marked population of Swainson's Thrushes in the Pacific Northwest, 42% of males and 31% of females returned to the previous year's breeding site. Similarly, corresponding figures of 59% and 45% for, respectively, male and female Wood Thrushes demonstrate that the former are more prone than are females to return to the previous year's breeding site and, especially, to the same territory; in addition, mean distance between captures in sequential winters of only 43–62 m in Costa Rica reveal high winter philopatry, too, for this species. In the case of Bicknell's Thrush, mist-net recaptures at the same sites over successive years show that older males, as well as females of all ages, are site-faithful on their breeding grounds, and winter philopatry has also been documented on the wintering grounds in Hispaniola; in the Dominican Republic, 14 out of 27 marked individuals were recaptured in successive winters, the distance between capture sites in the two seasons ranging from zero to 260 m, with a mean of 95·4 m. In contrast, only 18% of 306 Hermit Thrushes returned to the same locality in California in successive winters, and, of 81 individuals of this species ringed in South Carolina, only ten returned there in the following winter. In Mexico, however, many individual Hermit Thrushes were repeatedly captured in the same mist-nets, at the same location in Tamaulipas, during December to March over a three-year period.

For most turdid taxa insects form the bulk of the diet, at least during the breeding season, and the most insectivorous species are found within the saxicoline chats. This is partly because their bills are relatively slender, designed for surface and aerial foraging rather than digging or fruit consumption. Like most of its relatives, the ***Daurian Redstart*** *is therefore particularly at home gleaning invertebrate prey, such as spiders and caterpillars. Even so, somewhere between a fifth and a third of its dietary intake consists of plant material, mostly seeds and berries, and this type of "mixed economy", biased towards insects, is widespread in the family.*

[*Phoenicurus auroreus auroreus*, south Ussuriland, Russian Far East. Photo: Yuri Shibnev]

Although site-fidelity and territoriality are not the same thing, it is a very short step from the first to the second. If a solitary bird returns to or stays within precisely the same area because the resulting high degree of familiarity confers elevated survival chances upon that individual, it follows that the area that it occupies will be only as large as its needs dictate, and it will be the fittest bird of its species in that area. Consequently, it will always be likely to win if any confrontation arises over the resources that it exploits, and this will perpetuate its presence there over a longer term. J. A. Tobias, in his studies of European Robins, has shown how such familiarity, which is a "value asymmetry", has precisely this effect. The reason why residents almost always win against challengers is the inequalities in physical condition between the two: residents have maximal foraging efficiency owing to minimal levels of boundary disputes with known neighbours, and to their greater familiarity with the distribution of resources within their own territories. The time at which dominance tends to reverse in favour of new holders, 5–6 days in winter, is predicted by the time that it takes for them to settle territory boundaries and achieve baseline foraging effort. D. W. Snow noticed that older male Common Blackbirds might tolerate the intrusion of known neighbours in certain contexts, as when feeding on fallen fruit, but would single out and drive off a new trespasser which might be likely to attempt to use the opportunity to establish himself permanently there. It has been demonstrated that, unsurprisingly, overwintering resident Wood Thrushes experience a lower mortality rate than that of wanderers.

In Africa, certain *Cossypha* robin-chats are notoriously aggressive in defence of their all-year territories. In intraspecific territorial display, a singing male will crouch, holding the head low, the back sloping almost vertically up and the tail fully fanned, and then chase his rival while giving much bill-snapping, the two sometimes grappling in mid-air and falling to the ground with claws interlocked. The targets, however, are not just conspecifics. Robin-chats will pick on almost any bird of vaguely comparable size, especially in autumn after completion of the post-breeding moult, or when young are in the nest. Even shrikes, which are well known for their own intrepid aggression towards other, often much larger species, are pursued. A male White-browed Robin-chat was once seen to pounce on a Black-headed Gonolek (*Laniarius erythrogaster*) and viciously peck it. A Cape Robin-chat did likewise with a Yellow-tufted Malachite Sunbird (*Nectarinia famosa*). Many wheatears are similarly merciless. Finsch's Wheatears fight each other very fiercely in winter, and a Buff-breasted Wheatear was once seen to pursue and pin down with its feet a slightly larger Mourning Wheatear and to peck fiercely at the latter's head for half a minute, until the victim escaped. By the same token, investment in territorial display by these species, through song and, in the case of wheatears, song flight, can be surprisingly heavy. The display of the Rusty-tailed Wheatear is often very obvious, the male energetically fanning his tail and executing short pirouettes into the air, singing all the while. It can also be very prolonged: one individual of this species, in September, was seen to continue this display for almost 50 minutes.

In the tropics and subtropics, permanent territories may be defended jointly by the members of a pair. With the Karoo Scrub-robin (*Erythropygia coryphaeus*), for example, pair-members forage independently for a while, and then one will fly on to a bush, call and be joined by its mate; the two then greet each other in a very upright stance, calling and flicking out both wings horizontally two or three times. In the breeding season, there are many other types of vocalization and display, especially when conspecifics from adjacent territories are involved. In one display, the scrub-robin flails its wings with a peculiar slow rowing action; this is often taken up by its mate, and then by other pairs on conspicuous perches in adjacent territories. In contrast, species in temperate climates, and migratory ones, occupy solitary territories, and, for most turdids studied, both the male and the female then sing in defending their own patches. Only for the Common Stonechat have joint non-breeding territories been observed as typical behaviour, but these unions are unstable within the winter period and the majority dissolve in the spring.

Aggressive postures depend on which part of the body the bird needs to emphasize. European Robins, and other species with bright breast coloration, adopt a posture that emphasizes the extent of the colours. In an aggressive interaction with another male, a male Pied Bushchat sings while holding its tail depressed, its neck craned forwards, its white rump fluffed out, and the wings drooped to expose the white "shoulder" patches to a maximum. By way of contrast, the male Indian Robin, in asserting territorial rights against a rival, adopts a remarkable attitude: he stretches his neck, pointing the bill vertically up, everts the breast feathers, the white wing-coverts and the chestnut undertail-coverts, and cocks the tail until it touches the back of his head, all the while running about and pouring out a flood of squeaky song. Other turdid species likewise flaunt the tail in

Several chat genera rely on two main foraging techniques: the "perch-and-pounce" method, involving sit-and-wait tactics on a low perch, followed by a darting flight to the ground or nearby branch; and the "leap-and-snatch" method, involving a brief sally or jump to take flying insects. These modes of capture underlie the proliferation of Phoenicurus *redstarts,* Saxicola *bushchats,* Oenanthe *wheatears and* Cercomela *chats, including the* ***Familiar Chat****. The success of this species is further ensured by its ability to forage on seeds, berries, household scraps and pieces of roadkill.*

[*Cercomela familiaris actuosa*, Giants Castle, Drakensberg, South Africa. Photo: HPH Photography/ Photo Access]

The most successful of all chats in terms of overall abundance, geographical spread and subspecific diversification is the ***Common Stonechat****. This species mainly hunts from an exposed perch, usually situated low above the ground. It employs the typical "perch-and-pounce" method, flying down to take prey on the ground, alighting momentarily, then often returning to the same perch. In one study 80% of all foraging strikes involved this process, with a lesser investment in three alternative techniques, including aerial sallying (9%), hover-gleaning to branches or foliage (6%), and fluttering over some distance in pursuit of aerial prey (5%). The incidence of these tactics varies regionally and seasonally. In common with most chats the bulk of prey items are invertebrates, including spiders, earthworms and many insects. This last subset is rather diverse, ranging from relatively immobile beetles (Coleoptera) and caterpillars (Lepidoptera), to highly manoeuvrable hoverflies (Syrphidae) and dragonflies (Odonata).*

[*Saxicola torquatus*, Audierne Bay, Brittany, France. Photo: Jean-Louis Le Moigne/Bios]

*The **Western Bluebird** seems distantly related to true thrushes (Turdinae), and is provisionally classified alongside the solitaires (Myadestinae), but its foraging tactics and favoured prey are similar to those of chats (Saxicolinae). In spring and summer it hunts from a low perch, usually dropping to the ground to capture a range of invertebrates, in this case an orthopteran. During these seasons the diet is almost wholly made up of insects, but in the autumn and winter the bluebird switches to an intake of berries and other plant matter.*

territorial disputes. Male White-crowned Forktails (*Enicurus leschenaulti*) threaten each other at territorial boundaries on streams by erecting all of the body feathers, looking then like a powderpuff, and holding the tail vertically; the white feathers of the forehead may also be lifted and manoeuvred. In aggressive display towards conspecific Cape Robin-chats, the territory-holder faces his rival and slowly raises a fully fanned tail while singing loudly. Chasing may ensue, often with the holder's mate involved. Skirmishes with persistent trespassers may continue through the day. Among African robins generally, territorial disputes are common and can lead to breast-to-breast fighting. With Chorister Robin-chats (*Cossypha dichroa*), however, territorial rivalry may be suspended during the brood-feeding period, as two pairs were seen to intermingle while foraging near the common boundary of their adjoining territories.

Signalling behaviour of the Hermit Thrush involves at least 14 different displays. These are gaping, resembling a ritualized intention to bite; bill-snapping; crest-raising; the "spread" display, with puffing-up of the feathers; wing-flicking; tail-flicking; foot-quivering, whereby a rattling sound is produced as the feet are alternately vibrated in the leaf litter; the upward stretch; the horizontal stretch; the "withdrawn" posture, with the head between the shoulders and shivering of the wings away from the body; the freezing crouch; wing-flashing; tail-raising; and a noisy flight termed "winnowing". Most of these appear to be associated with direct aggression, exceptions being foot-quivering and tail-raising, which indicate attack/escape ambivalence, "withdrawn", which conveys submission, wing-flashing, which precedes retreat, and the freezing crouch, which is used in response to an aerial predator. Similar repertoires exist for other turdid species, but they have not been detailed.

Threat displays of the Eastern Bluebird include "facing", "gaping", and "wing-flicking", and this species' appeasement displays include "turning-away" and "fluffed posture". In turning-away, the bluebird fluffs out its feathers and then turns its head away from its opponent, this being performed also by an individual towards its mate. In fluffed posture, it retracts the head and fluffs the feathers. Of the threat displays, facing involves the turning of the head to face the opponent, usually when individual distance has been violated. Gaping is similar, except that the bill is held open; at high intensity, the head feathers are sleeked and the bird leans towards its rival. In wing-flicking, which is always directed at a conspecific, the bluebird perches in an oblique position and, with warbling and chattering notes as accompaniment, flicks both wings rapidly out to a plane level with the body; it may also fan its tail. In a "wings-out display", which is always directed against a non-conspecific, it faces its opponent, with legs fully flexed, body horizontal, plumage sleeked, and wings held horizontally to the side, and usually follows this with an alarm scream and an aerial attack. A "head-forward display", often preceding a supplanting attack on a conspecific, is given when facing an opponent, during which the body is kept horizontal, the head retracted, the tail slightly lowered and the body sleeked. In "oblique bill-up display", the body and tail are held at an angle to the head; in "horizontal bill-up display", the legs are extended, the neck stretched, and the head and bill pointed upwards, so that the black chin stripes possessed by both sexes are exposed to the opponent's view.

Territorial defence by Townsend's Solitaire, which is territorial in both summer and winter quarters, involves posturing, and supplanting actions with the aim of landing on a perched intruder, thereby forcing it to move, as well as chases and grappling. In stand-offs, the territory-holder gives a "puff display" by erecting the body plumage and pulling in the head and neck so as to assume a partially spherical shape, sometimes squinting to accentuate the white eyering; it is interesting that this is considered an appeasement display when performed by bluebirds. Chases can be no more than a mild escorting, in which the territory-holder flies up to join and briefly accompany a passing aerial intruder, but at higher levels of aggression the solitaire flies fast and directly at an intruder, which either retreats or becomes involved in a complex high-speed twisting, turning race through the undergrowth, around the territory. Grappling is full physical confrontation in which, from adjacent perches on the ground or in trees, two opponents launch at each other and spiral upwards, interlocking their feet, flailing and pecking, and sometimes tumbling to the ground to fight, often resulting in visible injury to one party.

The sizes of winter territories occupied by Townsend's Solitaire vary considerably, from as small as 0·01 ha and with as few as two juniper trees (*Juniperus*), but presumably large and productive ones, to relatively large, more than 5 ha in extent, and containing several hundred junipers, presumably small and less productive ones. Territory size is negatively correlated with the

*The **Buff-streaked Chat** spends much time on the ground, bounding from stones to pick up seeds and small insects. Equally often it forages from the top of a boulder or bush, whence most foraging manoeuvres (70%) involve a sally after flying prey, such as this lepidopteran. Sallies to the ground or to vegetation occur much less often. Morphologically, it looks like a cross between a stonechat and a wheatear, but partly on account of its foraging tactics it seems to deserve placement in a monotypic genus, perhaps a stepping-stone between the twin assemblages of* Oenanthe *and* Saxicola.

[*Campicoloides bifasciatus*, Wakkerstroom, Mpumalanga, South Africa. Photo: Warwick Tarboton]

density of juniper berries, and is affected by the number of competing solitaires. As with the European Robin, boundaries between territories are sharply defined, with little or no overlap; and, indeed, the European Robin shows the same proclivity for defending very small areas, as little as 0·04 ha, if these are sufficient to satisfy its needs. Similarly, American Robins and Mistle Thrushes may establish tiny winter territories to defend fruit resources, such as a single fruiting crab apple (*Malus sylvestris*). Defensive attacks by European Robins on intruders are more numerous in November–January than they are in February–March, and they are more pronounced, first, against conspecifics, second, in and just after cold weather and, third, when the number of intruders is lower. In this last context, too many intruders make the costs of defence too high.

Despite the strong evidence that winter territorialism among thrushes and robins is directly related to the defence of a food resource, a study of European Robins wintering in Spain revealed that the body condition of "floaters", individuals without territories, was no different from that of territory-holders. It suggested that, instead, the real benefit to territory-holders lies in concealment from predators, because, compared with floaters, they spend a higher percentage of time hidden and are able to forage in areas closer to cover. Moreover, separate work has shown that European Robins are slower to see, and hence to react to, potential predators in the neighbourhood when they fight than when they merely use threat display. The risk of predation, alongside the risk of injury or worse during fighting itself, may, therefore, be an additional disincentive to enagage in physical combat. Whether territory-holders have fewer or more fights than do floaters has not, apparently, been established, but it would seem to depend on the extent to which floaters attempt to become holders. If they have fewer battles, then there is still stronger supporting evidence for the value of territorialism; if more, this would be a better explanation of why floaters continue to float.

The spectrum of behaviour exhibited by bird species in response to predators is fully covered in the Turdidae. There are, as mentioned, the extreme skulkers, mostly in the genera *Zoothera*, *Luscinia* and *Brachypteryx*, which avoid exposure to predation, at least by hawks (Accipitridae), by hiding in the depths of undergrowth and by revealing themselves only briefly and/or only vocally. There are also the extreme extroverts, such as the Cape Robin-chat and the Karoo Scrub-robin, the latter of which is so bold in mobbing potential predators such as mongooses (Herpestinae), snakes and domestic cats that its Afrikaans names include *slangverklikker*, meaning "snake-proclaimer", and *katlagter*, or "cat-mocker". In this regard, the bold coloration of some of the desert-adapted wheatears, which are so aggressive to their congeners and conspecifics, would appear to represent a pugnacious but foolhardy challenge to any predator. This striking coloration, however, is possessed mainly by those wheatears which use more broken terrain, so that the black-and-white pattern helps to break up the bird's outline in a landscape of shadows, although it is possible that it also assists in reducing metabolic costs between dusk and dawn, and perhaps signals the extreme unpalatability of these birds.

*At the far extreme of the continuum between frugivory and insectivory lies the **Bearded Scrub-robin**. This species has never been recorded eating seeds or fruit, and seems to subsist entirely on a wide range of invertebrates. These it captures by flipping leaf-litter with the bill, or digging in sand or soil. It has also been observed making short aerial sallies after flying insects, breaking open termitaria to access grubs, and hunting the insects flushed by swarms of driver ants. In general, it is quite a difficult bird to see, but it ventures from cover in the half-light of dawn and dusk to feed openly on roads and clearings.*

[*Erythropygia quadrivirgata quadrivirgata*, Mkuzi Game Reserve, Zululand. Photo: Warwick Tarboton]

True thrushes owe their unparalleled success, in large part, to an ecological flexibility which allows them to exploit both invertebrates and fruit. Most are adapted to life on the ground, but make free use of elevated perches: they are capable of foraging terrestrially or arboreally on a wide range of prey items and plant material. Nonetheless, the bulk of the diet comprises invertebrates, most of which are gleaned from the ground. As its name suggests, the ***Groundscraper Thrush*** *is partial to digging or sifting the topsoil and leaf litter with its bill or feet. In so doing it reveals the grubs and sundry invertebrate items which are its staple.*

[*Psophocichla litsitsirupa litsitsirupa*, Kruger National Park, South Africa. Photo: Hanne & Jens Eriksen]

Some members of the family have a permanently "worried" look. S. L. Hilty neatly captures the psychological jizz of Swainson's Thrushes, describing them "as if perpetually fearful, and apt to flee at the slightest movement" and which, at fruiting trees, "stare wide-eyed, then bolt for cover after hurriedly fluttering for a few berries or gobbling *Cecropia* catkins." A very few are absurdly bold. Tristan Thrushes exhibit the extreme tameness of insular animals that have evolved in the absence of predators. One explorer was able to capture specimens of this species with his bare hands or knock them down with a stick; moreover, when camping on Nightingale and Inaccessible Islands, he would be woken up early in the morning by the thrushes hopping around on his body, and in the camp laboratory they walked around among his glasses and journals, inquisitive about everything. Rather more familiar is the tameness of European Robins, which can easily be trained to take food from a person's hand, and which often hop around gardeners' feet as they turn the earth; indeed, an adult once repeatedly flew to the hand of a researcher holding and measuring a brood of five-day-old nestlings and fed them from his fingertips! Likewise, the American Robin forages in among the feet of strollers and joggers in public gardens, as in New York's Central Park.

When directly threatened by a predator, however, all thrushes and chats react in broadly similar ways, depending on context. Bassian Thrushes stay absolutely stock-still when a potential predator comes near, and blend perfectly with the leaf litter. Siberian Rubythroats do likewise, having first turned their back on the intruder in order to conceal the red throat. The Brown Scrub-robin flies up to a perch about 3 m off the ground, there remaining motionless and silent. Turdids in more exposed situations typically make a low fast flight for cover, where they land and hide. In the case of some of the whistling-thrushes, the haven may be the darkness of the caves at the mouths of which they nest. A Mocking Cliff-chat (*Thamnolaea cinnamomeiventris*) outwitted a would-be collector by dodging down and through the burrows of rock hyraxes (*Procavia*), reappearing in completely unexpected places when compared with where it had last been seen. A foraging Red-backed Scrub-robin disturbed by the approach of an observer may fly up briefly, and then drop back to the ground behind a grass tussock and run like a mouse to the cover of the nearest thicket. Sometimes, however, the reaction is to remain motionless. In western North America, adult Mountain Bluebirds (*Sialia currucoides*) hide in grass when a bird-eating raptor appears. Similarly, in the Old World, Redwings have been seen to respond to the appearance overhead of a Eurasian Sparrowhawk (*Accipiter nisus*) by freezing and pressing themselves down in grass, seeming to mimic the large autumn leaves scattered across it; this is presumably the equivalent of the freezing crouch of the Hermit Thrush. As a final example, breeding Fieldfares exhibit a remarkable behavioural adaptation to counter a perceived threat: they defecate on would-be predators (see Breeding).

Avian predators of turdids are typically hawks and falcons. In North America, Sharp-shinned Hawks (*Accipiter striatus*) commonly account for *Catharus* thrushes. Eleven such hawks in Colorado, in the west-central USA, were found to have 3·2% of their diet composed of Hermit Thrushes, many of them fledglings, and migrant Swainson's Thrushes are also frequent victims of this raptor. In Europe, many migrating Common Nightingales, during their autumn migration across the Mediterranean Sea, are caught by Eleonora's Falcons (*Falco eleonorae*). Several other avian predators exist, however, including the Great Grey Shrike (*Lanius excubitor*), which frequently takes Grey-cheeked Thrushes in the taiga–tundra shrublands. On one occasion, a young female Hermit Thrush was seized in flight by a Western Scrub-jay (*Aphelocoma californica*) which launched a surprise attack from a hedge. The larger gulls (*Larus*) pursue tiring migrant thrushes and chats as they approach land, catching them in the bill or using the feet or wings to knock them into the sea.

Body mass is now thought to be a decisive factor in predation avoidance, since extra weight probably compromises escape-flight efficiency. In his work on Common Blackbirds, W. Cresswell has examined the conflict between increasing body reserves, in order to reduce the risk of starvation, and curtailing body reserves, so as to reduce the risk of predation. Since highly efficient foragers would be expected to manage this balance well, he predicted that relatively poor foragers, in having less foraging success, would paradoxically lay down more body reserves against the risk of starvation. This turned out to be the case: Common Blackbirds with high relative foraging rates had lower body reserves during the winter months, and it is these efficient individuals, therefore, that are most likely to escape predation during this period. Almost certainly, foraging efficiency is in part a function of age, and the age-class of Common Blackbirds that is most vulnerable to predation will be the relatively inexperienced first-

As with all Turdus *thrushes, the main terrestrial foraging technique of the* ***Sooty Thrush*** *requires a three-part sequence of actions, the first involving a brief burst of running or springy hops, the second a pause to listen or observe, often with head slightly cocked, and the third a quick pounce if prey is detected. This last action might result in an insect being seized and swallowed in a single movement, or else to a bout of soil digging or leaf-tossing in order to uncover suspected prey.*

[*Turdus nigrescens*, Cerro de la Muerte, Costa Rica. Photo: Michael & Patricia Fogden]

years. By extrapolation, this applies to all thrushes and chats and, indeed, to all avian species.

Of course, inefficient foragers, young individuals, will also be more liable to death by starvation. For every species of thrush and chat that has been studied in sufficient depth, survival rates of young birds are lower than those of adults. In the case of European Robins in Britain, the mortality of yearlings after 1st August is 72%, whereas annual mortality of adults is 62%; for the same species in Belgium, the corresponding figures are 71% and 54%. The mortality of yearling Common Blackbirds in Britain after 1st August is 58%, whereas adults have an annual mortality rate of 44%. In North America, the corresponding figures for Swainson's Thrush are 74% and 44%, and for the American Robin approximately 75% and 48%, while for the Omao, in Hawaii, mortality of one-year-olds and two-year-olds combined is 60% and that of adults 34%. Survival of first-year Song Thrushes is correlated negatively with the length of cold-weather spells in winter, whereas adults are able to withstand such periods because of their dominance and efficiency at berry sources. Survival of adult Song Thrushes, on the other hand, is correlated negatively with the length of warm summer droughts, when there are neither earthworms and snails nor berries for them to exploit.

There are other effects, too. In order to live a long life as a thrush or chat, it is helpful to be male and to be tropical. For example, adult mortality in one British study of Common Blackbirds was only 41% for males but 66% for females, and at one site on Hawaii the annual survival of male Omaos was twice that of females. Among White-starred Robins (*Pogonocichla stellata*), the survival rate of breeding birds in South Africa was 77–90% for males, as against 68–84% for females, and in Malawi the average annual survival was 79–83% among males but as low as 60–71·5% among females. Similarly, the annual adult survival rate of Chorister Robin-chats is 87% for males and 70% for females. In the case of this species congener, the Olive-flanked Robin-chat, an extraordinary level of difference between the sexes has been recorded, with an annual mortality rate of just 13·7% for males contrasting with the 43·3% found for females. One species to buck this trend is the Wood Thrush. Data derived from one long-term study of this Nearctic turdine indicate that females live on average about a year longer than do males, generally reaching senescence in their eighth year, whereas males become senescent in their seventh year.

Meanwhile, R. E. Ricklefs, using a large sample of museum specimens, estimated annual survival rates of American thrushes and found them to vary from a mean of 56% in temperate North American populations to 68% in subtropical South American populations, 76% in lowland tropical populations, and 80% and 85% in tropical montane populations in Central and South America, respectively. Survival rates of these species are most strongly correlated with the difference between maximum and minimum mean monthly temperatures; in other words, survival is inversely related to seasonality of temperature. Many questions arise from this, but it is well understood that migration, a common response to strong annual fluctuation in temperature, brings with it elevated risks.

There are few data on longevity among the Turdidae, and single records tell very little, but it is interesting that, of the two longest-lived thrushes recorded in the wild, one, a Mistle Thrush from temperate climes, and a migrant, was at least 21 years old, while the other, a Chorister Robin-chat from the tropics, and a resident, achieved at least 26 years. Even the tiny White-starred Robin has been recorded as living to 14 years of age. Otherwise, a captive male Blue-shouldered Robin-chat was still siring two broods annually at the age of 24.

Voice

Of all the many distinctions in the ornithological world to which the thrushes and chats lay claim, it is for the sheer beauty and versatility of their songs that they probably achieve the highest public esteem. No other family combines such richness and phrasing of some species with such astonishing imitative capacity of others. In North America, the forest thrushes all carry the flame for the family; in the Neotropical Region, the solitaires, one or two nightingale-thrushes and one amazing *Turdus* do so. In Africa, the robin-chats and scrub-robins are the supreme vocalists, this position being held by the nightingales and shamas in Eurasia.

Ecologists and systematists working on some of these birds have been prompted by what they hear to shelve their sometimes

dry terminologies and to break out into song of their own. Here are Slud's words on the Black-faced Solitaire in Costa Rica:

> "The disembodied song, hanging in the air like an echo, its struck-crystal timbre harmonizing with the chill surroundings, is almost impossible to trace... Stressing virgin clarity of tone instead of vocal pyrotechnics, this solitaire is surely one of the most refined singers of this or any country. Its song has reached a substance-shedding extreme to which the nightingale thrushes and *Hylocichla* thrushes, so to speak, aspire."

Here is G. M. Sutton waxing more personally lyrical over the Brown-backed Solitaire (*Myadestes occidentalis*):

> "It was so brilliant, so amazingly complex, that I could scarcely believe my ears... The... body of the song, the song proper, was a slowly descending, sadly sweet whistle accompanied by such a profusion of grace notes... so beautiful, so wondrously like musical fireworks, that I opened my mouth and gasped. Never in all my journeyings had bird-music wrung from me such ineffable applause, or filled me with such wild, half-furious exultation. 'I've never heard! I've never heard!' I whispered to myself, as if confessing that up to that high moment my ears had never fully functioned."

And here is Skutch on the same species:

> "How shall I set about to describe a song so utterly unlike all familiar bird songs, and how can I convey the reverential feelings that it inspires as one stands listening to it amid the dark mountain forests?... The *Guarda Barranco*'s music is a chiming of sweet-toned pipes, a wild, jingling melody that, heard from a little distance, fills the listener with a profound sense of the freedom of the forest and its mystery... I loved the music of the Guardian of the Ravine for its wild, unstudied exuberance, which expresses the untamable spirit of nature... a wild untutored mountaineer, careless of studied art, but overflowing with joyous vitality that must find vocal expression."

Again and again one finds the voice of a thrush or a robin being picked out as the sweetest song to be heard in a country or a continent; and again and again one finds the voice of a thrush or robin being used in poetry to fix a moment of union between man and nature (see Relationship with Man).

Of the songs that impress human ears, perhaps the best are those of the most solitary species. The name "solitaire" was particularly well chosen, conveying, as it does, not only the isolation of the singer but also its diamond-like vocal purity. Invariably, these songs are composed of rich, pure sounds that have recognizably musical dimensions. The words "flute", "bell" and "whistle" commonly appear in descriptions, and some of the very best singers operate in conditions, such as cold still canyons, or warm still nights, in which their voices will resonate and amplify so as to carry over unexpected distances. On the other hand, some turdids are simply very loud. The song of Swynnerton's Robin (*Swynnertonia swynnertoni*) is a startlingly powerful utterance for so small a bird, as are the final notes of the crescendo song of the White-browed Robin-chat, at which, in Oatley's evocation, "the bird's whole body seems compulsively committed to pumping out the song—the tail jerks, the wings flutter and the air-sacs in the neck and clavicular region are visibly inflated".

By way of contrast, the songs that are often least impressive come either from among the most gregarious species, such as the American Mountain Thrush (*Turdus plebejus*), the Sooty Thrush (*Turdus nigrescens*), the Redwing and the Fieldfare, or from those, such as the forktails and water-redstarts, for which the ambient sound of running water represents too strong a competitor. The song of the highly sociable Grandala has seemingly atrophied to a version of the call, and this is to some extent true also of the Fieldfare and its half-hissed cackles. The Fieldfare's partly onomatopoeic Finnish name, *räkättirastas*, perfectly captures the cacophonous *racket* produced by loose groups of singing individuals in the trees around houses where people are trying to sleep; by chance, the alliterative suffix *rastas* means simply "thrush".

Of course, the solitary/sociable aesthetic is not clear-cut. So shrill, displeasing and persistent is the song of the fairly solitary Glossy-black Thrush (*Turdus serranus*) that A. H. Miller wrote "we noted almost with relief the cessation of their song". Perhaps he took further relief in shooting some, whereby he was able to determine that, in South American *Turdus* species, song is directly related to gonad condition and breeding activity, whereas, in the case of the Andean Solitaire, it appears to continue independently of sexual development.

Like other passerines, the thrushes and chats sing mainly during the breeding season, and mainly at dawn and dusk. Indeed, many species in this family, including the Omao of Hawaii and the Malabar Whistling-thrush (*Myophonus horsfieldii*) of India, are well known as the earliest singers in the morning and the latest in the evening. At key points in the breeding cycle, however, individuals can sing almost all day, and a few species sing also at night, at least on moonlit nights, as does the Spotted Palm-thrush (*Cichladusa guttata*), or in lamplit areas, as does the European Robin. Nevertheless, owing to the strong territorialism of many turdids, and to the fact that this can extend throughout the year (see General Habits), song is common in the non-breeding period, too, although it is often then different in quality. During the breeding period, only the males commonly sing, although there are many exceptions to this, as illustrated by, among others, the Veery during pair-formation, when both sexes sing back and forth to each other, and various African robins, including the Brown-backed Scrub-robin, pair-members of which duet, and the Cape Robin-chat, the female of which performs shorter, quieter versions of her mate's song. With regard to the last-mentioned, however, Oatley relates how a colour-ringed female in his garden, following the death of her mate of seven years, performed full territorial advertisement song daily from his songposts, persisting in this behaviour for 12 weeks. Outside the breeding season, however, if a species sings at all, and especially if it defends individual winter territories, then both males and females sing, as in the case of the European Robin.

Some species, such as the *Neocossyphus* and *Stizorhina* myadestines, deliver relatively undeveloped, primitive songs, and the turdine cochoas and Rufous-brown Solitaire (*Cichlopsis leucogenys*) offer nothing better than convergently similar long

The foraging methods of Turdus *thrushes are a common sight on garden lawns in both Old and New Worlds. They run, pause, and stab at the ground, especially after rains have summoned worms to the surface. These are extracted with swift determination, but how are they detected in the first place? In answer to this debate, it was found that an* ***American Robin*** *deprived of sight, smell and touch, could still forage perfectly well on buried prey, presumably by using audial cues alone. This explains the tilted head of the hunting thrush, a posture that facilitates the detection of infinitesimal wormy sounds below the lawn's surface.*

[*Turdus migratorius*, Grey County, Ontario, Canada. Photo: George K. Peck]

high whistles. For most thrushes and chats, however, song typically consists of extended series of highly modulated phrases. Each phrase may resemble the preceding one exactly, closely or moderately, depending on the species and the individual, but it usually exhibits some difference, so that the number of discrete phrases used in a song is high. Among the slower-singing thrushes, these differences may be very obvious. In parts of China, the Common Blackbird is known as "one-hundred tongues" on account of the variety of its song, and such a name will be understood by everyone who has heard the species sing. With some other turdine thrushes and the faster-singing chats, however, it can sometimes be difficult to discern the variation, or, at least, its extent, and if the phrases are sufficiently disjunct, as is so with the Whinchat, then each phrase becomes thought of as the song itself. The difference between these two general types of song as exhibited by thrushes, one relatively complex and continuous and the other relatively simple and strongly spaced, has been thought to reflect the difference in the degree to which the songs are used for female attraction (the first type) or male repulsion (the second type), but modern evidence tends to suggest that this interpretation is too simplistic.

The function of avian song is still a matter of much study, and the Turdidae, owing to their accessibility and amenability, have been key experimental subjects in this aspect of biological science. With this work there has emerged a growing appreciation that the complexity of many species' songs cannot be ignored as just random meaningless babble, but that it is, instead, a crucial part of the birds' existence and as essential to them, and to our understanding of them, as are blood and feathers. Song is information. It conveys with considerable precision the circumstance and status of the singer, and it allows the listeners, including local territory-holders, floating males prospecting for a territory, unmated females and even, if the singer has one, its mate, to make decisions on the basis of that circumstance and status.

Perhaps the most obvious example of this concerns nocturnal singing by the Common Nightingale. This wonderful sound, one of the greatest inspirations to the human listener (see Relationship with Man), conveys one major piece of information: that the singer is unmated. When the males of this species arrive back on their breeding grounds in the spring, all are unmated and all sing at night; the typical pattern is for a rapid increase in singing intensity after nightfall, reaching a broad peak in the middle of the night, and tailing off before dawn. Within a fortnight, however, most females have arrived and most have found partners, so that the males of these pairs are diverted towards activities other than the expensive and now needless business of nocturnal self-advertisement; it should be noted that singing at night results in increased consumption of body reserves. They continue to sing at dawn and dusk, thereby advertising their territorial ownership, but, apart from a short period when their mates are laying, they now leave it entirely to the unmated territorial males to sing throughout the night and to broadcast their status and their need to the listening darkness.

Listening, rather than just hearing, is certainly happening. Late-arriving unmated females, if there are any, will doubtless be seeking to discriminate between performances of available males in order to assess their quality as prospective parents. Mated males in adjacent areas will almost certainly adjust their behaviour accordingly: lack of a female on the territory means that they have less interest in investigating the area. Radio-tracking studies have shown that, while mated territorial Common Nightingales spend 90% of their time within their own territory, for 10% of the time they move quietly into ground held by at least one neighbour, mainly before and during the female fertile period. The time that they spend on such forays correlates negatively with the song rate of these neighbours; in other words, high song rate leads to short intrusion time, and *vice versa*. Song rate therefore appears to indicate male quality, and low song rate is an unintended disclosure to adjacent listeners of opportunities for extra-pair copulations. Radio-tracking has further revealed that non-territorial Common Nightingales also make surreptitious investigations of this sort as they prospect for appropriate sites, approaching the edges of occupied territories mainly in the hour before sunrise, and eavesdropping on their holders' songs in order to assess the quality of the singer.

When two rival Common Nightingales begin to countersing, which tends to happen when all or part of a territory is under dispute at the start of the breeding season, something very akin to a human argument happens. This involves, first, an exchange in which each listens to and directs itself at the other, and then, if neither is convinced of the other's superiority, an escalation into an approximately face-to-face overlapping duel in which the two sing at each other simultaneously, with the rate of the song and

*Snails make up a large part of the diet in a few thrushes, most famously the **Song Thrush**. The tough calcified shell deters most avian predators, but this species has learnt a behavioural trick to bypass the snail's defences: it carries its victim to an "anvil", usually a rock, root or paving stone, and beats it to smithereens. By holding the shell's rim, or the snail itself, and by hurling the hapless mollusc downward and sideways with a vigorous flicking motion, the thrush cracks open the shell to reveal soft flesh within. This is wiped on the ground to remove inedible fragments, and finally consumed.*

[*Turdus philomelos clarkei*, Sussex, England. Photo: Roger Wilmshurst/ FLPA]

the level of interruption increasing. Thus, degrees of self-confidence are being conveyed and tested to the limit. In the case of Song Thrushes, countersinging can be extraordinarily loud, the voice being used very much as it is by arguing human beings, as a means of conveying the physical power and level of aggression of the owner. In contrast, the song of European Robins in this situation becomes an almost continuous, low-amplitude "twittering", a kind of subsong, presumably owing to the greater predation risk that loud singing would engender.

Even when aggressively countersinging, however, the singers are capable of learning from each other. When male White-crowned Wheatears countersing, each uses the same song type as that of its rival, and, when a tape is played to one of them, he responds by switching to the song coming from the tape. This ability to pick up and use new material is widespread in the family, and in its extreme form results in the mimicry of exceptional distinction which many species display. Moreover, it is apparent also at the other end of the spectrum with such species as the simple-songed Redwing. Populations of this thrush in southern Norway have been shown to possess clearly defined, annually constant song-dialect areas. Researchers have found 27 such areas, ranging in size from 2 km² to 159 km², with a mean of 41·5 km², within each of which almost all males sing the dominant song type, although some may produce a secondary song type based on the dominant type in an adjacent dialect area. Something similar has been found among both Common and Thrush Nightingales, neighbouring males fine-tuning their repertoires to match each other so far as possible. This conformity, the taking-over of elements from a rival and using them in reply, is assumed to be a strong indicator of territory tenure and, thus, important in repelling rivals and attracting mates. It hints at a tension between the needs for stability and innovation. Stability may be desirable because it permits an environment of minimal conflict, and results in a local "dialect" or "accent" which may help to indicate adaptive occupancy of a particular tract of land; and innovation may be desirable because it permits adaptation to the real, changing environment, and may help to indicate the relative genetic diversity of the singers.

Thus, for example, the Veery can distinguish between the songs of neighbours and those of strangers, reacting far more aggressively when one of the latter intrudes on its territory than when one of the former does so. In this species, as with the nightingales, it would appear that familiarity with neighbouring songs allows stability in relations and, hence, minimal affray and risk. This may also be the case with the Bearded Scrub-robin, different songs of which even the human ear can distinguish by the intervals between phrases and the duration of the series. For the Varied Thrush, on the other hand, studies of song structure suggest that males alter the frequency and duration of their long, thin song notes in order to reduce habituation by their neighbours. Further, while both Swainson's and Hermit Thrushes have predictable sequences to the songs that they sing, the Grey-cheeked Thrush deploys at least 14 constant discrete sets of notes in five fairly constant sequences, or "song types", but the song types themselves have no fixed order and appear to be given randomly. In the late evening in Newfoundland, in east Canada, Grey-cheeked Thrushes form "singing groups" in which individuals perch and sing close to one another. To what extent are they copying and, conversely, to what extent are they avoiding copying their neighbours?

They are, at any rate, being stimulated to sing by each other, as singing intensity, at least among turdids, is a function of population density. The song frequency of an American Robin, for example, is positively correlated with the number of its neighbours. A most poignant further instance is that of the Olomao (*Myadestes lanaiensis*) population on Molokai, in the Hawaiian Islands (see also Status and Conservation). This species became increasingly silent there as it grew rarer and more thinly distributed, and, although it continued to be observed into the 1980s, its song had by then not been heard for decades. Presumably, it continued to breed for some time without the necessity of defending territorial space against other males or of seeking new female partners, activities which are also a cost in terms of increased predation risk and energy loss. The offspring of these silent breeders would themselves, of course, be unlikely to acquire songs of their own.

Yearling male Common Blackbirds initially learn their songs from their neighbours, a situation that applies also to Common Nightingales and is presumably normal for all thrushes and chats. This first-spring exposure is extremely important to the ultimate acquisition of full song. In the early stages of the spring, the yearling Blackbird may repeat the same phrase many times in succession, but as the season advances it steadily develops the ability to vary and recombine the phrases which it learns. "Sentences"

Thrushes are not well known as adaptable opportunists, seeming instead to have a few tried and trusted foraging tactics with which they faithfully persevere. In many cases, however, they have learnt to make use of concentrated supplies of insect prey. Some species follow ant swarms, or large herbivores, to hunt the insects disturbed by their passage, sometimes even alighting on mammals to glean their ectoparasites. Others, like this ***Plain-backed Thrush****, are attracted to rubbish tips and dung heaps at the edge of towns where insects, grubs and worms abound.*

[*Zoothera mollissima*, Naini Tal, India. Photo: Christian Artuso]

Some thrushes eat small vertebrates such as rodents, amphibians and reptiles, as this male ***Blue Rock-thrush*** *so aptly demonstrates. It has captured a small* Podarcis *lizard, a form of prey that is often found in abundance on the sunlit rocks of the rock-thrush's favoured habitat. There is even some evidence that breeding adults preferentially target such lizards during the nestling phase, and use them to provision their offspring. This makes sense in view of the protein, calcium and energy content of a soft-bodied animal, versus an insect or a fruit.*

—chains of phrases in a preferred order, but lacking pauses—are sometimes formed, and repeated sequences of particular phrases are elaborated, at least by some individuals. Discernible variations in quality of song, such as were noted also for the Common Redstart by J. Buxton, very probably reflect different ages of singers, but also, inevitably, the different environments in which they are raised. In the early parts of the season, Common Blackbirds seem to practise their songs, often sitting in the middle of a tree. Bearded Scrub-robins quite often do the same thing, prefacing a period of "public singing" in the treetops with a spell of "private practice" in the undergrowth.

The extent to which such "practice" is confined to younger members of the population is not established, but for Common Blackbirds, at least, song-learning appears to continue throughout the individual's life, with little material being discarded, so that over five years or more the only change in the repertoire is in its increasing diversity. The rich, fluting phrases that are the hallmark of the mature Common Blackbird song may have been copied from neighbours, but the variations become increasingly individual; it is in the high-pitched flourishes, or "codas", concluding each phrase that the opportunity arises for direct mimicry of non-blackbird sounds, although these are often hard to detect. One coda incorporation that began to be heard on suburban estates in Britain in the 1990s was the car alarm in its various manifestations. Experimental work by T. Dabelsteen and co-workers has shown that the habitat-induced "degradation", in terms of carrying distance, of the Common Blackbird's song is inversely proportional to the height at which it is heard, but is unrelated to the height at which it is transmitted. This suggests that the main reason for a male to sing from a high perch is to improve his ability to hear responses to his songs, rather than to maximize the transmission distance of his own.

In Australia, mimicry is most advanced among bird species which are highly territorial and live on the forest floor, where visibility is low. While many thrushes and chats conform to this pattern and sing from low perches in deep cover—Crossley's Ground-thrush (*Zoothera crossleyi*) of Africa even singing from the ground—many are nevertheless open-country species using low but exposed perches, and a few are forest-canopy singers. A comprehensive explanation of avian vocal mimicry is still lacking, but there are some pointers. For example, mimicry by the Black-eared Wheatear is reportedly greatest in the 15-day period between the males' arrival on the breeding grounds and the arrival of females, in which case it is not likely to be used for attracting females. Moreover, as just noted, Common Blackbirds introduce mimicry into the phrase coda, which has been demonstrated by research not to be used by or directed at females but, instead, to be aimed at neighbouring males; it is, presumably, the phrase codas, and the important status information that they contain, to which high-perching singing males are listening. Both of these facts suggest that mimicry is primarily a male–male signal of status and quality, although in some extreme cases its function may have shifted.

The speed at which vocabularies can be extended is striking. A singing White-crowned Wheatear, one already noted for instantly imitating tape-recorded song, began to mimic the motor-drive and shutter click of a camera even while its picture was being taken. The White-throated Robin-chat immediately copies novel sounds within its preferred frequency range, sometimes causing great confusion to people using whistles for maintaining contact in the bush. Whinchats copy imitations from each other. At one locality, calls of a Common Swift (*Apus apus*) and a Common Nightingale mimicked by one male Whinchat entered the repertoire of its neighbour within a few days, and were being used by half of the local population after a week. This last anecdote is a reminder that mimics do not necessarily acquire other species' sounds through direct auditory contact, but can do so by copying from the vocabulary of another mimic. With the Rufous-capped Robin-chat, such instant vocal copying is integral to the interactions within local populations. A male of this species, when singing against its neighbours, will suddenly interject a particular imitation, of, say, an African Fish-eagle (*Haliaeetus vocifer*), only for it to be repeated by all the neighbouring robins, and then, abruptly, another individual introduces the call of another species, which in turn is taken up by the others, this being followed by a further one, and another, and so on. In this example, the "copying" may, of course, be only repetition, since most or all of the population may have learnt the calls long before, but it tends to confirm that the main context of turdine mimicry is masculine.

Interaction between males is, however, by no means the only context for mimicry. *Cossypha* robin-chats have also acquired the ability to deploy mimicry of other species' alarm calls when an alarm call is appropriate, as when their young are at risk. Not only

In temperate thrushes invertebrates dominate the diet during the breeding season, with fruit predominating for the rest of the year, although even in mid-winter insectivory is never entirely revoked. These photographs show two species of Turdus *with Siberian breeding ranges: the* ***Eyebrowed Thrush****, mostly confined to tall coniferous forests; and the* ***Dusky Thrush****, found in montane shrubland and riverine birch woodland at the fringe of tundra. These habitats are productive in summer, but inhospitable in winter, when both these species are forced to migrate to more southerly climes. There, they commonly form flocks and switch their attentions from insects to fruit, ranking among the most frequent visitors to berry-laden shrubs and trees.*

do they give their own distinctive alarms in such situations, but they also intersperse them with the alarm calls of many other species. This is presumably adaptive, since the young rapidly associate the alarm calls of other species with genuine danger. Interestingly, the White-browed Robin-chat, the only member of the genus not to use mimicry in its songs, is an accomplished mimic of alarm calls. A further, and remarkable, context in which mimicry is used by robin-chats was recorded by Oatley and involved a pair of Chorister Robin-chats. This pair shared its habitat with Southern Boubous (*Laniarius ferrugineus*), a malaconotid species in which the male and the female duet. The robin-chats were seen on one occasion to call to each other in precisely the way in which the boubous do, one individual using one call and the other using a different one to reply, in an extended sequence. The robin-chats were, therefore, not simply mimicking the calls of the boubous, nor even, as with the alarm calls, merely using them in the context in which the calls are given, but also, and most awesomely, adopting the exact roles of the original pair of callers.

A parallel example of seemingly "intelligent" use of mimicked sound has been reported for a six-year-old captive White-rumped Shama. What most impressed E. Tretzel when he taught the shama to sing a musical scale was not the rapid learning or the accurate reproduction *per se*, although both these aspects were remarkable, but the fact that the scale was introduced and concluded with other sound groups in such a way as to create a passage with a pleasing effect of completeness, implying "a special sense of form and compositional ability on the part of the singer". Research on the Rufous-capped Robin-chat has demonstrated that this species indiscriminately mimics every sound that it can in its acoustic environment, with the one constraint that it cannot mimic complex vocalizations. The example of the White-rumped Shama, however, suggests that, even if the sounds used by these mimics are simple, the configurations into which they are assimilated may be anything but that. Similar processes of individual variation and "signature" may lie behind the already mentioned variations on a theme made by the aptly named Varied Thrush and the unpredictability of song-type sequence exhibited by the Grey-cheeked Thrush. But why do some Cape Robin-chats mimic extensively while others never imitate any sounds?

The prevalence and range of mimicry in the thrush family is extraordinary, with at least 78 of the 336 species, 23% of the Turdidae, known to use it in some degree. The Common Rock-thrush has been recorded as imitating the songs of as many as 23 Palearctic bird species, including the entire song phrase of a Chaffinch (*Fringilla coelebs*). In southern Africa, the average repertoire of a territorial male Chorister Robin-chat in KwaZulu-Natal included some 25 imitated calls of other species. This robin-chat has been known to imitate the yapping of small dogs and the horns of railway locomotives, while Rüppell's Robin-chat (*Cossypha semirufa*) copies various mechanical sounds and has been heard to mimic both the call and the drumming of a Bearded Woodpecker (*Dendropicos namaquus*). In recent studies, it was established that a single Kalahari Scrub-robin (*Erythropygia paena*) had a repertoire of over 40 calls of other species. Even more impressively, the total number of bird species known to be imitated by the Bluethroat is at least 64, of which 14 are found only in the New World, where the Bluethroat occurs only in a tiny part of the extreme north-west; these imitated Nearctic species range from the Bristle-thighed Curlew (*Numenius tahitiensis*) to the Golden-crowned Sparrow (*Zonotrichia atricapilla*). The Rusty-tailed Wheatear is reported as imitating the whistling of the wings of vultures, the bleating of sheep, and the sound made by the striking of an axe. A further interesting example of mimicry by turdids comes from the southern Neotropics. In the darkness before dawn on a rainy night, when petrels (Procellariidae) were leaving their hillside nests and returning overhead out to sea, an Austral Thrush singing above a shoreline camp-site very softly gave a direct imitation of the sounds of the petrels at a distance.

For a combination of range and quality of mimicry, however, nothing matches the accomplishment of Lawrence's Thrush (*Turdus lawrencii*) in South America. This is especially notable, as the South American *Turdus* assemblage is otherwise relatively undistinguished in its vocal and mimicking ability. In a discovery that was therefore as unexpected as it was astonishing, the late T. A. Parker found that the song of this modest-looking thrush consists entirely of near-perfect imitations of Amazonian forest wildlife, particularly the calls and parts of the songs of many bird species ranging from tinamous (Tinamidae) and parrots (Psittacidae) to formicariid ground-antbirds and to grosbeaks (Cardinalidae), with a single individual copying the sounds of up to 35 other species. Study of recordings of some 30 or so Lawrence's Thrushes revealed imitations of no fewer than 173 bird

*The **Eastern Bluebird** eats insects all summer but in autumn and winter it consumes a huge number of fruits and berries. In common with other seasonally frugivorous turdids, this species plays an important role as an agent for dispersal of seeds, especially as it wanders widely in winter and is thus likely to have travelled some distance from the parent plant before defecating. If seeds are retained too long in the intestinal tract they are damaged by digestive enzymes and germination is impaired. Of interest, therefore, is the discovery that some berry-bearing plants produce a laxative chemical that ensures rapid progress through the avian gut.*

[*Sialia sialis sialis*, Freeville, New York, USA. Photo: Marie Read]

Among the strangest of all thrushes are four species in the genus Cochoa, *all of which are beautiful creatures of the middle storey and subcanopy of humid Asian forests, where they are relatively difficult to observe because of their habit of perching motionless for long periods. Their sluggish demeanour, and their simple but extraordinarily high-pitched songs, bring to mind some Neotropical cotingids. Likewise, they appear to be largely frugivorous, with broad gapes designed, if this photograph of a* ***Green Cochoa*** *is anything to go by, to admit the passage of large drupes. They are often found in fruiting trees, but rarely noted foraging on the ground, or sallying for insects.*

[*Cochoa viridis*. Photo: Khun Chitapong Kuawong]

species, as well as ones of frogs and insects. So faithful are the renditions that ornithologists have begun to use them to judge whether certain species are present: several apparently out-of-range species have been found at sites simply because they were searched for after their songs were heard in the repertoire of Lawrence's Thrush. Males sing for hours from songposts in the canopy, with intermissions of 5–15 minutes. Playback produces no visible response, suggesting that the song is directed at females, and Parker predicted that the species would prove to have a promiscuous or polygynous mating system (see also Breeding). There is a puzzle why it extensively incorporates imitations of one common and frequently vocalizing raptor, the Black Hawk-eagle (*Spizaetus tyrannus*), while never mimicking another, the Roadside Hawk (*Buteo magnirostris*). This seems to have been solved by Tobias, who finds that Lawrence's Thrushes almost always avoid short single-note songs, like the hawk's, and choose instead songs with a little more complexity, usually lasting a second or more, like the eagle's.

If, in the case of Lawrence's Thrush, sexual selection drives the mimicry, so that the extraordinary ornamentation of its song is akin to the extraordinary ornamentation of a bowerbird's (Ptilonorhynchidae) bower, there remains the puzzle over what is the motive power behind mimicry in other species. Buxton, in his study of Common Redstarts, contemplated the notion that listeners might be discouraged by the illusion that various competitors were present, which is a prototype of the Beau Geste hypothesis, but he could not then explain why the redstart so persistently mimicked a bird so ecologically uncompetitive to redstarts as the Willow Warbler (*Phylloscopus trochilus*). On the other hand, if all imitative thrushes and chats are programmed simply to assimilate all the sounds of their environment, as does the Rufous-capped Robin-chat, it could be argued that such mimicry signals that any individual managing to hold a territory in so heavily and diversely occupied a parcel of habitat must be of the highest quality. This is not exactly consistent with the Beau Geste hypothesis, which proposes that the signal creates an illusion of heavy and diverse occupation by direct competitors; instead, it is more of an honest signal, although the opportunity to be dishonest presumably exists for this species, as for others, through the vocal copying of neighbours without having primary contact with the source of the mimicked sound.

Another intriguing discovery of Parker's, and one which is reasonably consistent with the idea that mimicry is a display of "personal quality", was that two close relatives of Lawrence's Thrush, the Pale-breasted and Hauxwell's Thrushes, responded to playback of their own, plain songs by singing songs full of mimicry. One must assume that these responses were intended to demonstrate to the intruder a breadth of ability that would register in the latter's mind the need for caution, yet it seems as if the birds were so disconcerted by the sudden proximity of a confidently singing conspecific that they were temporarily left in a state of jabbering incoherence. This impression is reinforced by the fact that, in at least one instance, the delivery was at the volume of subsong, or "whisper song". In high-intensity contexts such as courtship and confrontation, however, the songs of some species become ever more strangled and wheezy, a trait displayed by the Black Redstart, the Thrush Nightingale and the European Robin. Increasingly loud countersinging is presumably the more frequent response when neighbours have more equal status.

Variations in the quality, type and timing of song by thrushes and chats are considerable, but they are, in fact, relatively poorly documented and are only slowly being understood. Context, age of singer, season of year and time of day all play a part in such variations, as, indeed, does background noise. Common Nightingales, for instance, can adjust the volume at which they sing to compensate for traffic-generated white noise, although not without a cost in terms of energy. In the course of a spring day, for example, the Common Blackbird delivers a pre-dawn song, which is relatively subdued and slow; a dawn song, which is the most beautiful, varied and loud; a daytime song, which is less protracted and often less ornamented than that at dawn; and a dusk song, loud but relatively repetitive and often curtailed. Similar within-day variations almost certainly occur in many other species, but they probably exist in forms often too subtle for the human ear to distinguish between them. These subtleties doubtless convey different types of information to the various listeners. It is increasingly clear that song in the breeding season serves various purposes, albeit most importantly and predictably female attraction and male deterrence. With bluebirds, it also facilitates the transfer of food to incubating or brooding females, nestlings and fledglings, and it warns mates, nestlings or fledglings of the presence of a potential predator. Among many species, from solitaires to wheatears, song given during song flight is often discernibly, if subtly, different from perched song, and it is likely that it has a greater specificity with regard to one or another function, most probably mate attraction.

Song-playback experiments in the territories of 26 male Bluethroats resulted in an increase in song and song-flight activity among apparently unmated males, those having no females visible in their territories, whereas males seen to be guarding females did not respond to song playback but remained silent, closely guarding their mates. This interesting finding has been interpreted as indicating that, for this species, song serves not only in mate attraction but also in male–male competition. Nevertheless, while it is entirely likely that song is as much a deterrent to other males as it is an attractant to females, any outbreak of song at an unexpected time of day is likely to indicate that an unmated male is attempting courtship, which, of course, implies the presence of an unmated female. It is hardly surprising, therefore, that nearby unmated males would instantly commence giving songs and song flights of their own; and it is equally unsurprising that a mated male would elect at this moment to stay very close to his female for fear that she may be mistaken for the expected mateless bird.

The situation may alter dramatically later in the breeding cycle. There is, for example, a short period of 3–4 days when mated male Common Nightingales resume nocturnal singing; this is the period when the female is laying eggs. The reasons for this reversion to high song output are unclear. The male may be attempting (a) to demonstrate his quality to the female and thus stimulate her reproductive effort; or (b) to deter rival males, as intensified singing, even though it risks announcing the female's fertility, on balance reduces external interference; or (c) to attract females for extra-pair copulations at a time when his mate is not in a position

*Thrushes are essentially solitary, territorial birds in the breeding season, but those inhabiting high latitudes are sometimes gregarious, especially in winter. Five species inhabit Europe during this season, two of which are migrants, and all of which have gathered to eat apples on this English lawn. Pictured here, clockwise from the top, are a **Fieldfare**, a **Song Thrush**, a **Common Blackbird**, a **Redwing** and a **Mistle Thrush**. In this instance they have been brought together by low temperatures and a shortage of food, but they make a common enough congregation in fields and paddocks along many a country lane.*

Photo: Mike Wilkes/ Nature Picture Library]

to prevent him. In the case of European Robins, it is the second of these options. Males of this species sing and patrol their territories most intensively during the female's most fertile period, and experiments indicate that they do so to signal their presence as a deterrent against neighbour intrusions, in order to minimize the risk of cuckoldry. There is a particular need for this, since the female vocalization used persistently in this fertile period is her "seep" begging call. Neighbouring males are attracted by this sound, as it reveals the time-window in which they can obtain paternity through extra-pair copulation. In contrast, although noon is the time when most female American Robins lay and immediately following which they are reportedly at their most fertile, their partners sing rather little at this time. This turdid's song, however, may not be used in the same way as is that of the European Robin; thus, synchronous emergence of female American Robins from their nests at dawn causes synchronous termination of the dawn chorus, whereas asynchronous nest visits by females over the day and in the evening result in asynchronous and scattered periods of song during those periods.

With Common Redstarts, the pattern of male singing is apparently somewhat different again. The male sings from his arrival on the breeding grounds, from territorial establishment, through mate acquisition and up to the moment when the female starts to bring nest material to the hole that he has found for her. While the female builds the nest he is completely silent or, at best, gives no more than a subsong, but he restarts singing as soon as egg-laying begins, and continues all through incubation. When the eggs hatch the male again ceases singing, and he stays silent until the chicks are independent, resuming only if a second brood is to be raised. Further contrast is provided by Common Stonechats and Bluethroats, songs of which diminish significantly or halt almost completely once incubation begins, although unpaired males continue singing right through the summer, and males with failed nests immediately resume singing.

In the case of Song Thrushes, the singing pattern throughout the year is often very distinct but highly variable, and involves variable numbers of singers. There are several major pulses lasting for weeks, but these are not well understood; the amount of rainfall is possibly a key spur, and cold weather is generally an inhibitor. Crucially, it is only at dawn and dusk that all the males of pairs sing, while later in the day often only unpaired males persist, so that censuses based on daytime songsters underestimate the population; moreover, in southern England, at any rate, many males of pairs that subsequently breed sing very little or not at all from February onwards. In one part of Switzerland, Song Thrushes exhibit two peaks of singing in the breeding season, one roughly from late February to early April and the other from mid-May to early July. The second pulse starts at the end of the breeding season and persists for too long to be associated with male deterrence or female attraction, and it is postulated that it may serve to teach newly fledged birds and/or as a means for staking a prior territorial claim to the area for the next breeding season. With Black Redstarts, autumn song given between the end of moult and the abandonment of breeding territories, and delivered mainly by males two or more years old, helps these males to establish territories in food-rich sites, as at log stacks with high insect abundance, and thus increases the holder's survival chances. It also improves reproductive success in the ensuing spring by drawing in experienced females to pair, briefly, with the singer as a basis for the coming season's endeavours; in one study, 59% of such autumn pairings were renewed in the following spring. In North America, Townsend's Solitaire sings throughout the year, with peaks from April to May and from September to November, corresponding to the time of establishment of summer and winter territories, respectively. Whereas, in spring, the males of this species sing more often and more loudly than do the females, the two sexes devote equal amounts of time to singing on their winter territories, which are, of course, individual territories. This is not, however, entirely the case with wheatears; although song is deployed by both sexes on their individual winter territories, it is generally less frequent among females than among males.

In autumn, in particular, many species of thrush and chat, and perhaps all of them, produce a subsong. This has three characteristics that distinguish it from full song. First, it is a very quiet vocalization, typically audible at less than 30 m; second, it is sustained for many seconds in a curious rambling agglomeration of twittering and warbling notes, into which elements of the true song, as well as calls and pieces of mimicry, are woven; and, third, it is typically delivered from low in the vegetation or on the ground. Subsong can be heard at a very early stage from certain species, including wheatears when only two weeks out of the nest, when it appears to be associated with the establishment of individual distance. Migrating Redwings in perched

flocks give subsong, presumably for similar reasons, and Eyebrowed Thrushes (*Turdus obscurus*) do likewise when in spring flocks. Various ant-following chats in tropical Africa deliver such songs, and individual distance, again, may be a prime driver in these often rather competitive contexts. Among species in which both sexes sing, both also utter this quiet rambling version. A type of subsong, commonly called "whisper song" in North America, is heard in the spring months from turdids in aggressive interactions or during courtship. These songs may be a little louder than typical subsongs but, unlike full song, they are heavily aspirated. Measurement of heartbeat rates in Common Blackbirds indicates that even subsong, although often given in seemingly relaxed circumstances, is mildly stressful; in aggressive and courtship subsongs, the heartbeat rates are probably maximal.

Most members of the Turdidae have several calls. The Cape Robin-chat has only a single call, used for both contact and alarm, but this is unusual as a general condition, and apparently unique in the genus *Cossypha*. More typically, the Common Blackbird has many calls. These include a short contact call; a longer flight call; an aggressive warning call; a mild alarm call; an aerial-predator alarm; a distinctive ground-predator alarm; a territorial-defence whistle; a distress call; a courtship call; a nestling-feeding call; and a nestling-warning call. There may be more, or possibly fewer, owing to the somewhat subjective way in which calls are reported and collated, but this enumeration will probably be found to be matched by many of the species in the family once they have been more closely studied. Vocabularies probably reach the maximum breadth among species which are both sociable and territorial, since the diversity of contexts of communication is then greater. More solitary and more sociable species probably both have somewhat reduced vocabularies.

The word "chat" derives from the sharp burry "chak" sound that certain species in the subfamily Saxicolinae make as a general alarm call. It is typical of the Common Stonechat, the English name of which supposedly reflects the fact that its call sounds very like two stones being knocked together. Another, rather more intense alarm call common to many chats is a clearer "hwee" or "whit" sound, and many species have the habit of combining the two together. This "whit-chak" combination is the hallmark of *Saxicola* chats and, to a lesser extent, the wheatears in the genus *Oenanthe*, but it is also uttered in various manifestations by a number of essentially Palearctic genera and species. These include the Bluethroat, Indian Blue Robin and Siberian Rubythroat, in *Luscinia*, and, especially, the *Phoenicurus* species, such as Common, Daurian (*Phoenicurus auroreus*), Moussier's (*Phoenicurus moussieri*) and Güldenstädt's Redstarts. The early-nineteenth-century English poet John Clare, in his poem "The Firetail's Nest", refers to a nesting female Common Redstart which "pipes her 'tweet tut' fears the whole day long". Northern Wheatears use the combined call when the "chak" or "tut" alone is not enough to warn off an intruder, and Common Stonechats do so in similar situations, the "whit" call serving as a warning while the "chak", combined with short flights and wing-flicks, has a distraction function. There is an echo of these calls and their meanings in the European Robin, which gives "ssssiiip" calls as an alarm warning, causing other birds to fall silent and hide, and "tic" calls as a challenge and distraction.

Nestlings and newly fledged individuals have strong begging, location and distress calls. This is, of course, as may be expected of a family in which the young leave the nest typically a few days before they are capable of strong flight (see Breeding).

Finally, many thrushes and chats make mechanical, non-vocal sounds in various contexts. Some of them, for example, snap the bill quite loudly during violent confrontations and when captured. The Collared Palm-thrush (*Cichladusa arquata*) often claps its wings together in flight. Some solitaires and other North American thrushes, when approaching a conspecific intruder in a winter territory, make "winnowing" sounds with their wings just prior to landing, this noise presumably serving as a warning of their readiness to attack. Hermit Thrushes, when in an anxious state of indecision over attacking or fleeing, rattle dry leaf litter by making a foot-quivering manoeuvre.

Food and Feeding

Key to the success of the Turdidae is the dietary flexibility of most of its members, the ability to switch opportunistically between invertebrates and fruit. Despite the crucial role that it plays, however, fruit is fundamentally the first alternative to invertebrates, and nearly always the lesser partner in turdine diet. The typical pattern, at least in temperate species, is for invertebrates to dominate the spring and summer diet, with fruit an increasingly impor-

*All turdids, including the **African Thrush**, drink with the standard passerine motor pattern, first submerging the bill beneath the water surface, then tilting the head back so that the bill points slightly upward. This action presumably gathers water inside the mandibles, then causes it to trickle down the gullet with ease. A few thrushes are also capable of drinking without raising the bill above the horizontal, but this is less frequent and is usually accompanied by rhythmic contractions of the gular region.*

[*Turdus pelios chiguancoides*, Gambia. Photo: Mike Wilkes/ Nature Picture Library]

Chats drink in a similar manner to thrushes, as illustrated by this ***Güldenstädt's Redstart****. Similarly, their favoured drinking sites are sources of standing water, such as ponds, puddles and bird-baths, but flowing streams are also utilized, as long as they are not too turbulent. Not surprisingly, species inhabiting humid regions drink more than those of waterless lands: many desert-dwelling chats, including a range of wheatears* (Oenanthe)*, go months without drinking, subsisting merely on the limited water contained in their diet of beetles and seeds.*

[*Phoenicurus erythrogastrus grandis*, Shey marshes, Ladakh, India. Photo: Otto Pfister]

tant component from late summer until late winter, but rarely totally replacing the animal component. In the diet of the American Robin, for example, the proportion of fruit shifts from less than 10% in the spring to more than 90% in the autumn and winter; it also, incidentally, increases from morning to afternoon, presumably reflecting the more favourable conditions for foraging on many terrestrial invertebrates in the early part of the day. Some species probably feed entirely on invertebrates, but none is known to subsist entirely on fruit, although a few come close.

True thrushes, the Turdinae, forage for invertebrates mainly on the ground, taking small creatures in the leaf litter, on the surface, and also in the topsoil, where the often staple diet of earthworms is to be found. Typically, the foraging technique involves a three-part series of stop/start and pouncing actions: running or hopping very briefly in quick spring movements, pausing to listen and observe, and, when food is seen or suspected, making a quick dab or pounce at the substrate and either seizing and swallowing the prey item in a single movement, or sweeping aside litter to expose it or digging at the earth to uncover it. The three components vary, of course, with opportunity. Often the thrush makes repeated runs or hops and pauses before effecting a feeding strike, and often it makes repeated feeding strikes at an advantageous spot. Frequently, too, individuals will flick aside litter without making a discovery, doing so repeatedly in the quest for a find; thrushes in forest and woodland where the top litter is dry can give themselves away with the resultant rustling that they make. One writer describes how the Orange-billed Nightingale-thrush, after flicking aside a leaf, raises its head up quickly "as if fearful its actions might have attracted attention".

Members of this subfamily forage not only in deep shade amid trees but also out in the open, and they are the most familiar of sights on grass lawns in private and public gardens, their technique of stop/start and pounce on full display. The English poet Ted Hughes brilliantly captured the strange intensity of such foraging by the Song Thrush:

> "Terrifying are the attent sleek thrushes on the lawn,
> More coiled steel than living—a poised
> Dark deadly eye, those delicate legs
> Triggered to stirrings beyond sense—with a start, a bounce, a stab
> Overtake the instant and drag out some writhing thing.
> No indolent procrastinations and no yawning states,
> No sighs or head-scratchings. Nothing but bounce and stab
> And a ravening second."

On more litter-rich substrates, Song Thrushes displace loose material with the bill by means of a rapid flick of the head, sometimes driving the bill slightly into the substrate to displace dry soil as well. There can be five or more successive flicks as a thrush scours a promising spot. In both this species and the Common Blackbird, the bill-flick is sometimes accompanied by a simultaneous, but scarcely visible, backward scratch of the foot, using the left foot with a leftward flick and the right foot with a rightward flick; this co-ordinated movement of the bill and foot is an attribute shared with few other bird families. In more tangled undergrowth, individuals use the bill to yank or toss back twigs and stems in order to reach substrates. In an amazing modification of this behaviour, a Common Blackbird was seen to employ an 8-cm twig to sweep snow 5 cm deep from a small area in order to get at the ground beneath. When foraging in deep litter, some species, including the two just mentioned, will use the feet and legs repeatedly to scratch litter and soil away from a promising spot, making sharp darting movements or flicks of the head as they do so, thereby removing detritus and exposing and breaking the surface of the soil.

What cues does a ground-foraging thrush use to find its food? Clearly, when a bird makes a short sudden rush forwards and snatches an item, it is responding to a visual cue only. Sound, however, is evidently also important. In experiments in which four American Robins were disallowed visual, olfactory or vibrotactile cues, the birds were able to forage effectively on buried mealworms, suggesting they were using only auditory stimuli; this deduction was reinforced when, in response to white noise, their foraging success fell significantly. Olfactory and vibrotactile cues have not been investigated, but both are suspected of playing a part, perhaps varying in degree with species and/or context. The Bassian Thrush in Australia stops and listens at a spot, peering intently at the ground, and then raises itself up on its toes and rapidly vibrates its body for several seconds. These vibrations apparently cause worms to rise to the surface or, at least, to move and thereby reveal their location more precisely.

Thrushes are not restricted to terrestrial sources of water for their drinking requirements. This ***Kurrichane Thrush*** *is taking advantage of water trapped at the base of a snapped branch, and similar use will be made of any such arboreal pool by forest species. Temporary water supplies appear after rainfall in all manner of situations, including guttering, bowl-shaped epiphytes, upturned seed-pods and the like. Thrushes have also been seen to gather dew or melting frost, and some are known to eat snow during the winter.*

[*Turdus libonyanus*, Okavango swamps, Botswana. Photo: Geoff McIlleron]

This type of behaviour is also performed by the closely related Common Scaly Thrush. Whether the bird hears or feels the worms' response is not known, but these are species which often forage on the forest floor and adjacent trails in very low light intensity, when visual cues are likely to be relatively weak. As a matter of interest, the importance of vibrations in bringing earthworms to the surface in areas close to lorry-bearing roads, and in grass exposed to helicopter down-draughts, has been noted in Britain.

Other thrushes which commonly excavate the soil for invertebrates seem likely to have similar systems of detecting hidden prey. None is yet known, however, that is so remarkable as the reported "wind-breaking" also used by the body-shivering Bassian Thrush, a technique requiring internal physiological adaptation (see Morphological Aspects). The thrush hops or runs several paces and then stops momentarily, probing, and moves on. A noise somewhat louder than the bird's footfalls, coincident with a "vent-dipping" movement very like that used in defecation, and believed to be "a burst of air from the vent", has been heard immediately after each stop, followed by probing or more hopping. It is assumed that this sound, audible to human ears at 5 m, has some effect in stimulating a movement by an underground worm, giving away the latter's position. It has been heard only when Bassian Thrushes are foraging.

A much commoner additional technique for finding prey is foot-quivering. This is performed by a number of species, including the Bassian Thrush, but is particularly pronounced among migrant *Catharus* thrushes, which also use this behaviour as an aggressive signal. The bird stretches its head and neck forwards, the bill parallel to the ground, and rapidly vibrates its toes on the substrate. Immediately afterwards it stops stock-still to scan, often then pecking forwards at the ground; observations revealed that the Veery made forward pecks on 60% of such occasions, the Grey-cheeked Thrush on 67%, and Swainson's Thrush on 70%. Similar behaviour by certain African robins has been witnessed. When foraging in leaf litter, the Brown Scrub-robin sometimes appears to "mark time" by pattering the leaves, first with one foot and then with the other, and, again, it is presumed to be attempting to disturb small invertebrates from their hiding places in the litter.

When a food item is found, it is usually snapped up and swallowed at once. Earthworms, which often wrap themselves reflexively around the bird's bill, are sometimes beaten on the ground, as are other large invertebrates that need to be processed before ingestion. The Song Thrush has a familiar trick when dealing with snails. It carries its victim to a place with a hard surface, such as a stone, a large tree root, a cement floor or a brick wall, and, holding either the shell by the aperture or the snail itself, it proceeds to beat it on the chosen "anvil" with a combined downward and sideways flicking action of the head, so that the snail loops up and over the bill from one side to the other, thus achieving maximum speed at impact. Usually the shell breaks after just a few strikes, and the snail is then exposed and, after being wiped on the ground, eaten. Other thrushes eat snails, but usually smaller ones that do not require this hammering process. Furthermore, Song Thrushes need to be vigilant, as their larger congeners, if in the vicinity, are quite liable to rob them of their prey. A relative that also uses anvils but, having no sympatric congeners, appears to run no risk of robbery, is the Gulf of Guinea Thrush. This species accumulates such large middens of shells at hammering sites that it has been speculated they may possibly be used in part as signals of territory quality or of the territory-holder's ability to provide food.

Thrushes are not usually territorial while on migration, but the maintenance of distance between individuals, which may be achieved partly by foot-quivering, may be important in ensuring access to areas of ground undepleted by other foragers. Competition between ground-foraging thrushes certainly occurs. Studies have shown that the feeding rates of a Common Blackbird decline significantly with the arrival of a competing individual at a foraging patch: when the nearest-neighbour distance was always less than about 5 m, rates dropped to 16–43% of the feeding rate of a lone individual. Feeding-rate declines were similar whether the individuals interacted aggressively or apparently ignored each other during feeding, and the effects of a single competitor on a blackbird's feeding rate remained the same even when the foraging patch was twice as large. There is, therefore, a trade-off between the benefit of group-feeding, such as collective vigilance for predators, and the cost of monitoring other individuals within the group in order to avoid interactions. This trade-off is different for dominant individuals, presumably older birds or males, compared with subordinate ones, presumably younger or female birds. Dominant individuals may even profit by using subordinates as

Given that nest-building in thrushes and chats is almost always the sole responsibility of females, it is interesting that this ***Sooty Thrush*** *(pictured carrying nesting material) is a male. Where species of* Turdus *are concerned, males often accompany females during the nest-building phase in order to guard them from the advances of rivals. Occasionally they help collect a small amount of plant matter for the nest, but they tend to pass this to the female, rarely if ever actually adding material to the structure.*

[*Turdus nigrescens*, Cerro de la Muerte, Costa Rica. Photo: Michael & Patricia Fogden]

food-finders, and the persistent displacement of subordinate birds may well explain some of the differential migration patterns exhibited by some turdine species (see Movements).

Collective vigilance is certainly a benefit for species adapted to more open-country foraging, since it allows an individual to forage for longer. Birds in larger flocks gain energy more rapidly than do those in small ones or those foraging solitarily. Interestingly, however, both Redwings and Fieldfares, two of the most familiar of open-country foragers during the non-breeding season, have higher rates of energy intake on old pasture when they forage in mixed flocks than when they keep to single-species flocks. It is usually the case that the Fieldfares join the Redwings on old pasture, and they are thought to use the Redwings as cues to the location of prey items. The Redwings must also benefit, however, through the decrease in time individually dedicated to predator vigilance.

Observations of foraging Fieldfares revealed that an individual typically made an average per minute of 8·1 pauses, 2·5 crouches, 1·3 ground probes and 0·75 snatches. The crouched position evidently indicates a greater lunging effort to obtain the prey; bigger earthworms are extracted when a Fieldfare crouches than when it does not. The forward movements can be rather leisurely walks among the other thrushes or light-footed tripping hops. A study of Fieldfares in Sweden indicated that 37% of all ground-stabbing attacks result in the capture of in-soil prey, while 58% of ground-gleaning attacks result in the capture of on-soil prey. It can take only a second to extract the smallest worms, those smaller than 37 mm, and a few seconds to mandibulate them into the carrying position for delivery to the young; the extraction of the largest ones, those longer than 137 mm, takes about 8 seconds, with more than a minute required for them to be mandibulated as feedable items.

Where sociable thrushes co-occur, their ecological separation appears to be related to bill size. Indeed, bill size is evidently critical in resource-partitioning in any syntopic assemblage of thrushes or chats. On the non-breeding grounds, Redwings and Fieldfares segregate their terrestrial prey rather neatly. In one study, the former was found to take 67% on-soil items and 33% in-soil ones, whereas the corresponding figures for the latter were 44% and 56%, respectively. In winter, the on-soil invertebrates are smaller than the in-soil ones, and it is energetically more rewarding for the smaller-bodied, smaller-billed Redwing to go for the former and for the larger-bodied, larger-billed Fieldfare to go for the latter. Thus, only 20% of soil items taken by Redwings are larger than 10 mm, whereas 45% of those taken by Fieldfares exceed this value. Moreover, there is a degree of ground-habitat partitioning between these species, with Redwings preferring long-established pastures, where on-soil prey are more abundant, and Fieldfares preferring newer pastures, where earthworms, although less abundant, are easier to detect and reach. Naturally, when it comes to taking berries, the heavier Fieldfare may be dominant, but the smaller Redwing is more able to hover-pluck berries that the Fieldfare cannot reach. Similarly, sally-hovering by Townsend's Solitaire allows it to reach berries at the tips of branches or on the undersides of snow-encrusted branches that are unavailable to larger or less agile competitors such as the American Robin.

There is, of course, also competition from ecologically similar but unrelated species. *Catharus* thrushes wintering in Panama, compared with resident species in the same guild, feed more frequently on non-flying ants, beetles (Coleoptera), insect larvae and gastropods, but most significantly on non-flying termites (Isoptera), centipedes (Chilopoda) and millipedes (Diplopoda). The immigrant thrushes also show a clear preference for berry-like fruits with small to medium-sized seeds. Thus, they do not generalize on superabundant invertebrates, but specialize on a few invertebrate taxa of two types. The first type consists of small, hard-bodied foliage-dwelling insects such as beetles and ants, which are of relatively low nutritional value, and the second comprises invertebrates well known to produce distasteful or toxic chemicals, such as non-volant termites, centipedes and millipedes. The facts that migrants take a low quality and low diversity of animal prey and that they also possess highly overlapping diets could be taken to imply that they are weakly integrated into the tropical bird community. In reality, however, the absence of much dietary overlap between migrants and residents using a similar foraging substrate indicates how spectacularly well they are integrated into that community.

Ability to exploit relatively poor and, in some cases, seemingly noxious foods, notably ants, is certainly one reason for the success of the Turdidae. The chat radiation in Africa and Asia, surely one of the most complete, in terms of geographical cover-

age, of any taxonomic group of birds on these vast continents, owes much to this ability. Nowhere is this more evident than with the wheatears, which uncannily derive a boundless energy on seemingly the least nutritious of foods, namely ants and other literally desert-hardened invertebrates, notably beetles. Ants, however, are eaten extensively by other genera, too, particularly those adapted to dry rocky landscapes; the Southern Anteater-chat's scientific name *Myrmecocichla formicivora*, meaning "ant-eating ant-thrush", makes the point very firmly. Many of these open-country, ant-eating species cast pellets owing to the amount of chitin in their prey, and they have pronounced wing-flicking movements when they move to snap up a food item. When taking prey insects, the Blackstart, the Pied, Desert and Rusty-tailed Wheatears and, most of all, the White-crowned Wheatear commonly flash open both wings, occasionally briefly holding them open, and the assumption is that this action startles the victim into a self-disclosing movement, or somehow disorients it. Possibly, there is a link between this behaviour and the noxiousness of the victim, which may need to be grasped at a particular angle to minimize the risk to the predator. Alternatively, and more plausibly, the wing-flashing actions of these chats with prey signal their presence at and possession of a resource.

Like the true thrushes, the chats most commonly forage on the ground, many using the same technique of hopping, pausing and pouncing. However, with some obvious exceptions, such as the whistling-thrushes, they have a bill that is too small for digging and is designed, instead, for surface-gleaning. Naturally, therefore, the saxicolines forage more by visual cues than do the true thrushes, so that their movements on the ground involve shorter pauses and more direct bounding strikes across the substrate to secure prey. These are often labelled "dash-and-jab" movements, and they are most strongly developed among open-country birds. The possession of a small bill, however, means that the body is also small, and this circumstance allows many species of chat to employ foraging techniques which would, for heavier birds, be energetically too expensive to repay the effort. These saxicoline techniques are the "perch-and-pounce", also known as still-hunting, perch-foraging and ground-sallying, which involves flying from a low perch to take prey on the ground, and, less frequently, the "leap-and-snatch", in which the chat sallies or leaps into the air to take flying insects. Several highly successful chat genera, including *Phoenicurus*, *Saxicola*, *Oenanthe* and *Cercomela*, use perch-and-pounce as their main foraging method, with leap-and-snatch as a secondary method; so, too, do the myadestine bluebirds in the genus *Sialia*. The smallest, lightest species of chat, those in the genera *Sheppardia*, *Pogonocichla*, *Stiphrornis* and, to a lesser extent, *Tarsiger*, have become part-time flycatchers, while *Cossyphicula* forages almost entirely by aerial sallying. Up on the sides of desiccated ravines, the Hooded Wheatear also takes most of its food in the air.

Ants play another key role in the feeding ecology of many turdid species. In Africa and the Neotropics, army ants or driver ants move across the forest floor in broad columns that disturb all the living creatures in their path. Many thrushes and chats are drawn to the front and sides of these swarms, where they pick off the hundreds of invertebrates as they flee. In Africa, the genera *Stizorhina*, *Neocossyphus*, *Pseudalethe*, *Alethe*, *Pogonocichla*, *Swynnertonia*, many *Sheppardia* and many *Cossypha* species, some *Zoothera* thrushes and some *Erythropygia* scrub-robins follow or, rather, "lead" ant swarms, the first four genera semi-obligately. In the Neotropics, some *Myadestes*, *Turdus* and *Catharus* species, as well as the Wood Thrush in *Hylocichla*, are known to follow army-ant swarms, but in all cases this is done opportunistically, owing presumably to the relatively recent oscine colonization of South America, by which time the obligate ant-following niche was already occupied by various members of the suboscine antbirds (Thamnophilidae). Within Turdidae, the ant-thrushes, alethes, akalats and robin-chats take up positions at the head of the ant columns in an alert, agitated state, eager to feed but anxious to avoid the ants themselves, although they frequently eat them, and anxious also to hold a good foraging position in relation not just to conspecifics, but also to other ant-following birds. Consequently, there is much subsong and calling by the birds while attending swarms. Up to 14 Brown-chested Alethes have been seen at one column, and as many as 50 Fire-crested Alethes regularly gather to accompany the ants through the forest. The birds hop on the ground just ahead of the column or perch just above it, and either dash forwards or sally down to seize prey.

Occasionally, other types of "driver" are used. A pair of Rüppell's Robin-chats was once watched while following a suni antelope (*Neotragus moschatus*) and catching in the air the insects that flew up as the suni wandered about. The Orange Ground-thrush (*Zoothera gurneyi*) associates with mole-rats (*Cryptomys*),

*The **White-starred Robin** is one of a small minority of turdids to build a domed nest. The structure is made of dead leaves, rootlets, tendrils and moss, and is usually placed on the ground against the base of a tree or rock. This widespread African chat is not only aesthetically pleasing but taxonomically intriguing. In particular, the existence of an unspotted subadult plumage is almost unique in the family. The various races differ substantially in morphology and voice, but in a patchwork fashion, such that hypothetical subdivision into two or more species would not be straightforward.*

[*Pogonocichla stellata*, Vumba Highlands, Zimbabwe. Photo: Peter Steyn/Ardea]

The use of dead leaves as a platform for the nest structure is rather common in the saxicoline chat radiation, as is the placement of nests in recesses, rather than in the forks of branches. Members of the genus Cossypha *are typical in these respects, building messy, open-topped nests wherever these can be lodged inconspicuously. The construction of this* ***White-crowned Robin-chat****, balanced in the nook provided by the hanging sheath of a palm, demonstrates the advantage of dead leaves: not only do they cushion the nest itself, but added as an outer layer they mimic fallen foliage and thus provide a degree of camouflage.*

[*Cossypha albicapillus albicapillus*, Gambia. Photo: Michael Gore]

profiting from their mound-building activities, which cause litter-dwelling invertebrates to flush from cover. Brown Scrub-robins do likewise, and one has also been seen to follow a daylight-roving porcupine (*Hystrix*) in the forest, evidently for the same purpose. Proof of the value that such "drivers" can represent is the finding that Seychelles Magpie-robins (*Copsychus sechellarum*) on Frégate double their feeding success rate when following a giant tortoise, a person, a cow or a pig, compared with when foraging alone. The situation is sometimes reversed. In the Mediterranean region, for example, Dartford Warblers (*Sylvia undata*) habitually follow Common Stonechats as they forage around their territories. When together with a stonechat, the smaller warbler looks for prey largely on the ground close by, but it feeds mainly in the cover of shrubs when searching alone. It is assumed that either the chat is a reliable indicator of optimum search areas or the warbler exploits its vigilance when looking for prey on the ground, or both. There is, however, a cost to the chat which is manifest in the fact that its feeding success rate is reduced by half when in the company of the warbler, although it is difficult to see why this should be so, unless perhaps the warbler is simply a visual distraction. The chat's response consists mainly of regular perch changes, but the warbler will frequently simply follow it. In Africa, on the other hand, the Common Stonechat and another warbler, the Black-lored Cisticola (*Cisticola nigrilores*), associate in a way which has not yet been evaluated for the advantages conferred, and which may be mutually beneficial; and Red-backed Scrub-robins and Spotted Palm-thrushes have likewise been seen to associate. Blackstarts occasionally form loose foraging flocks with several *Sylvia* warblers, but such behaviour appears to be unreported for other chats.

Although thrushes and chats are by no means so adaptable as, say, the crows (Corvidae), there is much evidence that they indulge in other types of local foraging opportunism. Seychelles Magpie-robins take scraps from tables inside houses and verandas, and Oriental Magpie-robins visit dungheaps in search of maggots, this habit earning the latter species the local name around Hong Kong of "pig-manure bird". Hooded and White-crowned Wheatears, denizens of the hottest, driest deserts, visit nomad camps to take ticks from livestock and pick up any scraps thrown to them, and at Eilat, in south Israel, a White-crowned Wheatear regularly exploited the scavenging opportunites provided by the open-air section of a restaurant on the waterfront. In the Afrotropics, the Fire-crested Alethe occasionally gleans ectoparasites from sitatunga (*Tragelaphus spekei*) and the Chorister Robin-chat does likewise from bushbuck (*Tragelaphus scriptus*). An Indian Robin has been watched while it foraged in the light of fluorescent lamps of a power-station control room, and Sick listed *Turdus* thrushes as among the few birds recorded as feeding under electric lights in Brazil. American Robins nesting near a lake frequently went to forage along the water's edge, taking washed-up insects or insects attracted to lakeside debris. Likewise, a male Common Redstart, having arrived back on its breeding grounds early, during a thaw, frequently flew down to take drowned insects, flushed down in the melting snow, from the surface of water.

Perhaps the most remarkable opportunistic predatory behaviour known for any member of the family is to be found in two groups of Atlantic Ocean islands. On Tristan da Cunha and its satellites, the Tristan Thrush has expanded its foraging niche to the maximum. It has evolved a brush-tipped tongue, helping it to remove the content of the seabird eggs that it breaks open, and it forages down to the seashore for detritus. Recently, however, biologists have noticed the species' capacity for attacking day-flying birds, grappling juvenile *Neospiza* buntings in mid-air, and pursuing and killing fully grown White-bellied Storm-petrels (*Fregetta grallaria*). The storm-petrels visit the islands by day, and are therefore targeted by the thrushes, which chase them in strong level flight 2–5 m above the ground. The thrushes probably also attack storm-petrels when the latter are forced to land in cover to evade pursuit by Brown Skuas (*Catharacta antarctica*). The White-bellied Storm-petrel is about the same size as the Tristan Thrush but weighs less, with a mean of 53 g, as compared with the thrush's 91 g. On two occasions, a thrush was seen perched on top of a living storm-petrel, using its feet to hold down the latter at the base of its wings, and hammering at the back of its victim's head, thereby exposing and caving in the skull, enabling the thrush to eat the brain. Generally, the thrushes have difficulty in consuming much else of the corpse, but they penetrate the skin at certain points to obtain pieces of tissue.

When this extraordinary behaviour was first documented, it was stated to be the first evidence of any thrush regularly killing other birds with a fully ossified skeleton. Thirty years earlier, however, the Austral Thrush was reported as attacking and killing Blackish Cinclodes (*Cinclodes antarcticus*) and Grey-backed

A relatively small proportion of turdids are cavity-nesters, and this behaviour seems to be derived, rather than ancestral. Most ***Common Redstarts*** *breed in holes in trees, but open cup-nests have been found, suggesting that placement of nests in cavities is facultative. It has been further postulated that the hole-nesting habit in redstarts evolved as a defence against brood-parasitism by cuckoos* (Cuculus). *Certainly, cavity nests present difficulties to egg-laying adult cuckoos, as well as their offspring, who find it difficult to evict the host's brood. However cavity-nesting arose, and in direct contrast to the situation in cup-nesters, it is usually the male that selects appropriate nest sites. These he advertises to the female using special displays. The male Common Redstart, for example, flies to a favoured hole and fans his red tail conspicuously as he enters. In the presence of the female he also perches in the aperture and "flashes" the white feathers of his crown. If the cavity is a good one, as in the case of this Welsh oak* (Quercus), *the female adopts it and builds the nest alone.*

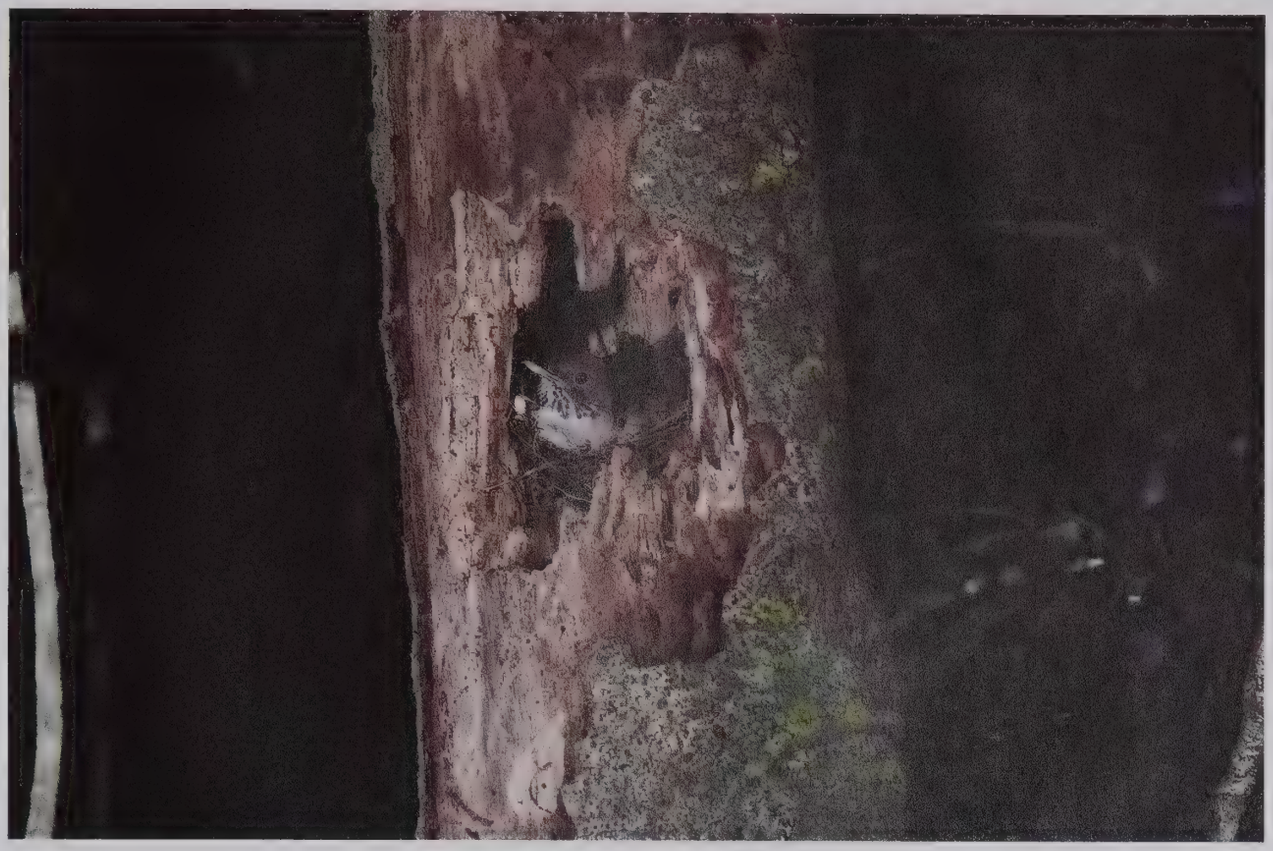
[*Phoenicurus phoenicurus phoenicurus*, Wales. Photo: Mike Read]

Hole-nesting also occurs in the myadestine clade, principally in the Sialia *bluebirds. This photograph shows a male* ***Mountain Bluebird*** *clinging to the entrance of a cavity, perhaps to check its suitability for breeding, or to show it off to a female. Males do not usually contribute to the nest-building process itself, but they spend much time in the vicinity during the female's fertile period, essentially guarding her from the attentions of neighbouring males. This type of supervision is important in this genus, as the incidence of extra-pair copulations is especially high.*

[*Sialia currucoides*, White Mountains, Arizona, USA. Photo: Tom Vezo]

Storm-petrels (*Garrodia nereis*), albeit not with quite the same piratical vigour as that of its Tristanian counterpart.

The less opportunistic a species is or, at least, the more regularly but thinly distributed its predictable food resources are, the more likely perhaps it is to behave in a territorial manner. Many species of thrush and chat establish winter feeding territories and home ranges: a steady food supply puts a bird in optimal condition, and thus enables it to continue to assure that food supply. These territories, because they are individual ones and are not required to furnish enough food on which to raise a brood, are typically smaller than summer breeding territories, although the latter, of course, owing to the strong seasonality factor, may be disproportionately rich in food resources. As an illustration, the average size of a Hermit Thrush's summer territory is 0·7 ha, compated with its winter one of only 0·55 ha. In the Neotropics, both resident and immigrant *Catharus* thrushes tend to be intolerant of each other. For example, the Slaty-backed Nightingale-thrush (*Catharus fuscater*) is interspecifically territorial against congeners where their altitudinal ranges overlap, this species and the Spotted Nightingale-thrush (*Catharus dryas*) excluding each other, at least in Venezuela, and the largely resident Orange-billed Nightingale-thrush is aggressive towards migrant *Catharus* thrushes. In the drier parts of north-east Africa and the Middle East, many species of wheatear, piling in for the winter, find themselves competing against congeners as much as against conspecifics for foraging space. Because the habitats of wheatears are so two-dimensional, their territories can be an order of magnitude larger than those of similar-sized or larger *Catharus* thrushes of the tropical rainforest. Recorded territory sizes are 2–4 ha for the Northern Wheatear, 3–6 ha for Finsch's Wheatear, and 5·8 ha for Hume's Wheatear, although they can be as small as 0·8 ha for Desert and Pied Wheatears. The last-mentioned, however, is more aggressive to members of the same sex, suggesting some sexual niche separation in this species.



Niche separation according to sex is known to occur with European Robins, despite the fact that males and females have separate winter territories. Compared with males, females forage more on the ground than from perches, although both sexes increase their amounts of ground-foraging with decreasing temperatures, which doubtless render invertebrates less mobile and thus less easy to spot from a perch. With this species there is also a subtle separation of niches through such seemingly minor features as bill size and tarsal length. Long-billed European Robins tend to eat a greater variety of prey sizes than do short-billed ones, and individuals with shorter tarsi tend also to feed on a greater variety of prey sizes. Hence, minor variations in morphology can influence the pattern of foraging behaviour quite strongly, and this, in turn, has implications for patterns of habitat use and seasonal displacements. Some of these morphological differences are, of course, sexual.

In the case of Black Redstarts, the occupation of territories in the autumn enables individuals to monopolize rich food resources

In almost all thrushes, solitaires and chats incubation is never undertaken by the male. Thus, while the ***Redwing*** *is sexually monomorphic, it is nonetheless safe to assume that the bird pictured here protecting the contents of the nest from a shower of rain is a female. As is the case in all* Turdus *thrushes, her nest is an open cup-shaped structure most frequently placed fairly low down amongst the branches of shrubs, hedges and saplings. In this genus in particular, and in true thrushes in general, nests are only infrequently placed in the recesses favoured so widely in the saxicoline chats.*

[*Turdus iliacus coburni*, Myvatn, Iceland. Photo: Collection J./ PHONE/Bios]

While some nests of Turdus *thrushes are placed in recesses, the incidence with which this type of location is favoured is perhaps highest in species of tall tropical forests, such as the* ***White-throated Thrush****. In this habitat predation levels are extremely high, and understorey vegetation relatively scant, so the bulky nests of thrushes would often be too obvious and vulnerable if placed in saplings or shrubs. Instead they are commonly placed on ledges or in half-hidden nooks such as can be found in the stems of palms, or broken stumps, or the complex folds of buttress roots.*

[*Turdus albicollis crotopezus*, Alagoas, Brazil. Photo: Anita Studer]

and thereby to increase their survival chances over the winter, when they move to other places, and it appears also to contribute to greater reproductive success in the following spring (see Breeding). Similarly, experiments with European Robins show that there is a trade-off between the benefits of solitary winter territorialism, which allows access to larger individual food items, and early pair formation, which leads to loss of such access but enhanced breeding success. Males provided with supplementary food were forced to repel intruders more frequently, but they nevertheless advertised for mates earlier and paired earlier. Pair-members which had this extra food supply temporarily withdrawn spent less time in consorting than did others. So, elevated food supply helped individuals to afford the costs of sharing their food resources, and thus to pair and lay clutches early.

The adaptive value of winter territorialism has also been demonstrated in North America for Townsend's Solitaire, a species which is unusual in defending a highly specific type of food resource, juniper berries (see General Habits). Individuals with small territories and fewer berries, usually birds in their first winter, suffer disproportionately high mortality. Nevertheless, each territory always appears to contain far more berries—several million at the start of winter, according to one study—than an individual solitaire could possibly consume, but these huge numbers are judged to function as an insurance with regard to unpredictable incursions by large flocks of berry-eating competitors, notably American Robins, which, unlike Cedar Waxwings (*Bombycilla cedrorum*) and Western Bluebirds, are too big to be displaced by aggression. Only when bad weather strikes, and the availability of food drops dramatically, are there periods when Townsend's Solitaire abandons territoriality in favour of a general wandering through the landscape in search of food.

Even in winter, most thrush species are less specialized on fruit as a food resource, and few, if any, are so universally dependent on the fruit of just one genus as is Townsend's Solitaire, which, incidentally, prefers areas with several species of juniper, probably as a hedge against crop failure in any one of them. In one study of Wood Thrushes in Costa Rica, the fruit and/or seeds of no fewer than 750 plant taxa were recorded in the species' diet, and a study of American Robins in the USA found the fruits of over 50 plant genera in a sample of 1169 stomachs. Therefore, the defence of fruit is elsewhere a much more occasional matter. Mistle Thrushes are perhaps the nearest Old World equivalent of Townsend's Solitaire, being strongly territorial around certain heavily clustered winter fruit resources such as holly (*Ilex*) and mistletoe, and maintaining their control of these small areas, though not necessarily through permanent occupation, for months on end. Fieldfares very occasionally exhibit aggressive "territorial" behaviour over a local fruit patch in very cold weather, but they are too nomadic for any defence of a food resource to last for longer than about two weeks. Nevertheless, the effects are basically the same as when birds defend larger territories all winter. As an example of the latter situation, individual American Robins defending, or "owning", hawthorn (*Crataegus*) fruit supplies have longer feeding bouts, ingest more fruits per bout and forage for fruits more slowly than do intruders, which are forced to attempt to pick fruits almost three times as quickly and ingest twice as many fruits as do owners during their incursions. Such speedy consumption of food is almost certainly not so efficient as the more measured ingestion and fruit choice allowed by resource ownership. Sometimes, however, the strategy of defending a particular patch is wrecked by the influx of a flock of foraging birds, not necessarily of the same species or even of the same family. When this happens, the owner sees its fruit and its future at the site stripped away, and its response may be to join in with the invaders and move on with them.

Moving on is, of course, rather more important for the food plant than for the bird that it supports. The role of thrushes and chats as seed-dispersers is increasingly being recognized, but there appears to be an intriguing trade-off for the plant between the benefits of its seeds being dispersed and the costs of their having to travel through the birds' gut. Several studies have shown that such seeds have a relatively low germination rate, as low as 17–24% in lowbush blueberry (*Vaccinium angustifolium*) seeds taken by American Robins, for example. It is important for the fruit, therefore, that the seeds travel through the gut slowly enough to be dispersed in new areas, but quickly enough not to be impaired for germination. Research on *Witheringia solanacea*, a Costa Rican cloudforest shrub of the family Solanaceae, indicates that this plant's fruit produces a laxative chemical that ensures an appropriately timed passage through one of its main consumers, the Black-faced Solitaire.

In some cases, the seeds are so large in relation to the body of the thrush that they are regurgitated, rather than moved through

*The **Slaty-backed Nightingale-thrush** always places its substantial nest low in an understorey shrub or tree, usually in an upright fork. It inhabits the dripping cloudforests of Central and South America, from Costa Rica to north Bolivia, and it is fitting that it makes use of the most abundant material available in such habitats: bryophytes. It drapes living mosses on the outer surface of its nest, sometimes to an impressive extent, producing a tail of hanging plant matter that mimics the clumps of mossy debris littered all about. The inner layers of the nest are made of leaves, stems, rootlets and plant fibres, and the cup itself is often lined with black* Marasmius *rhizomorphs.*

[*Catharus fuscater hellmayri*, Monteverde Forest Reserve, Costa Rica. Photo: Michael & Patricia Fogden]

*For all its brazen nocturnal eloquence, the **Common Nightingale** is a furtive bird by day and its nest is rarely seen. It is usually situated near the ground, expertly camouflaged amongst tangled debris and leaf litter. In this case it is an open cup, but a domed roof is sometimes added. The female incubates alone, but the male assists in providing her with food, an arrangement that recurs in a variety of thrushes and chats. Courtship feeding in the fertile period may signal the quality of males or their territories, but the advantage of provisioning incubating birds is more direct: it greatly reduces their need to leave the nest, and shortens the incubation period.*

[*Luscinia megarhynchos megarhynchos*, Gaston Copse, Bidden Grange, Hampshire, England. Photo: J. A. Bailey/Ardea]

the digestive system. This happens much more rapidly, and is probably better for seed dispersal. In Brazil, for example, six species of *Turdus* have been recorded as feeding on the bunched fruits of *Livistonia australis*, regurgitating the pits after about an hour. In some instances, the process is even quicker. Here, too, there is, however, a catch for the tree, as a single frugivorous bird species can act as a seed-disperser or a pulp predator for the same plant species. The threshold of these roles is strongly influenced by the ratio of gape size to fruit size. In the Mediterranean region, for example, thrushes of different sizes, from the European Robin up to the Fieldfare, consume olives (*Olea europaea*) of different sizes, from small to large, with the result that all species will swallow some fruits whole but merely peck into others. This also happens with such foods as the dangling, catkin-like fruiting spikes of *Cecropia* trees in the Neotropics, and many other larger tropical fruits, some of which thrushes will not even trouble to peck but will simply discard if they prove too large to be swallowed whole.

Fruit choice is important, as incorrect decisions lead to a waste of foraging time. American Robins foraging on haws use a two-step decision-making process of fruit selection. They need to select first the shrub in which to feed, and then which fruits to pick. Their choices among shrubs correlate with three plant traits: fruit abundance, fruit size, and fruit pulpiness. Once shrubs are selected, American Robins then make visual choices among fruits based on fruit size, taking the largest that they can swallow without difficulty. They also make choices based on colour, red berries commonly being targeted over other colours, and white ones usually being avoided. It has been demonstrated that even the ultraviolet reflection of berries is used by foraging birds as a positive cue in their selection. All studies tend to show that discrimination in fruit choice increases with age, naive juveniles being much less careful in their decisions than are older birds; it is only with time, for example, that they learn to avoid fruit with high seed loads.

This discrimination is doubtless due to the fact that fruits often carry compounds that are not necessarily good for birds, but which, if eaten at precisely the right stage and in rationed amounts, may have little adverse effect on the consumer. The different metabolic rates of small birds mean that certain toxins can be avoided altogether. For instance, one food of the Fieldfare is mezereon (*Daphne mezereum*), which is poisonous to man, and there are even reports of humans becoming ill after eating Fieldfares that had themselves eaten mezereon. Consumption of a small red pepper by Red-legged Thrushes in Cuba prompted C. Vaurie to conclude that the birds' digestive systems "must be quite insensitive", since a pepper that he experimentally chewed was "enough to burn off the lining of my mouth" and, when swallowed, made him "break out in profuse perspiration". Still more amusing, albeit with potentially very serious consequences, this time for the thrush, in terms of predation risk or simply death by falling, is A. Stockton de Dod's anecdote about several Rufous-throated Solitaires feeding and becoming intoxicated on overripe *palo amargo* fruit (*Colubrina berteroana*). She watched one of them as it tried to sing: it sat hunched with its feathers fluffed out, moving its bill without at first producing any sound, appearing to fall asleep and then jerking its head up when about to fall, managing finally the "tweet" part of the song but with the "tu-tu-tu" part drifting away, before it fell off its perch, the fall being broken by ferns, only for it to fly back up and attempt to sing again.

Moderation is, however, the normal practice when fruit-eating. Hilty noted a pattern of activity and inertia among foraging

*This **Black-faced Solitaire** is settling on to her nest, a mossy cup tucked against the trunk of a tree, amongst the stems of creepers. Most of her congeners tend to fix their nests in similar crevices against vertical surfaces, or on steeply inclined slopes. As such, they have tended to benefit from the building of broad forest trails or roads, upon whose banks and cuttings they frequently nest.* Myadestes *solitaires look rather odd for thrushes, being small, upright-perching, arboreal birds with short, broad bills and dense, velvety plumage, but ample research places them firmly amongst the Turdidae.*

[*Myadestes melanops*, Costa Rica. Photo: Michael Fogden/ DRK]

Andean and Rufous-brown Solitaires, and B. K. Snow and D. W. Snow reported the same thing with regard to the winter feeding of frugivorous thrushes in Britain. Fieldfares tend to feed in bouts of 1–2 minutes, taking as many berries as possible, and then resting for 17–26 minutes, the mean resting period being 21 minutes. The largest Fieldfare meals recorded, in one instance 21 ivy berries, ten haws and four hips, each amounted to 6–7% of the species' mean body weight. Individuals that occasionally established territories at fruit resources, however, tended to eat fewer fruit, in shorter bouts, and with shorter intervals for digestion. By way of contrast, a single American Robin, on a very cold day, was seen to pack its oesophagus with fruit in the last two hours before nightfall. The storage of fruit in an extensible oesophagus has been documented for other frugivores, and may be an adaptation to overcome the constraints on food-processing by the gut.

The low moisture content of junipers makes them a more concentrated source of energy and nutrients than are typical succulent angiosperm fruits. This, however, means that Townsend's Solitaires have to drink frequently during the winter and, in arid habitats, will temporarily leave their territories in order to visit a reliable water source, which may be as much as 1 km distant. Townsend's Solitaire usually drinks with the standard passerine motor pattern, submerging the bill and then inclining the head back to swallow. It is also capable of drinking without tilting the head above the horizontal: it stands at the water's edge, leans forward, and submerges its bill, rhythmically contracting the gular region as if sucking, while the neck, head and mouth remain inclined below the horizontal. Other thrushes display similar actions. They drink from standing water sources such as ponds, puddles, streamsides and, of course, birdbaths, but they will also gather dew or melting frost on tree foliage and roofs, and some will eat snow during the winter. Some species, however, notably the desert-adapted wheatears, appear to go without water altogether, but it should also be remembered that some chats acquire both water and sustenance from nectar. In the winter months, the Red-backed Scrub-robin probes aloes (*Aloe*) to obtain nectar, such that its face becomes stained orange with pollen.

Nestling thrushes and chats, at least in the first four days or so after hatching, tend to be fed with softer-bodied prey, such as earthworms or caterpillars. These are highly nutritious and easily digested, allowing rapid chick development, which is good for both the young themselves and their parents as, the shorter the nestling stage, the smaller the risk of nest predation and the sooner the parents can attempt another brood. The adults of some species, the bluebirds being examples, partition the family diet in a marked way, selecting soft-bodied items for their offspring while themselves consuming harder-bodied prey. From anecdotal evidence, it would seem that small lizards are preferentially given to young, in this case older nestlings, rather than retained by the adults for themselves. By the time the young are ready to leave the nest, however, their diet has shifted mostly or entirely to whatever the adults are eating. Once out of the nest, they continue to beg for at least a few days, but also very quickly make their first efforts at feeding themselves. Foraging efficiency is acquired only slowly. Among American Robins, for instance, adults capture larger food items, make more captures per unit time, take fewer steps, and make fewer unsuccessful feeding attempts, than do juveniles, which take about 35% longer to capture each food item, require 60% more steps to do so, and obtain 25% less food per unit time.

In normal circumstances, the daily energy expenditure of a breeding European Robin, Northern Wheatear or Western Bluebird falls between 75 kJ and 100 kJ, or very roughly 2·5–3 times the night-time basal metabolic rate. Evidence varies over how stressful the quest for such energy then is. The average daily food consumption of nestling Ring Ouzels is 2·5 g at day one, 10 g at day five, 19 g at day ten, and 25 g at day 15, which clearly indicates how parental energy expenditure must grow over the course of the nestling period. In the Northern Wheatear, it would appear that the resulting stress is strong. Thus, males and females of this species differ in foraging rates and time-budgets in the run-up to hatching. During the pre-laying and laying stages, the females forage at higher rates than those of males, perch less often, glean more on the ground, and fly less. Although incubation is the least costly phase for females, owing to their low activity, it places restrictions on foraging time that can be overcome only by high foraging rates. After the eggs hatch, females switch to hunting from elevated perches, in the manner of males, and then experience considerable body-mass loss as they fly widely within the territory, to and from the nest. Similar weight changes are observed with Mountain Bluebirds, which lose an average of 3 g during the nestling period, and with Black Redstarts. In both these species, supplementary feeding increases the weight of nestlings at fledging and eliminates weight loss by the adults, which invest

As befits its owner's bodily stature, the nest of the ***Mistle Thrush*** *is a bulky affair, usually placed 2–10 m up in the crotch of a tree, or in the upright fork of major branches. Sometimes it is balanced on top of a horizontal fork, although in this particular case one of the branches has been sawn off. The nest itself is usually built from dry grass, plant stems, roots and moss, and bound together with mud, but here the dominant external feature seems to be lichen.*

[*Turdus viscivorus viscivorus*, Bermillo de Sayago, Zamora, Spain. Photo: Francisco Martín Martín]

more time in maintenance. On the other hand, Western Bluebird adults feeding nestlings older than one week are neither food-limited nor working maximally. The adults can meet their own energy requirements, and those of 4–6 nestlings, while spending less than 10% of their daily activity time in the pursuit of prey; indeed, a difference of two in brood size causes only a minor difference in activity costs, no more than 3 kJ per day.

A juvenile European Robin is estimated to require approximately 4·5 kg of food in its first year of life. When it is adult, however, and weighing about 20 g, it needs almost twice that amount, something of the order of 8·5 kg, which corresponds to a little more than its own weight in food per day, although, if it were totally frugivorous, these values would increase substantially. In order to achieve such an intake of food, hedgerow-dwelling European Robins in Germany, which eat small invertebrates 2–6 mm long, must each consume 700–750 such prey items per day. Wintering Townsend's Solitaires need to consume 250–500 juniper berries daily, although the quantity depends on the species of juniper, the weather and the temperature. The Western Bluebird, with a body mass of 24–31 g, has to consume almost its own weight in insects per day in order to maintain its energy balance. Rather surprisingly, a captive individual of a considerably larger species, the Grey-winged Blackbird, was recorded, 100 years ago, as eating almost its own weight in earthworms every day, but very possibly the high water content of earthworms was responsible for this. The minimum energetic requirement for a wild bird of comparable size, such as a Fieldfare weighing about 120 g, in optimal conditions in mid-winter, is around 220 kJ; such an animal can find food readily, and without long daily foraging flights, on damp ground and on berried bushes in parks and gardens, where micro-climates are often relatively mild owing to the sheltering effects of houses, shrubbery and trees. On the other hand, when the temperature at this season drops to 3° C, the requirement rises to 360 kJ, and it reaches 450 kJ at -5° C, so that, in such conditions, birds are compelled to feed almost continuously simply in order to stay alive.

Breeding

Thrushes and chats are almost entirely territorial, socially monogamous breeders, which means that a pair occupies a breeding territory and the sexes usually have very specific roles. The male establishes the territory initially, following which the female finds and bonds with him and, while he devotes the majority of his time to patrolling and defending the area, she builds the nest and incubates the eggs; both parents feed and tend the offspring. Overt deviations from this pattern are very few, but the story is considerably more complex and intriguing than this outline suggests. Social monogamy, nesting by a single pair, is almost exclusively the breeding system used by the thrushes and chats. Until comparatively recently, this was assumed to equate with sexual monogamy, but the Turdidae have proved to be an important, perhaps the most important, group for the experimental study of sexual behaviour among apparently monogamous birds. The discoveries that have been made shed light not just on the covert practices of pair-bonded birds, but also on many otherwise unexplained patterns of behaviour that such birds display; and the covert practices themselves are fully consistent with Darwinian principles of survival of the fittest and of the self-interestedness of genes.

The first key to breeding success is, however, the territory. Without it, a male stands no chance of obtaining a mate. Non-migratory species of thrush and chat are commonly territorial all year, although for many species there is too little information to be certain, while migratory species may or may not hold territories outside the breeding range. All turdids, however, whether migratory or sedentary, hold breeding territories. The importance of possessing a high-quality breeding territory is paramount. This is what drives the different migratory regimes of temperate species, whereby males invariably arrive back earlier than do females; the males are seeking to claim or reclaim the best sites. For Northern Wheatears, for example, territory quality, rather than individual quality, appears to explain much of the variation in breeding success. To the human eye, determination of territory quality is not easy, and can really be judged only retrospectively, on the basis of breeding performance. Nevertheless, some simple cues have been identified. For example, a method of increasing the attractiveness of a site to Eastern Bluebirds is to furnish it with two nestboxes, rather than just one. An explanation of this appears not to have been formally identified, but it seems very likely that, since the standard turdid response to nest failure is to shift nest-site, the possession of a highly suitable alternative site within the territory is a major form of insurance for both members of the pair. Buxton's well-observed and rather sad account

of a male Common Redstart which frenziedly tried to interest his mate in a succession of nest-holes in his territory, following the pair's eviction from a site by a pair of Eurasian Wrynecks (*Jynx torquilla*), bears this notion out.

The smallest Common Redstart territory documented by Buxton was only 50 × 100 yards, which is equivalent to 0·4 ha or 4000 m². It contained 37 silver birches (*Betula pendula*), 19 willows (*Salix*), 19 poplars (*Populus*), 13 ash trees (*Fraxinus excelsior*) and one each of cherry (*Prunus*), sycamore (*Acer pseudoplatanus*) and beech (*Fagus sylvatica*), along with some big elder bushes (*Sambucus nigra*), some traveller's-joy (*Clematis vitalba*) and a few other bushes and shrubs. Even so, breeding territories of this species have been recorded at one quarter of this size and, as Buxton observed, the extent of the territory is less important than the cover it contains. This is true also of Common Blackbirds, for which shrub coverage is correlated positively with breeding success and negatively with territory size. Breeding success of the Common Stonechat is linked to nest cover that thickens well in mid-season, such as bracken (*Pteridium*) and moorgrass (*Molinia*), as opposed to that which does not, such as heather and gorse (*Ulex*). Wood Thrushes select nest-sites non-randomly within a tract of forest, and females build nests in areas that have a higher density of trees, a higher canopy, a higher density of shrubs, and a greater average shrub height than found at randomly selected points; moreover, the average concealment of successful nests is greater than that of unsuccessful nests. In South Africa, Cape Robin-chat territories vary in size by an order of magnitude, from as small as 0·05 ha to 0·75 ha, but size variation within a given habitat is less than that between different habitats, suggesting that the driving factor behind major size variations is habitat quality.

In the case of the Common Blackbird, the Northern Wheatear and several other turdid species for which relevant measurements have been made, territory sizes tend to be larger at the start of the breeding cycle than at the end. With Eastern Bluebirds and probably all such species, this temporal reduction is thought to be the product of one or a combination of factors. First, prey availability may increase, thus reducing the area needed within which to forage; second, males may be under pressure to guard mates more closely so as to prevent extra-pair copulations, while females may be under pressure to prevent egg-dumping by other females; and, third, the original size of the territory may have been for the purpose of establishing control of several potential nest-sites, but, once one has been used successfully, defence of the others perhaps becomes less important. There may also be an effect of "packing", as later-arriving males squeeze themselves into less valuable habitats between existing territories. The breeding territories of American Robins can be tiny, but this is because they are essentially only for mate-guarding, as the adults range more widely to forage in a communal, undefended area up to 300 m away. Colonial Fieldfares take this condition to an extreme. In fact, even Common Blackbird territories are insufficient for providing all food for the young, and for this species, and perhaps many others, a major though not exclusive function of the territory is, again, that of enabling mate-guarding by the male. This is suggested by the fact that the greatest intensity of male intolerance falls during the female's fertile period, and by his attempts to expand an envelope of territory around a nest-site when a female places the nest, perhaps with intentional ambiguity, on the boundary with another territory.

Proclamation and maintenance of breeding territories are achieved largely by song, notwithstanding the fact that young male Common Blackbirds will sing if they can merely find a song perch, irrespective of a territory. Song is backed up with a repertoire of visual displays and behavioural features. The latter are commonly given throughout the year in various agonistic contexts, but often become more overt, frequent and exaggerated in the breeding period. One type of behaviour which is largely confined to the breeding season and which probably serves mainly

The diet of most adult chats consists of myriad flies and beetles, but these items are at once relatively costly to obtain and bereft of the proteins essential for growth and development. It comes as no surprise, therefore, that many breeding chats switch their attention to soft-bodied prey such as caterpillars, arriving with billfuls of them at almost every visit to the nest, as illustrated by this ***White-browed Robin-chat****. Caterpillars are relatively large, protein-rich and easily captured, providing an excellent source of nourishment for growing chicks.*

[*Cossypha heuglini heuglini*, near Harare, Zimbabwe. Photo: Alan Weaving/ Ardea]

Earthworms are a favourite food of adult thrushes, and they make ideal snacks for nestlings too. Many Turdus *species gather an impressive wormload from lawns and fields before returning to their hungry brood. One such species is the* ***Fieldfare****, a bird with an interesting breeding system and nest defence strategy, at least in Scandinavia, where groups nest semi-colonially in an attempt to minimize heavy losses to predation. This they achieve through a unique communal mobbing tactic involving directional defecation. This seems to ward off most raptors and crows, none of whom show much enthusiasm for getting plastered with sticky faeces and losing the power of flight.*

[*Turdus pilaris*, Germany. Photo: Konrad Wothe]

in mate attraction, although inevitably also signalling territorial occupancy powerfully to neighbouring males, is the aerial song or display-flight. Such flights are not particularly well documented for the Turdidae in general, and seem to be rare or lacking among the true thrushes, but they are widespread in the Myadestinae and the Saxicolinae. On Kauai, in Hawaii, the male Puaiohi (*Myadestes palmeri*) has a display-flight in which he flies up while singing, and then glides back down silently to land near his mate. The Pied Bushchat sometimes performs a display-flight with delayed-action wingbeats, similar to that sometimes given by domestic pigeons or the European Greenfinch (*Carduelis chloris*) in aerial display. A more sustained and more complex aerial display is that of the Bluethroat. The male makes a steep fluttering ascent and then hovers with rapid wingbeats at a constant altitude of 1·5–50 m above the ground, hovering for longer periods the higher he ascends; this is followed by a slow descent with the body held level as the wingbeats decrease in amplitude, shifting to a spinning glide with the tail fully spread and wings in a downward arc, and ending with a head-first dive to the original perch. The performance may last from less than 10 seconds up to as long as five minutes, and cover a distance of more than 300 m, but lower flights are more frequent in the immediate vicinity of a female. The male Güldenstädt's Redstart has a soaring display-flight on quivering wings, showing off his striking white wing patch, and the Plumbeous Water-redstart performs a slow, fluttering aerial display, with the short square tail spread out to its fullest extent. Wheatears all have a display-flight, involving songs and sudden dives to the ground, which is sometimes undertaken in pitch blackness long before dawn, this period of the day perhaps being good for sound transmission.

Early pair formation is associated with greater breeding success, and this can be explained in a variety of ways. As mentioned in the preceding paragraphs, among migratory species, the earliest-arriving males are likely to be of highest intrinsic quality and to obtain the best territories, and they quickly establish pair-bonds with the earliest-arriving females. For the European Robin, however, Tobias has demonstrated a subtler trade-off, one which doubtless applies to other species also. To begin with, there is strong competition for females, such that 20% of males fail to pair; and then, although pairing is initially costly in terms of individual foraging success, as birds on individual territories encounter large food items more often than do those in shared territories, in the long term bachelors are compelled to invest more time in advertising for a mate. Thus, at a certain point it pays to switch from the individual territory to the shared territory. European Robins studied by Lack in south-west England made this switch in the period from mid-winter to late winter.

European Robins are sexually similar in plumage, and pairing, as observed by Lack, appears to be the initiative of the female. Abandoning her own territory at dawn, she enters that of a male and flies directly up to him. He either retreats or, more often, postures aggressively and sings loudly at her, at which she may posture and sing back, holding her ground without getting into a fight. If forced to retreat, the female nonetheless quickly returns by flying back up to the male, something that no rival male would do. In this first phase of pair formation, the two proceed to posture back and forth for an hour or two, sometimes for one or two days, until the male accepts the female on his territory. In the second phase, lasting for several days, she then familiarizes herself with the new territory, making short flights to all parts within it, and the male follows her closely, singing very quietly. There then ensues a long "engagement period" during which the two robins largely ignore each other, the female keeping a low profile and the male singing at moderate strength.

Homologous behaviour is exhibited by the Hermit Thrush and the Veery. Initially, the courtship chase is merely a form of attack by the male and escape by the female, the latter, however, following a roughly circular course to stay within the territory. Within a few days the two individuals fly more slowly and deliberately, pausing and remaining motionless for a few seconds and then resuming; and by the fourth day the male accepts the female on the territory and, although he attacks all others, he no longer attacks her, even when she returns after a brief absence. Among migrants, of course, pair formation is a relatively urgent procedure. For example, a male Common Redstart established a territory on 17th April, a female arrived four days later, some form of pairing was evident by 24th, the first attempt at copulation occurred on 25th, nest-building began on 26th, and the first egg was laid on 3rd May. This species, the sexes of which are easily told apart, also has a courtship chase, but this is evidently more ritualized and presumably lacks the true aggression that initially characterizes the male's response in sexually monochromatic species. The female leads, zipping silently around and weaving through trees and branches and then away, the red tail of each sex very conspicuous and often fanned. Typically, the chase begins from the site of the future nest, and often terminates well away from it.

Presumably because incubation is undertaken by only one sex, sexual dichromatism is common in thrushes and chats. It greatly benefits females to be camouflaged and thus they are usually studies in shades of brown. Males, meanwhile, are free from the constraints of nest predation and many have evolved dramatic patterns and colours. This divergence in plumage would presumably have proceeded through sexual selection, with females consistently preferring the gaudiest males. Regardless of colour pattern, provisioning behaviour in all thrushes and chats studied thus far is characterized by biparental care, as these photographs of the ***Common Rock-thrush*** *attest. Indeed, it is usually males that deliver the bulk of the food consumed by nestlings, at least for the first few days after hatching. During this period the female continues to brood the young, but she gradually invests less time in brooding and more time in collecting food.*

[*Monticola saxatilis*, Burgos, Spain. Photos: José Luis Gómez de Francisco]

This dramatic photograph shows a female ***Black Wheatear*** *returning with prey to a typical nest-site, a rocky crevice in the arid hills of southern Spain. The nests of several species of* Oenanthe *have pebbly ramparts, but this species takes it to extremes. Its nests are characterized by a proliferation of pebbles, most of which are fetched by the male and deposited near the entrance as proof of his prowess. At one nest 9300 pebbles were counted, the largest of which was 28 g, well over half the weight of the bird! Closer inspection has shown that females prefer prolific pebble-bearers, and nests with most pebbles produce most young.*

[*Oenanthe leucura leucura*, Navalmoral de la Sierra, Ávila, Spain. Photo: Juan Manuel Hernández]

In contrast to the above, pair formation in sedentary populations of sexually dichromatic species may be rather less fraught and more protracted. Common Blackbirds, both in their natural range and in Australia, mostly form pairs in the middle and late winter, before the song period commences, although pairing can occur at almost any time except during the moult. The high rates of nest predation suffered by this species constrain breeding success and promote competition among females for high-quality nesting habitat prior to pair formation. Meanwhile, the distribution of females, which tend to share areas with particular males in pseudo-bonds but also often defend small areas against other females, and can fight viciously over access to a particular male, promotes competition among males for areas either already holding females or likely to do so in the spring. Mate choice is itself, therefore, constrained by this intrasexual competition, so that, typically, males and females having overlapping winter ranges pair off on a shared breeding territory. This leads to assortative mating on the basis of competitive ability: pairs are formed by partners of equal quality. The consequences of this later in the breeding cycle are considerable.

Older individuals which have already bred together successfully exhibit some tendency to stay together over the winter period or, at least, to reassociate in the spring. This happens with Common Blackbirds, which either remain together on the male's territory or occupy immediately adjacent areas during the winter period. Likewise, Mourning and White-crowned Wheatears occur in pairs from February to September; outside this period partners often live in separate but adjacent territories, maintaining a close bond or even, sometimes, remaining paired throughout the winter months. Tropical species such as the Bearded Scrub-robin remain in pairs on territory all year, and 27 out of 34 pairs of Common Stonechats in Kenya stayed together over an 18-month period. In the Palearctic, Black Redstart males, before dispersing for the winter, sometimes sing in the autumn and consort closely with their mate of the year, seemingly staking out their claim to the site for the following year. Indeed, in one study, such males produced 5·2 fledged young per breeding pair in the following spring, compared with 3·7 for males which failed to sing, although another study demonstrated that almost all autumn-singing males are full adults, and that this site dominance and pair confirmation resulted in 59% of autumn pairs re-forming in the following spring. In the case of the Mountain Bluebird, it is apparently the nest-site itself, and not its owner, to which the female is attracted, so that re-pairings in subsequent years are probably more a reflection of loyalty to the site than of fidelity between mates. This is homologous with the premium placed on territory quality by Common Blackbirds.

Courtship feeding of the female by the male, the former often soliciting by quivering her wings, gaping with the bill and sometimes making sounds typical of a young fledgling, is a feature of some members of the Turdidae. The variability of the phenomenon among species, and even within them, is not, however, easy to explain. Among European *Turdus*, for example, it is regular for the Mistle Thrush at and away from the nest and for the Redwing only at the nest; it is irregular for the Song Thrush and the Fieldfare and occurs only when the female is sitting; it has been reported but is unconfirmed for the Common Blackbird; and it remains unreported for the Ring Ouzel. Courtship feeding is seen regularly in some populations of the Eastern Bluebird, but not in others. Interestingly, the male Mountain Bluebird frequently feeds the female on or near the nest during the incubation and brooding periods, contributing up to 50% of her food at this stage, and experiments have shown this to increase significantly the more time she spends on the nest. There are several possible advantages in this. First, it may reduce the chances of nest failure through inclement weather or predation and, second it probably shortens the incubation period, thereby increasing the time available for the pair either to raise a second brood or to invest in the care of the fledged young. Courtship feeding by Townsend's Solitaire and by the European Robin begins long before nesting and lasts through the egg-laying period, which presumably enhances the bond and helps to build the female's reserves. In the robin's case, however, the "seep" call that she uses signals not only hunger but also fertility, and attracts neighbouring males, so that the resident male's best strategy, apart from high territorial vigilance and mate-guarding, is to provide her with food very promptly whenever she calls. In the case of the Common Rock-thrush, courtship feeding with mulberries (*Morus*) was witnessed so far in advance of the breeding season that it took place in March in East Africa, some 5000 km from the nearest breeding area. By contrast, such behaviour by the Common Redstart is vestigial in nature, often with no food being passed.

*Another cavity-nesting chat is the **White-headed Black-chat** of the miombo* (Brachystegia) *and mopane* (Colophospermum) *woodlands of southern Africa. The nest itself is a bulky cup of grass, leaf petioles and rootlets, always sited in treeholes. Natural ones seem to be favoured, but the abandoned excavations of woodpeckers (Picidae) and barbets (Capitonidae) are sometimes used. Regardless of their architect, shallow nest cavities are preferred, but they can be up to 30 cm deep. If deeper still, the female (pictured here) tends to fill the base copiously with dung, twigs and leaves.*

[*Pentholaea arnotti arnotti*, Chizarira National Park, Zimbabwe.
Photo: Peter Steyn/Ardea]

As a final example, the myadestine Omao, in Hawaii, demonstrates both vestigial and true courtship feeding. Both pair-members perform ritualized begging, perching side by side and silently begging from each other in turn, but the male also feeds the female, usually while away from the nest but sometimes, as with the Mountain Bluebird, while she is incubating or brooding.

There are many scattered anecdotes about courtship displays by thrushes and chats, but these are often vague and their meaning and context assumed. Moreover, there is no analysis or review to help with the interpretation of the various types of documented behaviour. As Lack noted, both pair formation and courtship feeding by the European Robin are entirely distinct from courtship itself, although the repertoire of pre-nesting behaviour by migratory species is often compressed into so short a period that these events must appear virtually the same. Courtship, however, is a pattern of behaviour which typically immediately precedes or, at least, invites copulation. In well-established pairs courtship signalling is probably minimized, while it is doubtless more pronounced between individuals unfamiliar with each other, and for semi-practised ones it presumably falls somewhere in between. The following are some examples from among the Saxicolinae:

a) The Grandala male turns to the female, calling "fit-fidu", fanning the tail, bringing the wings forward jerkily to the sunbathing position, and then in increasing excitement tilts the wings forward, fluffs the rump, fans and depresses the tail, lifts the head and opens the bill as if begging, making dancing movements. The female usually approaches him from the front, walks around him in a semi-circle and flutters on top of him, the male then mounts, and the action terminates with some wing-spreading and tail-spreading by the male.
b) A male Blue Whistling-thrush flew low over the female's head while making excited buzzing noises, the tail fanned, repeating the manoeuvre twice, singing (untypically) all the time from low perches, and flew once more to hover over her, landing beside her in a very upstretched stance, the bill vertical. The female flew to a nearby horizontal branch, and copulation followed.
c) A male White-starred Robin clung to the side of a branch slightly below a perched female. He adopted an elongated posture, the neck outstretched, the bill in line with the body, and swayed slowly from side to side, displaying the throat star; he then flew across a gully over the canopy in slow flight, with fluttering wings and fully fanned tail, calling and then breaking into song as he landed.
d) The male Rufous Scrub-robin (*Erythropygia galactotes*) stands on an elevated point near the female, raising and lowering the tail, and slightly fanning the wings; the female copies this. He pursues her in low flight over the ground, sings and wags his tail up and down, and then flies slowly and gracefully with the tail fanned, repeating this display-flight several times until the female accepts him.
e) The male Rufous-capped Robin-chat adopts a hump-backed stance, the plumage sleeked, the tail lowered and fanned, the

*After they hatch, thrush nestlings are blind and virtually naked, but typically covered in straggly down along the usual passerine feather tracts. At first their powers of movement are limited, but almost immediately they can gape for food and produce a thin wheezy begging call. The offspring of this **Orange Ground-thrush** hatched a few days previously, as can be deduced by the fact that their eyes are open, and their bodies are covered liberally with down. At this age, they are capable of begging vociferously, forcing the parents to return ever more frequently with cargoes of worms and other invertebrate morsels.*

[*Zoothera gurneyi*, Vumba, Zimbabwe.
Photo: B. & L. Worsley/ Photo Access]

*In most of its range the **European Robin** produces a clutch of four or five eggs. A brood of six is therefore unusually prolific, falling just one short of the record! This adult is raising its ravenous sextet in a recess under uplifted roots in a German woodland. This site is fairly typical, but it is much more common for robins to hide their nests within dense creepers on walls or trees, a metre or so above the ground. They take to nestboxes, as long as they are open-fronted, and regularly nest in other man-modified situations. Female robins usually commence incubation with the last or second-last egg, thus ensuring a relatively synchronous hatching date for her brood.*

[*Erithacus rubecula rubecula*, Germany. Photo: Günter Ziesler]

wings held away from the body and vibrating as he dances to left and right on the perch, attempting to approach the female, while giving a fast quiet song of pure imitation (see Voice). He may make short fluttering butterfly-flights. The female droops her wings, and quivers her whole body. The male, with tail erect, lifts his wings square away from the quivering body. After copulation, he caresses his mate by stroking her under the throat with the back of his head, uttering soft fluting notes.

f) The Common Nightingale male sings quietly near the female, cocking and fanning his tail, sometimes drooping the wings, and then pursues her in whirring flight with bleating calls, lands beside her, and sings and dances while holding the head low, the tail fanned and the wings quivering and spread.

g) The male Indian Robin displays his white wing-coverts prominently during courtship. Occasionally he performs a courtship-flight, with the wing patches everted prominently, but most display is on the ground near the female. Here, he first makes a dancing, circling run, with the wings drooped, the tail down, the breast puffed out, the neck stretched up, and the bill vertical—the emphasis is on movement, not on colour; when close to her, he cocks the tail sharply, stands sideways, and fluffs and quivers the whole body— the emphasis is now on colour, not on movement, "a mere patch of black, white and chestnut of no definite shape"; copulation then follows.

h) The Common Redstart male moves with bee-like flight in a small circle around the female, uttering excited harsh calls; he perches near her, flattens the body, raises the wings until they touch over the back, and quivers them to show off the shimmering pink undersides; with the tail depressed and fanned, the body pressed down and along the perch, and the head lowered and stretched forward to show her his black face and white cap, he gives a very high soft hiss, copulates, and then moves off in wild rapid flight around the female, before flying away, warbling a sweet song.

i) A presumed male Spotted Forktail chased a presumed female and, when she landed, he scissored his tail with more exaggerated spreading of the outer feathers, then fluttered with shallow wingbeats over water close to her, with the white wing-coverts prominently fluffed out in a broad V-shape. He then perched on a nearby bush and sang a soft song.

Leap-frogging behaviour is a characteristic of some species, such as the Puaiohi during courtship. It is also performed by the Buff-rumped Wheatear (*Oenanthe moesta*) during a remarkable duetting display which has been thought to have a territorial function, but which must surely be associated with confirmation or strengthening of the pair-bond.

Among species that nest in tree-holes, the male apparently selects the sites and has special displays to attract its mate to inspect and use them. The male Common Redstart, for example, flies up to the hole, fanning the red tail conspicuously as he enters, and then perches in the entrance and "flashes" his white crown feathers, sometimes also gliding down to the hole with the wings and tail spread wide. The male Pied Bushchat flutters in front of potential crevices while the female looks on, and, after he has entered and left a crevice, she inspects it, the procedure being repeated several times at one site. In the case of Eastern Bluebirds, the male, while holding nesting material, perches face inwards at the cavity entrance, with drooped wings and fanned tail; he repeatedly looks around, and puts his head in the entrance, and he half-enters the hole; from inside, he sticks his head out, still carrying nest material, and afterwards he performs a wing-waving display next to the hole. The social pair-bond is consid-

*The **Black-eared Wheatear** builds a nest essentially similar to those of other* Oenanthe, *being a rather flat cup of stems and moss, lined with down or slender fibres such as hair, and sometimes surrounded by a platform of twigs. It is usually placed on the ground, under an overhanging stone or tussock, but sometimes in rocky cavities in the walls of ruins or wadis. In southern Europe it is often concealed on dry hillsides amongst aromatic herbs, such as lavender* (Lavandula) *and thyme* (Thymus), *as seen here. After incubating the eggs for 13–14 days, the chicks are fed for a further 11–14 days, on this occasion by a male.*

[*Oenanthe hispanica hispanica*, La Rioja, Spain. Photo: José Luis Gómez de Francisco]

ered established once a female enters the cavity with the advertising male. There is, however, some evidence that the female can at least discriminate between proffered options. Given a choice of two types of nestbox, female Mountain Bluebirds which had bred successfully in one type tended to select that same type, while those which had failed in one type of box tended to select the other type. First-time breeders chose nestbox types similar to the one in which they had been reared, suggesting that some form of imprinting or early learning influences adult nest choice, and that good or bad experiences drive later choices. This is mirrored in other patterns of adherence or aversion to nest-sites by thrushes.

The degree to which hole-nesting is obligate in this family is not clear, but it seems likely to be semi-facultative. Eastern Bluebirds are virtually obligate hole-nesters, but in the late nineteenth century, when they were unusually abundant on Bermuda, and perhaps where predation or brood-parasitism pressures were different, some pairs on the island abandoned cavity-nesting and, instead, made open cup-nests. Likewise, Common Redstarts are widely thought of as hole-nesters, but open cup-nests of this species have also been found. There is evidence to suggest that the hole-nesting habit of this saxicoline may have evolved as a defence against brood parasitism by the Common Cuckoo (*Cuculus canorus*), the females of which have difficulty in depositing their eggs properly in the hole, and the young of which have difficulty in evicting the host's offspring. Some wheatears and *Cercomela* chats can nest in relatively open crevices and cavities among roots or, alternatively, deep in holes of various types, including bee-eater (Meropidae) burrows, old hirundine nests and even, in the case of the Familiar Chat, an old chamber in a Sociable Weaver (*Philetairus socius*) colony.

On the other hand, hole-nesting has a serious drawback in the form of nest-site scarcity and, consequently, nest-site competition. Because tree cavities are often so few, especially in managed woodland where old trees are removed, many other species lay claim to the spaces. As an example, Mountain Bluebirds have to compete with Buffleheads (*Bucephala albeola*), Northern Flickers (*Colaptes auratus*), Tree Swallows (*Tachycineta bicolor*), Black-capped (*Parus atricapillus*) and Boreal Chickadees (*Parus hudsonicus*) and Northern House Wrens (*Troglodytes aedon*), as well as introduced Common Starlings (*Sturnus vulgaris*) and House Sparrows (*Passer domesticus*). Furthermore, there are American red squirrels (*Tamiasciurus hudsonicus*), deer mice (*Peromyscus maniculatus*) and least chipmunks (*Eutamias minimus*) offering serious threats to nest-site occupancy. The aggression of the bluebird can save the day, and a pair has been seen to force to the ground and drive away the larger, chunkier Northern Flicker, but it has little chance if caught on a nest at night by an animal with teeth. In addition to all of these other species, of course, the birds have also to deal with conspecifics. Aggression between female bluebirds, to prevent egg-dumping as much as eviction, is high, to the extent that severe wounding, maiming and even death are commonly reported. Egg-dumping is, however, a relatively minor problem, only 1% of bluebird nestlings being the offspring of conspecific brood parasites; it is probably carried out by fertilized females who have lost their own nests through predation or accident.

Turning to the cup-nesting species, it is assumed that the female selects the nest-site, given that there is so much greater choice, and because it is almost always the female alone who builds. Female Song Thrushes, for example, test possible sites, by squatting in them, rotating while holding the tail raised, and hopping around them. Nevertheless, Skutch reported a male Clay-coloured Thrush which chose the nest-site and actively assisted in the construction of the nest, sometimes sitting in it. Similar observations of male support, but not nest-site selection, have been made for the Mistle Thrush, the Common and Grey-winged Blackbirds, the Ring Ouzel, the American Robin, the Cape Robin-chat, the Red-backed Scrub-robin, the Pied Bushchat, the Little and Spotted Forktails and others, although male help, if any, is usually only occasional and desultory. An individual Sharpe's Akalat (*Sheppardia sharpei*), presumed to be a male, has been seen to collect material and to pass it to its mate for incorporation in the nest; similar nest-initiation behaviour, with male proferring the female a large dead leaf (the first layer of the nest), is seen in European Robins.

With these open types of nest, there is a conflict between the need for concealment, in order to prevent predation, and the need for a view, allowing the opportunity to see approaching danger and escape from it. Song Thrushes have been found to seek a compromise between these two requiriements, never placing their nests in the most concealed sites but selecting sites with intermediate density of vegetation. On the other hand, at least two thrushes have curious strategies in this regard. The first of these, the Pale-breasted Thrush, uses the same nest repeatedly, so that, with the repair and supplementing of material with each brood, the nest

Most ground-nesting turdids, especially those with open cup-nests, lay eggs which are dull, mottled, or otherwise camouflaged. The ***Whinchat*** *is an exception to this rule, its eggs being a beautiful pale blue, lightly speckled with reddish-brown, and remarkably conspicuous. On hatching, the nestlings are very light at only 2 g, but thereafter they gain around 40% of body weight with each passing day for the next five days. Maximum weight gain is around day 5, during which the nestling adds in the region of 3·5 g to its own body mass, depending on the provisioning rate.*

[*Saxicola rubetra*, Burgos, Spain. Photo: José Luis Gómez de Francisco]

itself can reach very large dimensions. The second species, the Grey Ground-thrush (*Zoothera princei*), places its nest in a highly visible position in the crown of a low understorey tree, where it is easily confused with the bunches of dead leaves accumulated by squirrels in tree forks. Even so, this did not prevent eleven of 13 nests in one study from being destroyed by predators.

Commonly with the male in attendance, partly as a mate-guarding behaviour, the female typically begins a cup-nest by constructing a platform of dead leaves, twigs and other material, building up coarse outer walls by weaving together stems, rootlets, moss and sometimes mud or leaf mould. She shapes the cup by making snuggling, rotating body movements, thrusting down the breast and gently flexing the feet, pulling the top edges of material inwards and weaving them down to make a smooth-rimmed, tight-fitting structure, which she then lines with fine material such as thin soft grasses, rootlets, animal hair and/or feathers. With regard to the lining, however, there is one notable exception. The Song Thrush creates a lining from mud, dung and, especially, dead wood and wood pulp, which dries to form a hard, smooth interior. The function of this plaster-like lining is uncertain, but a recent suggestion is that it enhances nestling survival by rendering conditions inside the nest unsuitable for insect parasites, mainly the larvae of botflies (*Protocalliphora*) and nestflies (*Neottiophilum praeustum*). The general nest-building process is essentially similar for hole nests.

Thrushes that breed close to human settlements commonly incorporate man-made material, such as bits of string, cellophane, sacking, paper, cotton wool and so on, into their nests. Several species, including the Littoral Rock-thrush (*Monticola imerinus*), the Rufous Scrub-robin, the Oriental and Madagascar Magpie-robins (*Copsychus albospecularis*), the Indian Robin and the Buff-rumped and Mountain Wheatears, frequently incorporate the sloughed skins of snakes into the structure. The elaboration of nests by such means is presumably part of an attempt to disguise them by making them appear as natural as possible, through the use of everyday material in the local environment. Some species add living moss to the outside of the nest in order to enhance this effect. If, in particular, the birds add mud to the nest to hold the structure together, the moss and certain seeds that are probably added by accident can take root and grow. Skutch found some Clay-coloured Thrush nests to be "living gardens" as a result, and the nests of such species as whistling-thrushes and forktails, placed in damp crevices where moss grows naturally, frequently have flourishing green cover in their walls. On the other hand, a female White-crowned Forktail was seen to gather moss and other building material from near a stream, carry it to the water and give it a very thorough washing, before taking it to the nest-site; these actions doubtless had a sanitizing purpose, although they may also have washed out organic matter that would have helped the material to root.

The nests of some ground-nesting species, such as the nightingales, can be domed. Indeed, shortwings make beautifully constructed domed nests, as difficult to spot as are the birds themselves. Various African and Asian chats of arid environments nest in rock crevices and in burrows in the ground, and they have some intriguing adaptations that appear to serve as anti-predator mechanisms. Several of the wheatears use sand rat (*Psammomys*) burrows in which to nest, and observations in Israel indicate that the relationship between the two animals can be "semi-symbiotic". A pair of Buff-rumped Wheatears will use one of many burrows in a colony of fat sand rats (*Psammomys obesus*), but returns the favour by serving as a guard: when a raptor passes over the area, the wheatear's warning call sends the sand rats scurrying back into their burrows. Also in Israel, studies of the Blackstart's remarkable rampart-building behaviour, in which it places hundreds of pebbles and stones at and around the entrance to the nest-cavity, led to the conclusion that ramparts probably serve as an obstruction or barricade which a potential predator must take time to negotiate, allowing the female a greater opportunity to escape. A similar habit is shown by other members of the genus *Cercomela*, including the Familiar and Brown-tailed Chats and the Brown Rockchat (*Cercomela fusca*), the last of which may use earth, and by some wheatears, including the White-crowned, Black, Hume's, Mourning, Mountain and Cyprus Wheatears (*Oenanthe cypriaca*). The Mourning Wheatear also uses pottery shards, the Mountain Wheatear utilizes caked mud or twigs, and the Cyprus Wheatear also uses twigs, often to a predominant extent. One painstakingly analysed Familiar Chat nest contained 361 stones and 15 nails, the latter 7·5 cm long, in addition to 250 miscellaneous fragments of nest material, and had a total weight of 1163 g. Another chat nest was augmented by 147 stones in a period of just three days.

This behaviour has also evolved independently in arid-country larks (Alaudidae), and one plausible explanation is that stone

Like the majority of its congeners, ***Townsend's Solitaire*** *nests primarily on the ground, usually in recesses in banks, or under jutting rocks, roots or stems. It lives in relatively dry coniferous forests from Alaska to Mexico and cannot depend on the ready supply of moss and flexible plant matter available to most of its tropical relatives. The result is that it builds a simple cup of twigs and stems, lining it with grass, strips of bark and pine needles. In the breeding season adults and young subsist on insects and their larvae. In winter, however, some populations survive on a diet entirely made up of juniper* (Juniperus) *berries.*

[*Myadestes townsendi townsendi*, north-west Montana, USA. Photo: Tom Ullrich/ Oxford Scientific Films]

aprons ameliorate the nest micro-climate by absorbing heat at midday. At least in the case of the Black Wheatear, however, the phenomenon has, as discussed earlier (see Morphological Aspects), transmuted into a test of male fitness. In a study of this species in southern Spain, one nest was found under which 9300 pebbles had accumulated over several years; the average weight of these was 6·8 g, the heaviest being 28 g, two-thirds the weight of the bird itself. The rate of collection is at least comparable with that of the Familiar Chat: in a series of 42 successive trips in a 25-minute period, the average time per trip, from leaving the nest to returning with a stone, was 24·7 seconds. Female Black Wheatears with mates that carry heavier loads appear to enjoy higher reproductive success, perhaps partly owing to the superior genes that they obtain for their offspring by selecting as mates males which are able to incur the heaviest burdens. On the other hand, females also contribute more to reproduction themselves when mated to a superior male, and correspondingly reduce their reproductive effort if the stone-carrying abilities of the mate is experimentally reduced by removal of some of its primary feathers.

Thrushes and chats are renowned for the unusual choices of nest-site made by some of the family's members. Whereas the more conservative and retiring species tend to be relatively inflexible in this respect, the typically bold and aggressive species often make decisions that reflect a dare-devil opportunism. Discarded tins, pots, oil-drums and cans are frequent choices by such turdids as White-throated and Cape Robin-chats. Rufous Scrub-robins in Turkey appear actively to prefer such sites over natural ones, so that refuse dumps can be good places to find this species, nests of which have also been found in tractor engines. Blackstarts have been recorded nesting in a vehicle exhaust, and a Familiar Chat bred in a constantly used customs road-boom. Lack reeled off a list of odd sites utilized by the European Robin, including a jam-jar, a letterbox, an old boot, a pulpit, a human skull, a dead cat, an unmade bed, and a gardener's jacket pocket. He also related how a pair built a nest in a wagon which, just after the young hatched, was moved 160 km and then returned, one of the parents accompanying it and feeding the young en route. Cyprus Wheatears have built nests in aircraft or in aircraft hangars next to roaring engines. Perhaps most astonishing, however, is the report by B. E. Smythies of Oriental Magpie-robins which built nests in the camera compartments of all six "Hurricanes" of "A" flight stationed at an airfield in Arakan, in Myanmar, during the 1939–1945 war. When the camera was removed from one aircraft after an operational sortie, a female was found to be incubating eggs in the nest, having remained there throughout the flight.

The time required to build a nest depends on conditions of weather and female physiology. Cold or wet spells can depress activity, while the state of female readiness to lay may both be driven by and drive the speed of nest construction, although there is almost always a gap between the completion of the nest and the laying of the first egg. Broadly speaking, turdid nests are usually completed in 3–6 days, but Oatley reports a remarkable feat by a Red-backed Scrub-robin, who built hers from scratch in eight hours, while the European Robin who used a gardener's jacket pocket almost completed her nest in less than four hours. Interestingly, the Common Blackbird has been found to build its first nest of the season in 7–11 days, whereas it takes much less time, sometimes as little as two days, to complete later ones. Over a period of 11 hours, a female Common Redstart took material to the nest 239 times, and Buxton calculated that a total of about 600 visits may be appropriate for a female building from scratch in a fairly standard cavity, although smaller cavities require smaller quantities of lining. He was astonished at the size of stick that a female could carry, and thought that some were maybe twice her own weight. Sometimes, the redstart found it difficult to get a large stick through the entrance; on such occasions, either she succeeded after a considerable amount of shifting the stick to one end of her bill or, often, she dropped it, yet then continued with the intended action and entered the hole.

Although the first egg is laid sometimes within a day of the nest's completion, there is more commonly a period of several days before laying begins. Even in the aforementioned case of the eight-hour nest built by the Red-backed Scrub-robin, the lag between completion and first egg was four days. This is the fertile period for the female, when she is most receptive to copulation. Male Western Bluebirds, for instance, attempt to copulate at a steady rate from 60 days before laying until the onset of incubation, but female acceptance of within-pair copulations increases to 80% only in the ten days before laying, and remains high throughout the laying period. It is also, therefore, the period when the male must guard his mate most intently. The strategy of the male European Robin is to sing loudly and strongly as a means of discouraging potential cuckolders from venturing near, whereas the male Common Redstart, in contrast, becomes relatively si-

*The **Spectacled Thrush** is a classic* Turdus*, usually building its bulky cup of grasses in low vegetation and feeding its offspring a diet of worms and other soft-bodied invertebrates. Likewise it often lines its nest with mud, a practice found in a wide variety of congeners. Females of many* Turdus *species collect damp mud and mould it into the cup of their nests with their bodies. The mud seems to function as a reinforcing agent, and probably helps to insulate the contents from low temperatures or heavy rainfall. In drier climates* Turdus *nests can often be identified long after the vegetable part has rotted away because a hard baked cup of mud survives. This Neotropical species lives on Caribbean islands, and in cleared areas of Venezuela, north Brazil and the Guianan shield, a humid region where nests presumably disintegrate shortly after fulfilling their function.*

[*Turdus nudigenis nudigenis*, Le Larivot, Matoury, French Guiana. Photo: Olivier Tostain & Tanguy Deville]

Unlike some birds, provisioning thrushes do not swallow food for later regurgitation at the nest. Instead, items are clasped between the mandibles, ready to insert quite roughly into whichever gaping maw presents itself most enthusiastically. Although food items are almost exclusively invertebrates, they sometimes include berries or other fruit, as can be seen at this nest of the ***Olive Thrush****. As with many tropical turdids, this species has a poorly defined breeding season, nesting in all months wherever meteorological conditions are relatively constant.*

[*Turdus olivaceus abyssinicus*, Nairobi, Kenya. Photo: Michael Gore]

lent and simply follows the female closely wherever she goes. This latter strategy, called "mate-guarding", is also adopted by the Common Blackbird, which typically perches above his partner, watching her and the immediate surroundings at the same time, and by the Common Nightingale, the Rufous Scrub-robin and the Bluethroat, and it is probably employed by the great majority of thrushes and chats. For the Western Bluebird, it has been shown that the male keeps closer to the female, and follows her more frequently, when nearest-neighbour distances are reduced, as may be expected if the threat of extra-pair copulation increases with local density, and, furthermore, inter-pair distance diminishes when vegetative cover around the nest increases, suggesting the importance of keeping the female in view at all times during this period.

Why does the male have to be so vigilant over his mate? The reason is that she *may* be trying to slip away to copulate with another male, and other males *will* be trying to slip in and mate with her. The explanation for these impulses lies in maximizing the quality, as well as the quantity, of an individual's genetic output. The process, already outlined in the preceding paragraphs, by which the Common Blackbird forms pairs over the winter results in assortative mating between individuals of equal quality; and from this circumstance arise sexual-selection pressures, driven by the mutually beneficial interest that high-quality males and low-quality females have in each other. Low-quality females, which are typically mated to low-quality males, have the chance to improve the genetic quality of their offspring by engaging in extra-pair copulations with high-quality males. High-quality males, although mated to high-quality females, have no reason to reject sexual contact with low-quality females, as they can, through them, increase their output with virtually no cost, since extra-pair males avoid participating in parental care.

This leaves the low-quality males and the high-quality females. The former may be interested in the latter, but the latter plainly have no interest in the former. Indeed, the evidence suggests that an older female herself seeks to prevent her mate from straying by prolonging the period of her sexual activity, so as, first, to induce her partner to guard her, which reduces sexual coercion from other males, and, second, to monopolize his parental effort, since the mate-guarding male cannot easily pursue extra-pair activity or search for better mating options. An interesting facet of this disparity in quality between individuals in a population is that females seeking to find a sire other than their mate for their offspring can be remarkably effective at doing so, even when males are being especially attentive in their guardianship. Among Eastern Bluebirds, for example, males that stayed closer to their females had *more* offspring of other sires in their nests than did those that were less attentive, probably because they were inexperienced young birds with relatively little certainty about the female fertile period. In the case of Bluethroats, old males are far less vigilant in their mate-guarding than are young ones, but, while they experience the same levels of cuckoldry as do the young birds, it is *only* the same levels, and not higher ones, and these older males gain a considerable number of extra-pair fertilizations of their own in compensation. In all these extra-pair copulations, the courtship procedure must be hugely truncated in repertoire and time, but male Western Bluebirds have been found to perform a special display, seen only in extra-pair encounters, in which they shivered or flipped their wings rapidly while tilting forwards, often gaping and giving a high "mew" call, all of which has been interpreted as a submissive display intended to deflect an aggressive response.

Quality in these terms is to some extent measurable in terms of age. Since most thrushes and chats that fledge will die before or soon after reaching the age of one year, or, in tropical areas, rather more, any individual reaching two or more years of age has demonstrated a certain quality of survival. This may be mere external good fortune, but it may also be the internal good fortune of good genes. Female thrushes and chats are programmed to search for evidence of quality in potential partners, but, if circumstances force on them a social mate of suboptimal (or simply unproven) quality, they will inevitably be receptive to, and commonly actively pursuant of, a neighbouring mate of clearly higher quality. Extra-pair sires are typically males of superior quality to the social mate, and hence may confer genetic benefits on the extra-pair offspring, either through the intrinsically superior quality of the sire or through his compatability with the female's genetic make-up. This has been very elegantly shown for Bluethroats, in which the immunocompetence of extra-pair offspring is greater than that of the mated pair's offspring in the same nest.

How do females assess the quality of potential extra-pair mates? In the case of Bluethroats, males which have had their

blue and chestnut throat patches experimentally darkened lose more paternity within their own nests, presumably since their attractiveness to their mates as a sire is diminished, and they spend more time in guarding their mates against extra-pair activities and less time in singing than do males with intact colour patches. This implies that females are more likely to pursue extra-pair copulations when mated to an "unattractive" male, and they appear to win this sexual conflict, as they indeed obtain more such copulations despite the greater guarding effort of their experimentally darkened partners. Exactly the same results were produced when the ultraviolet reflectance of the blue breast of the species was experimentally reduced. Moreover, the spectral purity of the blue throat feathers and the width of the chestnut band are positively correlated with paternity in the male's own nest. Further evidence of the role of these colour patches in the sexual behaviour of the Bluethroat comes from the fact that this is one of several species for which artificial leg-bands appear to influence mate choice. Blue and orange leg-bands mimicking the natural sexual plumage of the Bluethroat permit males to guard their mates less and to intrude more into neighbouring territories, although the effect is relatively weak. Female Bluethroats, however, strongly favour symmetrically coloured leg-bands over asymmetrically coloured ones, confirming a well-known preference among female birds for symmetry in males.

Degree of infidelity has thus far been investigated by the use of molecular-genetic techniques to determine biological paternity of broods, or by direct observation of marked individuals, for at least ten members of the Turdidae. These are the Eastern and Western Bluebirds, Townsend's Solitaire, the Common Blackbird, the American Robin, the Clay-coloured and Bicknell's Thrushes, the European Robin, the Bluethroat and the Northern Wheatear. Not one of these ten has turned out to be genetically monogamous. In Western Bluebird nests, 19% of the young were found to have been sired by a male other than the one provisioning them, and in nests of Clay-coloured Thrushes this proportion exceeds a third. One of the best-studied thrushes with respect to paternity is the Bluethroat, for which the degree of extra-pair paternity appears to vary enormously from one year to another. Thus, in a decade-long Norwegian study, the proportion of illegitimate young varied among years from 7% to 33%, and in one French study it reached as much as 42%. Annual variation in environmental conditions does not seem to predict this very well, although, in Norway, there has been some indication that infidelity is lower in years with colder morning temperatures, suggesting that, during harsher climatic conditions, the birds may be energetically more constrained to look after their own survival, rather than pursue extra-pair activities.

For males, there is a powerful tension between the need to guard the mate so as to prevent loss of paternity, which requires caution, vigilance and quiet, and the impulse to venture beyond the territory in order to gain paternity at the expense of a neighbour. With the Northern Wheatear the latter interest prevails at the start of the season, probably because there are fewer male contenders at that time, but later-arriving males are much more fixated on mate-guarding. Among many species, however, there are not only neighbours to contend with but also "floaters", males which have failed to find a territory or a mate and which are constantly on the surreptitious lookout for either or both. The pressure from this sector of the population, largely hidden to human eyes, can be gauged from the speed at which widowed females can remate. As an entirely typical example, a White-capped Water-redstart female, after her mate had been accidentally caught in a mousetrap, remated with a new male within the same day. Populations of the Northern Wheatear, in any one breeding season, can contain 5–26% unpaired males, and figures for other species indicate that such a male sex-ratio bias is widespread in the family.

Experimental removal of males from territories during the females' fertile period, as has been done with Eastern and Western Bluebirds, Northern Wheatears and European Robins, all resulted in rapid incursions and courtship of the females by neighbouring males, suggesting that even short lapses in mate-guarding can cause a male to lose a share of paternity. Females, however, remained selective: copulations occurred only if the males in question were in better body condition than were the removed partners, providing further evidence for the considerable role of female choosiness in the evolution of extra-pair mating systems. Interestingly, this circumstance, at least in the case of the bluebirds, did not result in less attentiveness to brood-feeding by the cuckolded males, even if the detention treatment allowed them to observe their females' behaviour, which suggests that, if they have assurance of at least some paternity, their response is to treat all offspring as putatively their own. Similarly, if a replacement male is present during his new mate's fertile

*Related to the nightingales, but more colourful and confident, the **Bluethroat** has been a focus for recent European studies of breeding biology. As with many birds, close scrutiny of an essentially monogamous system has revealed complex breeding systems and extra-pair copulations to be rather more frequent phenomena than previously believed. In most populations 5–15% of breeding units are polygynous, and anything between 33% and a staggering 64% of fledged young are sired by extra-pair males. The female, by no means an innocent party, has a habit of sneaking into neighbouring territories during the fertile period!*

[*Luscinia svecica cyanecula*, Palencia, Spain. Photo: José Luis Gómez de Francisco]

period, he will feed all offspring as if they were his; if he is not present, he usually takes no part at all in feeding them. It should be noted, incidentally, that, when a female is the new partner, the situation is rather different: she removes nestlings if they are less than a week old, disregards them if they are 1–2 weeks old, and actively feeds them if they are older than this and therefore on the point of fledging.

This all-or-nothing strategy by males helps to account for the particularly extraordinary situation to be found with Bicknell's Thrush, many nests of which have not just multiple paternity, but also multiple male feeders. During a demographic study of this species in Vermont, each of 14 broods was observed to be fed by groups of 2–4 males and one female, while the four remaining broods were each fed by a conventional pair. Three males fed the broods of two females concurrently or consecutively. Genetic analysis, using micro-satellite markers, revealed multiple paternity in nine of 13 broods, and four males had offspring in more than one brood in the same year. Ten of 17 males sired offspring in the broods that they fed, and ten of 13 sires fed the broods in which they sired young. Females fed nestlings more than twice as often as did males. On the breeding grounds, the males of this species range more widely than do the females, having home ranges of 4·5 ha on average, compared with 2·3 ha for females. Individual male home ranges contain up to four nests and overlap extensively with those of 2–7 other males, often intersecting near nest-sites, whereas female home ranges tend to overlap very little. Nothing quite like this is known to occur among any other of the Turdidae, and it is all the more remarkable for being found in so poorly differentiated a species. It has been suggested that the phenomenon is driven by food abundance in this thrush's relatively harsh environment. In one year, the number of male feeders at nests was significantly negatively correlated with prey biomass: in other words, females mated with more males in order to obtain food for the young from within their several home ranges.

Most thrushes and robins breeding north or south of the tropics exhibit a marked seasonal breeding pattern, so that their nesting endeavours cluster into a period of a few months. This happens to a lesser degree in the tropics, although there is a frequent correlation between breeding and the rainy season, which often results in two peaks of breeding activity. In Central America, the Clay-coloured Thrush has one extraordinary surge of breeding activity, timed in response to the rainy season, to the extent that the local inhabitants dub the species the "rain-caller". So sudden and synchronized is this breeding wave that it brings with it an unconventional behavioural pattern akin to that of Bicknell's Thrush. In an intriguingly lek-like arrangement, males sing in close proximity to one another, defending territories which may constitute only a single tree, and females may mate with several of them; over half of all females produce broods with mixed paternity, and 38% of young are fathered by a male other than the one looking after them. As this phenomenon becomes more fully explained, it may be possible to examine the evolutionary circumstances of a more southerly congener, Lawrence's Thrush, which also appears to lek by using its remarkably mimetic song (see Voice). What hidden aspect of this species' ecology can account for such an anomaly?

Among the thrushes and chats, the female usually lays one egg per day, mainly in the morning, until the clutch is complete, but longer gaps are common in tropical species, with as many as 60 hours passing between the laying of the second and third eggs in the nest of the Cape Robin-chat. Clutch sizes vary with latitude, clutches of 1–3 eggs being laid by many tropical and southern temperate species, the number increasing to 4–7 in northern temperate latitudes. This pattern persists among species having both temperate and tropical ranges. Thus, the Mourning Wheatear has a clutch size of 3–6 in north Africa, but this reduces to 1–3 in Kenya. The Common Stonechat lays 4–6 eggs north of the Sahara, but in tropical Africa it lays 2–5, and in southern Africa, as the climate becomes more seasonal and temperate, the figure increases somewhat again; the mean clutch size in Kenya is 3 eggs, and in southern Africa 3·2. Similarly, the White-starred Robin lays two eggs in areas north of the River Zambezi, but three eggs south of it. Eight eggs appears to be the maximum for the Turdidae within normal limits, and is recorded for the Mountain Bluebird, the White-throated Rock-thrush (*Monticola gularis*) and the Northern Wheatear. Fieldfares have been used experimentally to demonstrate that, above a certain number of eggs, hatching success decreases, probably owing to the inability of the incubating bird to cover and tend the eggs efficiently.

Lower clutch size implies either greater longevity of the species or greater parental investment, or both, since limited resources enforce a trade-off between survival and reproduction. In which

Although the true origins of Catharus *thrushes are Neotropical, certain forms, such as the* ***Veery****, shift northward to breed and only return in the non-breeding season to their ancestral home. By adopting this strategy they make use of the seasonal flush of resources that typifies the temperate zone. Veeries nest near the ground in shady spots, usually in shrubs or low saplings, and often in woodlots or patches of disturbed forest with dense undergrowth. They are declining in North America's increasingly fragmented landscape, where they suffer elevated brood-parasitism and heavy losses to predators.*

[*Catharus fuscescens fuscescens*, New York, USA. Photo: C.H. Greenewalt/ VIREO]

The only African scrub-robin to extend as far north as Europe and Asia is the ***Rufous Scrub-robin****. Small numbers breed in the vineyards, citrus orchards and olive groves of Spain and Portugal, where this photograph was taken. The active nest depicted is placed in a classic location, the crotch of an olive tree* (Olea europaea)*, and contains a slightly below-average brood of three half-grown young. These are dutifully attended by the adults, both of whom, in a manner which can be taken to symbolize the richness of the Iberian summer, have arrived simultaneously with food.*

[*Erythropygia galactotes galactotes*, Portugal. Photo: M.D. England/ Ardea]

of these two areas an individual's best interests lie at a given point in life is strongly related to geography. Tropical species typically show a slower pace of life, in which adults favour their own survival over a faster rate of reproduction, as reflected in their small clutch sizes and high survival rates; for example, annual survival of White-browed Robin-chats and White-chested Alethes in Malawi is 83% and 87%, respectively, compared with 39–67% for various considerably larger European *Turdus* thrushes. Reduced clutch size in the tropics has been explained by the lack of a seasonal boom in food supply, so that parents are limited to rearing smaller broods; but small clutches may really be a strategy to ensure long life, since, if nest-predation risk is high, the parents will do better to spread their breeding investment over a longer period by reducing their seasonal fecundity and prolonging their own lifespan. V. Ferretti and her colleagues tested these alternative hypotheses by comparing food limitation and nest predation in two populations of Rufous-bellied Thrushes in different parts of Argentina, which differed with regard to clutch size. This revealed that food limitation, as reflected by the fact that nestlings grew slowly and commonly starved to death, was actually greater in the population with larger clutches, even when clutch sizes were experimentally equalized, implying that food limitation cannot account for these differences. In contrast, predation rates provided a very good explanation for the observed pattern: the population laying smaller clutches experienced higher rates of nest predation, as well as exhibiting various other aspects of behaviour associated with greater predation, such as lower rates of parental visitation to the nest, and faster nestling growth. A high rate of offspring mortality caused by predation, therefore, probably acts, in combination with long adult life permitted by relatively benign, aseasonal conditions, to make small clutches the most productive strategy in the tropics and southern temperate latitudes.

The difference that the presence or absence of seasonality can make is apparent from the amount of time spent with the fledged offspring by parent Common Stonechats in temperate Europe, as against tropical Africa. The post-fledging dependence period in African pairs, which do not have second broods, is 3–4 months. In Europe, in the case of first broods, it is often merely 3–4 *days*, at least so far as the female is concerned; the female then starts to build another nest for a second brood, although her mate feeds and cares for the newly fledged offspring for a further 5–10 days before leaving them to fend for themselves. Interestingly, while the difference in clutch size between tropical and temperate Common Stonechats has been shown to be genetic, the difference in number of broods per year is environmentally determined.

Ground-nesting species usually have cryptically coloured eggs in brown, grey and olive, open-cup tree-nesting species have bluish to greenish eggs with dark speckling and clouding, cliff-nesters have speckled or plain pale bluish or whitish eggs, and tree-hole nesters have plain white or, more rarely, pale blue eggs. Thus, the more exposed eggs need the more camouflaging colours and patterns, while the more concealed ones need to be visible to the nesting bird for their own security. These differences in egg coloration conform to a wider pattern among birds in general, as do the phenomena of reduced clutch size with season and of reduced clutch size and nestling period with openness of nest position. For example, the Common Redstart has a mean first clutch of 6·24 eggs and a mean second clutch of 5 eggs, and such hole-nesting species, probably owing to lower rates of nest predation, tend to have larger clutches than do open-nesting ones and their chicks tend to stay longer in the nest.

Incubation normally starts only after the full clutch has been completed, although Common Blackbird eggs generally hatch in the order in which they are laid. During egg-laying and before the start of incubation, a female may, particularly in wet weather, cover an incomplete set of eggs and, indeed, commonly roost on the nest, as has been recorded for the Common Redstart. She does not then apply her brood patch to the eggs, which remain cool, although, presumably, the earlier-laid eggs develop very slightly more than do the later-laid ones. The female can, however, make subtle adjustments which more strongly affect the hatching regime, by beginning to incubate before the last egg is laid. This happens with large clutches and late clutches of Common Blackbirds, resulting in greater hatching asynchrony and greater nestling-size hierarchy, the latter being an important cue for optimal parental investment in environmentally constrained circumstances.

In the great majority of cases, it is the female alone that incubates. Deviations from this condition exist, but they generally appear to represent unusual circumstances within particular species, as was the single instance of incubation by a male Cape Robin-chat. Reports of a more constant male participation in in-

*A saxicoline chat with thrush-like proportions, the **Blue Rock-thrush** occupies a wide range from the Mediterranean basin to the eastern archipelagos of Japan and the Philippines. In most regions it is a bird of crags, ravines, quarries and sea cliffs, where it either nests on ledges or in cavities, generally 2–5 m above the ground but sometimes high up on vertical precipices. The nest itself is a shallow structure, loosely constructed of rootlets and twigs, and lined with a few shreds of grass, feathers and downy plant material. After hatching, both parents feed the nestlings a diet of invertebrates, including soft-bodied and tough-shelled varieties, for a period of 15–18 days, after which the brood fledges. In Italy this species is common in craggy limestone hills and coastal regions, making use of castles and churches in rural valleys, as well as tall buildings in certain cities, including Rome. In spreading to these man-made structures and habitats it has adapted to nesting in stone buildings, as depicted so clearly in these photographs.*

[*Monticola solitarius solitarius*; Sonnino, Latina, Italy. Photos: Roberto Ragno]

Like all passerine birds, nestling thrushes and chats produce their droppings in a firm package. They are programmed to excrete these faecal sacs directly after a feed, so that the adult is present to deal with the situation, as demonstrated by this ***Black Redstart****. Genetically speaking, this taxon is very similar to the sympatric Common Redstart* (Phoenicurus phoenicurus)*, but it differs ecologically, avoiding woodland and preferring instead to nest in rocky places, often including buildings; this photograph shows an unusually open site. Hybrid pairs produce fertile offspring, but the two forms are maintained separate by their radically different habitats.*

[*Phoenicurus ochruros gibraltariensis*, France. Photo: Collection J./ PHONE/Bios]

cubation, as with the Blue Whistling-thrush, the Cyprus Wheatear and the Orange Ground-thrush, require fuller investigation and documentation. Often, however, males will feed incubating females on the nest. This is well documented for Townsend's Solitaire, Swainson's Thrush, the Bassian Thrush, the Spotted Forktail and many others. The incubating female Townsend's Solitaire occasionally exhibits "tremble-thrust" behaviour in which she stands in the nest, and thrusts her bill to the bottom of the cup among the eggs, simultaneously shaking her body conspicuously and sometimes flapping her wings. The function of this behaviour, which is also performed by the Eastern Bluebird, is unknown, but it may shake parasitic larvae from the nesting material.

Female Common Redstarts observed by Buxton incubated for about 75% of the day, taking short breaks 2–3 times hourly. Spells of incubation would last for 12–45 minutes, whereas breaks lasted for only 6–16 minutes. This pattern appears to be largely typical for the family, at least in temperate regions. Skutch watched a female Clay-coloured Thrush during one morning and reported her as incubating for 74·4% of the time, with spells of incubation of 34–84 minutes and breaks of 11–28 minutes; another female followed a similar regime, except that it included a stint of 188 minutes of continuous sitting, this on the tenth day after incubation began. During breaks in incubation, a female Common Redstart can very quickly find all the food that she needs. She seldom travels farther than 30–40 m from the nest, often indeed foraging in the canopy or at the foot of the nest tree itself, but she also then takes the time to preen and scratch, to maintain her plumage in optimal condition. The male's role during the incubation period, meanwhile, is to protect his mate and the nest through vigilance against potential predators, and he often acts as an escort and an usher during her breaks from the nest. Nevertheless, the fact that, among Common Redstarts, at least, the male sings better at this time than at any other suggests that he is advertising himself to any other females in the vicinity as a worthy genetic father.

Incubation periods are fairly uniform across turdid taxa, 11–15 days being the general span. The average period for the European Robin is 14 days, for the Song Thrush, the Common Redstart and the Hawaiian population of the White-rumped Shama 13·5 days, for the Common Blackbird, the American Robin, the Cocoa Thrush and the Wood Thrush 13 days, for the White-throated Thrush 12·5 days, and for the Veery and Bicknell's and Hermit Thrushes 12 days. Individual variation can, of course, be considerable. Common Redstarts, for example, have been recorded as incubating for 10·5 days and for 17 days, and the range for Common Blackbirds is 9–18 days. Longer periods can easily be explained by factors such as disturbance and poor weather, which may prevent the female from incubating or from maintaining a relatively high temperature for the eggs. Shorter periods presumably reflect an unusual degree of competence on the part of the incubating female, needing less time off the nest to forage or preen, but are probably also related to very favourable weather conditions. They also feature among hole-nesting species and those with higher rates of nest predation (see below).

Eggs pip and crack in typical avian manner, the hatching process usually taking less than 24 hours. The parent bird, usually the female, removes the eggshells. For the first few hours of life, Common Blackbird nestlings may be fed with saliva by the female. The male may discover the hatching of the young by direct observation, rather than by behavioural cues from the female; a male Common Redstart was seen to hover in front of a nest-hole, turning his head to squint into the darkness. Alternatively, he may find out indirectly, by observing the female carrying eggshells, collecting food, and so on. Sometimes, he may at first be kept from the nest by the female, although she soon requires him to supply food while she broods the chicks. She does this intensively in the first 3–4 days after hatching, but gradually, as the young develop feathers and thermoregulatory capacity, she reduces the amount of time she spends in this activity until, by 8–9 days, she broods only at night or in poor weather. By day 11, shortly before fledging, even nocturnal brooding may be discontinued.

Among the majority of the Turdidae that have been studied, from the Common Blackbird to Swynnerton's Robin, males deliver most of the food consumed by the nestlings, but, as the chicks' need for brooding diminishes, so the female begins to contribute more in this regard. The male often continues to be the major provider, as he visits with food both when the female is

*Having collected the extruded faecal material from one of its nestlings, this male **Blue Rock-thrush** is carrying it hastily away. He will drop it some distance off, where it cannot foul the nest cavity. For breeding birds the advantage of hygiene begins with disease control, but it does not end there. Cascades of bright white droppings and stinking guano may not be costly for breeding raptors and seabirds, but for a thrush they spell disaster. Predators hunting by sight or smell, such as the rats likely to be lurking in this Spanish barn, would hardly miss an insalubrious nest, nor skip an easy meal.*

[*Monticola solitarius solitarius*, Huesca, Spain. Photo: Ricardo Vila]

present and when she is absent, in the latter case feeding the young directly. When his mate is at the nest, he passes the food to her and she either distributes it to the young or eats it herself. Unsurprisingly, feeding rates increase as the nestlings grow bigger. Feeding rates of Swynnerton's Robin increase from 57 nest visits in the first three days of the nestling period to 135 visits in the last three days. The Cape Robin-chat makes six visits per hour per chick for the first 4–5 days, the number then rising to eight visits per hour per chick, with most visits in the early morning and late afternoon and fewest at midday. Feeding rates probably vary with quality, quantity and accessibility of food. In observations of Common Redstarts, food-delivery rates were highest around sunrise in one study and highest around noon in another, suggesting different activity patterns by the insect prey species. In terms of prey quality, caterpillars, being large, protein-rich, soft-bodied and easy to capture, are probably optimal; in contrast, flies, for example, are both smaller-bodied and harder-bodied, and are energetically costlier to obtain. Growth rates of chicks could be affected by the quality of the food brought to them and its required handling time, and by the predation risk that they incur (see below).

Loss of or desertion by one of the parents at the nestling stage places considerable stress on the remaining adult. A male Pied Bushchat in this situation managed to rear two of three nestlings to fledging, but it took him 18 days, rather than the normal 13–15 days. Eastern Bluebird females whose mates were experimentally removed also coped, but overall they had lower nesting success than did neighbouring pairs, and early in the season they were unable to provide sufficient food to raise any young to fledging. One of the most notable work rates on record is that of a female Common Redstart who was compelled to feed her chicks without the male's help; on day 13 after hatching, she provisioned her brood 419 times in 16·5 hours, equivalent to feeding each chick 70 times in the day. The evidence suggests that, although there may be some "heroic" achievements by single parents, in general both parents are needed in order to maximize reproductive output; mate desertion in favour of another partner at the nestling stage is, at any rate, virtually unknown in this family.

Studies have revealed that, each year, some 10% of Eastern Bluebirds die in the nest-hole as a result of starvation, exposure or abandonment. In the United Sates, prolonged, unseasonal cold rain in South Carolina on 9th May 1992 caused 100% loss of all nestlings more than one week old; the females were apparently unable to keep them warm enough or well fed, but younger chicks survived.

On hatching, the chicks are blind and virtually naked, with very sparse pale down in the usual passerine areas. Although their powers of movement are extremely limited, they can, of course, vocalize, with a thin begging call, and gape widely to receive food. Nestlings of *Turdus* species in tropical regions have less down than do those in temperate ones, presumably in response to elevated all-day temperatures. By days 4–5 the nestlings begin to open their eyes, although generally they do not keep the eyes open until about the seventh day and in some cases the eyes may remain closed until the ninth day. It is at around days 4–5 that the chicks begin to respond, by begging and gaping, to the sound of an approaching parent. American Robin nestlings have been found to compete for position in the nest according to their degree of food stress and the predictability with which a parent will perch on one sector of the nest rim, and some such behaviour doubtless applies to all Turdidae and, indeed, to most avian species. At around days 5–6 the primaries begin to emerge, followed some

two days later by the crown feathers and rectrices. By the eleventh day the nestlings are largely covered by feathers and ready shortly to fledge, but the yellow gape-flanges at the commissure are still very obvious. Weight gain by Whinchat nestlings, which weigh 2 g on hatching, is approximately 40% in each of the first five days, with a maximum recorded gain of 3·2 g on day 5, falling thereafter to 5–15% per day and reaching a fledging mass of 17–19·5 g. Although growth can be retarded by lower levels of food provision, it cannot be accelerated by overfeeding, as has been demonstrated for the Song Thrush. This is because the physiological and anatomical constraints are too great. Nevertheless, heavy nestlings of the Common Blackbird are more likely to survive to adulthood than are lightweight ones.

Fledging is semantically problematic, at least in the case of cup-nesting species. Typically, it means the developing of sufficient feathers to be able to fly, and for altricial birds it is, generally, coincident with departure from the nest. The young of cup-nesting thrushes and chats, however, often leave the nest before their flight capacity is adequately developed. Each spring, the suburban backyards of Europe are filled with the wheezy squawks of "semi-fledged" Common Blackbirds, stranded in the flowerbeds at the mercy of the neighbourhood cats. The Seychelles Magpie-robin almost became extinct on Frégate owing to this phenomenon. In these contexts, the behaviour appears remarkably maladaptive, but it clearly evolved as a means of reducing the risk of predation that every nest, and in particular every open nest, runs. Nestlings of certain species of scrub-robin have been reported as clambering around in the vegetation next to the nest before they are fully ready to leave its shelter, and the Red-backed Scrub-robin, apparently in response to unusually high rates of nest predation, has a nestling period of 11–12 days, notably shorter than that of its congeners, such as the 14–15 days of the Brown-backed Scrub-robin; moreover, its newly fledged youngsters are agile fliers at this stage, when the older Brown-backed are still incapable of sustained flight. Across passerine species in general, growth rates tend to be faster and nestling periods shorter among species which suffer heavier predation rates. For example, Veery chicks, with a 55% predation rate and an 11-day nestling period, grow considerably more rapidly than do those of the congeneric and similarly sized Swainson's Thrush, which incur only 35% loss and have a nestling period of 13 days. Similarly, the nestling period of the Eastern Bluebird, in which an average 49% of nests are predated, is some 3·5 days shorter than that of the slightly larger Western Bluebird, which suffers only 30% predation. Young bluebirds that leave the nest before they can fly are capable of climbing up trees, and this ability survives into adulthood and is employed by adults grounded and sodden by rain.

For many species, the act of leaving the nest is asynchronous. In the case of the Common Redstart, two days may pass between the exit of the first chick and that of the last. In these situations, one parent attends to the young in the nest, and the other tends those outside it. Brood division is probably widespread in the family, but its prevalence depends on local circumstance. It has been documented in detail for the Bluethroat, the Common Blackbird and the Wood Thrush and recorded for many other species, and this spatial dispersion of the young probably reduces both predation risks and foraging costs. The post-fledging dependence period in the Turdidae is highly variable, being influenced partly by latitude, as noted above for the Common Stonechat, and partly by the number of broods reared in a season, but in the great majority of cases it lasts between ten and 25 days. When a subsequent brood is initiated, the female may relatively rapidly abandon her existing offspring to the care of her mate while she builds a new nest. This can often occur less than a week after the young have left the nest, so that they are still far from competent and only just beginning to forage for themselves. The onus on the male to tend the offspring commonly lasts for a further three weeks while the female builds a new nest, lays a fresh clutch and incubates the eggs until hatching. Sometimes, however, the female will save time and reuse the previous nest, and the female White-crowned Wheatear may make a second nest and begin laying even while the first brood is still in the nest.

Juvenile Eastern Bluebirds acquire 50% of adult foraging efficiency after two weeks. Thus, whereas adults have a 67% success rate in taking terrestrial arthropods, two-week-old fledglings manage only 32%. In the following week, while they are still dependent, this efficiency presumably rises to a secure level.

Predation is the major cause of nest failure among thrushes and chats, as it is for most, if not all, passerines. One study of the Common Blackbird, for example, revealed a nest-predation rate of 5% per day at the egg stage. There are many types of nest

*The brood of this **Mistle Thrush** is approaching fledging time. "Fledging" refers to the completed growth of the feathers, but in practical terms the common way of measuring it is through the bird's first flight out of its nest. However, just to complicate the equation further, young turdids habitually leave the nest a few days before they can fly. They scatter in different directions, flopping about with useless wings and begging loudly from dense undergrowth. In so doing they seem to make themselves highly vulnerable to predation, but early fledging must have its adaptive merits. It is perhaps most easily understood as a hedging of bets, as predators will usually find one "squab" at a time, rather than a whole nestful at once.*

[*Turdus viscivorus viscivorus*, Calzada de Oropesa, Toledo, Spain. Photo: Jorge Sierra]

*After its progeny abandon the nest, this adult **Russet-tailed Thrush** will probably take responsibility for one fledgling, while its partner will feed the other. This phenomenon is termed "brood division", a partitioning of responsibilities that is common in thrushes and chats. Thus provisioned, the two fledglings will probably remain dependent for between 10 and 25 days, but the exact duration of this period varies with latitude (being much longer in the tropics) and parental intentions (being truncated if another nesting attempt begins).*

[*Zoothera heinei heinei*, Lamington National Park, Queensland, Australia. Photo: Roger Brown/ Auscape]

predator. Corvids such as crows and magpies are among the most familiar and problematic in many parts of the western world, particularly in suburban areas, but snakes and such mammals as racoons (*Procyon*) are far more important in some habitats, including forests. Large terrestrial snakes, such as Cape cobras (*Naja nivea*), are able to descend the often lengthy entrance tunnels of Southern Anteater-chats and other burrow-nesting chats, and cause heavy losses. Seemingly innocuous and endearing squirrels and chipmunks can also be particularly damaging. In the USA the southern flying squirrel (*Glaucomys volans*) is a major predator of Wood Thrush nests, and in parts of Europe Common Blackbirds suffer losses largely to the red squirrel (*Sciurus vulgaris*). Townsend's Solitaire nests, which are placed on the ground, are hit mainly by squirrels and skunks (Mephitidae), and the appearance of a rodent within 30 m of the nest elicits vigorous "wing-stretch displays" and "floppy flight displays" which commonly result in the potential predator's retreat. African chats can be particularly aggressive and fearless towards potential nest and nestling predators, including snakes, and the Familiar Chat is among the few turdids to be recorded as performing distraction displays. Nothing, however, is likely to deter the black bear (*Ursus americanus*) from its depredations of Wood Thrush nests and even Eastern Bluebird nestboxes. At the other end of the scale are seemingly random acts of destruction performed by other small birds, most notably the Northern House Wren, which punctures or removes eggs in Eastern Bluebird nests in such quantity as to account for, in one study, a third of all nest failures.

Researchers monitoring nests need to exercise great care, as some predators can use the smallest cues to detect a nest. In one study of White-starred Robins, the success rate of eleven pairs whose nests were inspected by a careful researcher was still significantly lower, at 18%, than that of 32 pairs with unchecked nests, which had a success rate as high as 78%. There is also the phenomenon of "meso-predator release" to contend with. Thus, in South Africa, nest predation by monkeys has been judged an important factor in the demise of the globally threatened Spotted Ground-thrush in the fragmented coastal forests, where monkey populations are thought to have increased following a reduction in the density of Crowned Hawk-eagles (*Stephanoaetus coronatus*), the primate's principal predator.

In recent years, biologists studying various northern thrushes have detected a phenomenon by which elevated levels of nest predation result from population peaks in certain rodents. Bicknell's Thrush suffers higher nest predation in years when cone crops of conifers are high, which generally occurs every other year, since the density of squirrels increases in such years; in low crop years, the species' breeding success is considerably higher. Similarly, Veeries experience very poor breeding success in acorn mast years, when rodent populations burgeon, since the rodents prey on nests while their predators, the raptors, also kill adults and juveniles. On the other hand, populations of Common Redstarts in northern Finland fluctuate negatively with the vole (Microtinae) cycle, because small-mammal predators switch to taking birds when vole numbers are low. Likewise, in Bialowieza

*As might be expected in a family for which premature fledging is the norm, young juvenile turdids have powerful begging and distress calls. In general, their plumage is also distinctly speckled, providing camouflage when they are at their most naïve and vulnerable. Some, including the **Eastern Bluebird**, can even clamber to safety up tall trees well before they can fly. Having benefited from these traits, this fledgling appears to be well on its way to independence, representing a successful contribution to the gene pool for the provisioning male, if indeed he is the father; around 20% of this species' chicks are produced by extra-pair copulations.*

[*Sialia sialis sialis*, Hamden, Connecticut, USA. Photo: Jim Zipp/Ardea]

Thrushes and chats that build open cup-shaped nests are often heavily persecuted by brood parasites. Having evicted the rightful occupants, this juvenile Red-chested Cuckoo (Cuculus solitarius) *is swaddled in the nest of a* ***Cape Robin-chat****, where it will receive the undivided attention of both adults. This type of parasitism results in substantial reproductive effort by the nest-builders, coupled with a complete elimination of reproductive success, a twin cost so severe that many turdids have learnt to be very choosy about odd-looking eggs. It possibly also explains the repeated evolution of cavity-nesting in the family.*

[*Cossypha caffra caffra*, Somerset West, Western Cape, South Africa. Photo: J.J. Brooks/ Photo Access]

Forest, in Poland, predators kill four times more nestling Common Blackbirds in years when rodent numbers are low than in a year when they are high, and in a year with high caterpillar numbers smaller predators left more eggs of this species untouched. In a remarkably complex circumstance, colonial-nesting Fieldfares in Sweden were found to suffer lower rates of nest predation than were those that nested singly, probably owing to the collective raptor-mobbing ability of the species, but colonial nesters depleted the local food resources more rapidly than did solitary pairs, leading to more nestling starvation. Futhermore, colony size of Fieldfares is affected by mortality of adults, which suffer higher predation from Tawny Owls (*Strix aluco*) in more conspicuous, larger colonies. Hence, in northern Sweden, where Tawny Owls are absent and 24-hour daylight during the breeding season allows better nest defence, average colony sizes are larger than those in southern Sweden. In a Norwegian study, however, although the risk of avian predation was confirmed as a reason for colonial nesting, the factor driving solitary nesting was nest predation by mustelids following the crash of rodent populations.

The unique mobbing behaviour of Fieldfares involves the use of directional defecation. The birds fly up to, or behind, a potential predator in a rapid attacking movement, but then brake and swerve upwards, letting loose a stream of sticky faeces that hits the predator. The effect of several such attacks can be devastating, since the faeces clog the feathers of a raptor or crow and render flight difficult or even impossible for it. The use of this technique is equally strong against flying or perched birds, but it is ineffective against mammalian predators.

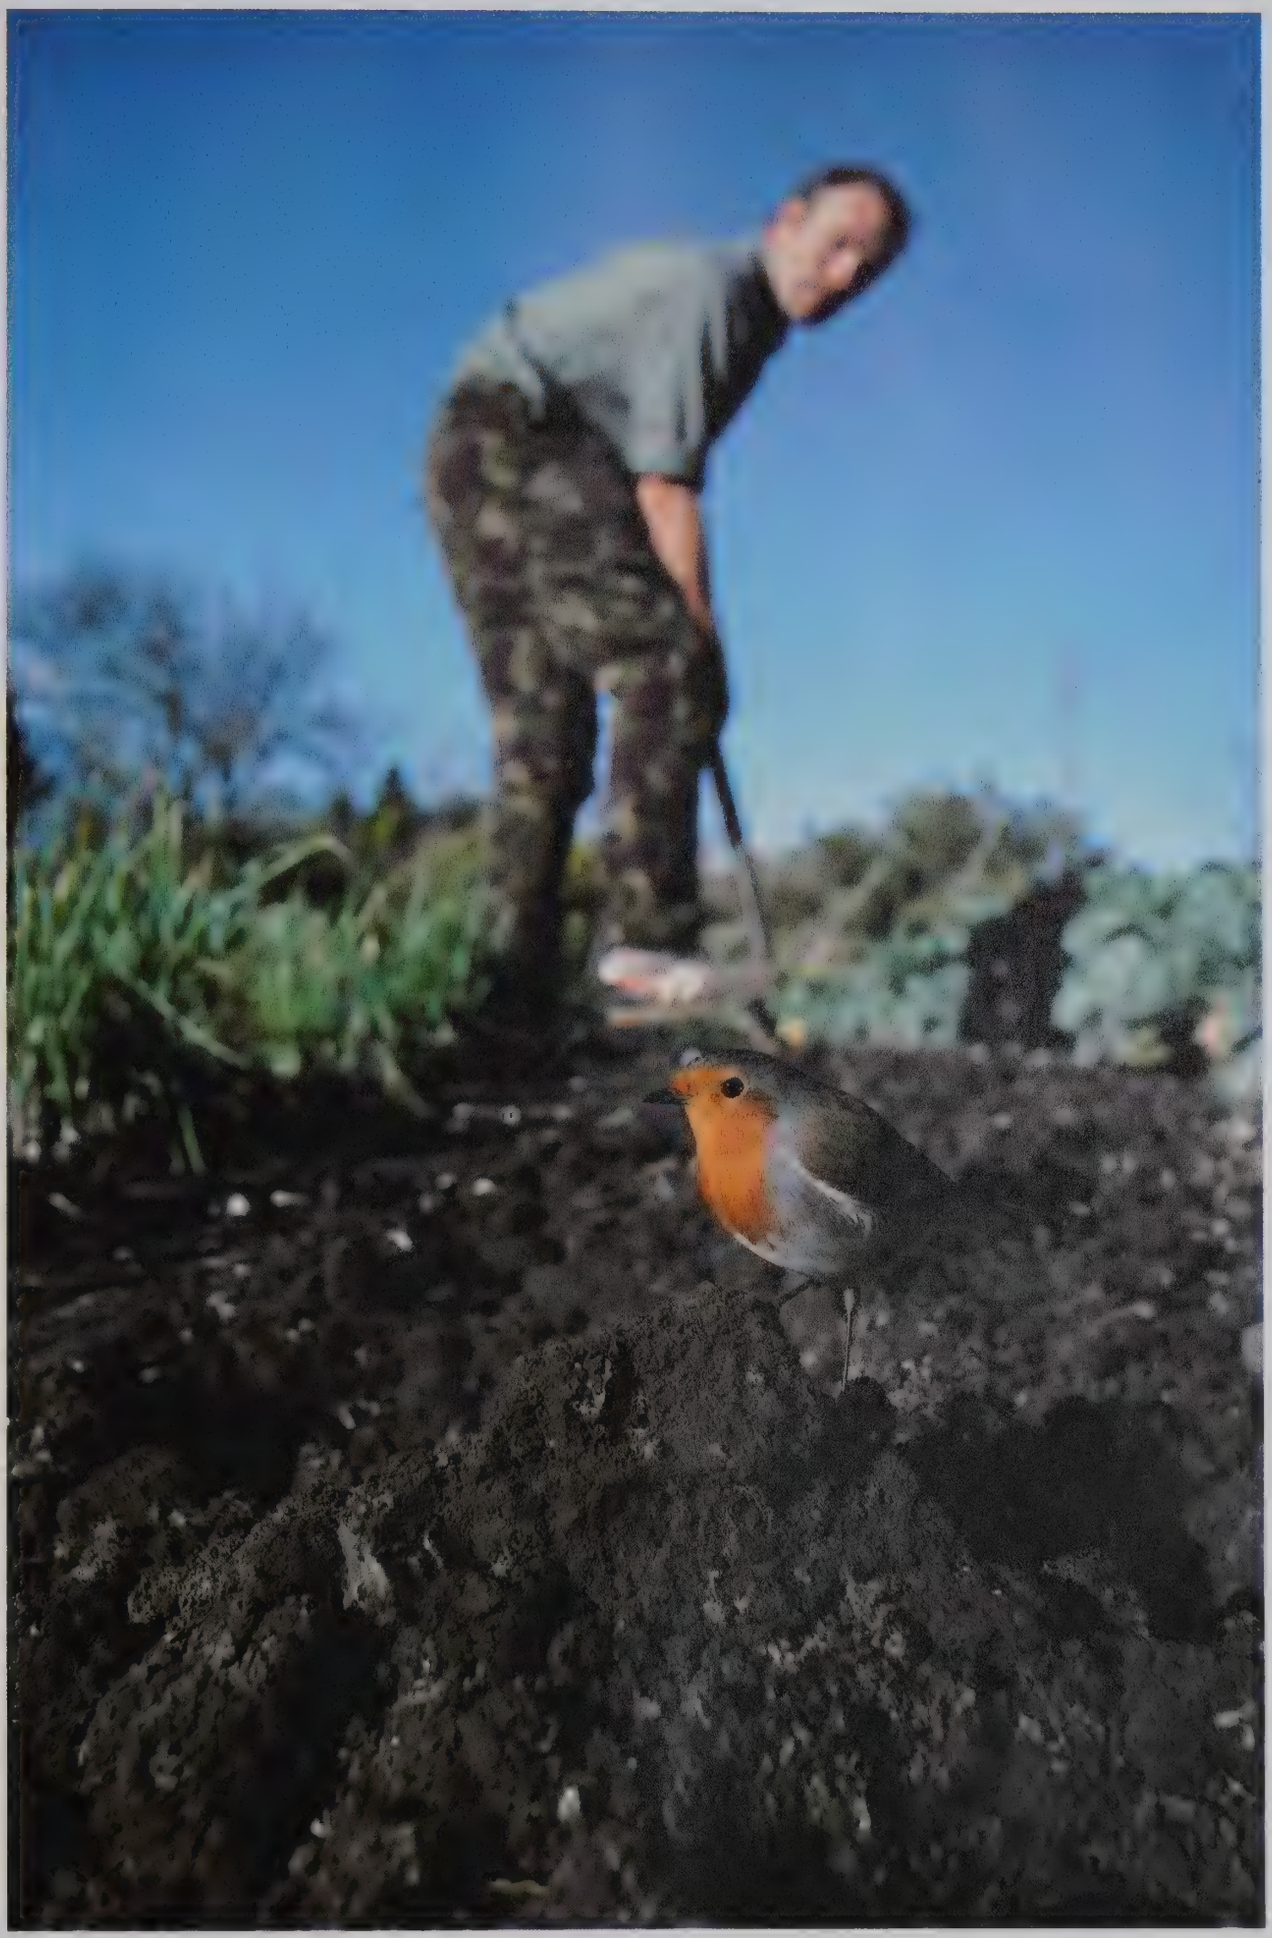
Curiously enough, however, another trick of the Fieldfare is to focus its colonies around an avian predator such as a Merlin (*Falco columbarius*), as raptors tend not to hunt close to their own nests but do, on the other hand, display levels of aggression towards potential predators that serve as an "umbrella" for the thrushes. Individual pairs of Groundscraper Thrushes in Africa do the same thing: they nest close to pairs of Fork-tailed Drongos (*Dicrurus adsimilis*), which are notoriously intolerant of potential nest predators.

Brood parasitism is another danger to nesting birds. In the New World, the parasites are various species of cowbird (*Molothrus*), and in certain parts of North America where fragmentation of habitats is extreme, and cowbird densities high, the impact of brood parasitism on *Catharus* thrushes has been a cause for concern, particularly with the Veery (see Status and Conservation). In the Old World, various species of cuckoo take their toll. The Orange Ground-thrush is occasionally parasitized by the Jacobin Cuckoo (*Clamator jacobinus*), the Lesser Shortwing and Blue Whistling-thrush by the Large Hawk-cuckoo (*Cuculus sparverioides*), the White-browed Shortwing by the Asian Lesser Cuckoo (*Cuculus poliocephalus*), the Siberian Blue Robin by Hodgson's Hawk-cuckoo (*Cuculus fugax*), and the White-throated Rock-thrush, White-tailed Rubythroat, various *Phoenicurus* redstarts, the Plumbeous Water-redstart, various *Saxicola* bushchats, the Northern Wheatear and the Spotted Forktail by the Common Cuckoo. Similarly, the White-starred Robin, Bearded Scrub-robin, Kurrichane Thrush (*Turdus libonyanus*), Cape Rock-thrush, Common Stonechat and various *Cossypha* robin-chats are parasitized by the Red-chested Cuckoo (*Cuculus solitarius*), the White-starred Robin once also by the African Emerald Cuckoo (*Chrysococcyx cupreus*), and the Kalahari and Karoo Scrub-robins are victimized by the Diederik Cuckoo (*Chrysococcyx caprius*), the Forest Robin (*Stiphrornis erythrothorax*) probably by the Dusky Long-tailed Cuckoo (*Cercococcyx mechowi*), Sharpe's Akalat by the Barred Long-tailed Cuckoo (*Cercococcyx montanus*), and the Chestnut-naped Forktail by the Brush Cuckoo.

The Red-chested Cuckoo's parasitism of *Cossypha* has long been a source of bafflement, as its egg is non-mimetic. It turns out, however, that this cuckoo's egg closely resembles those of the Cape Robin-chat in the ultraviolet part of the spectrum, invisible to human eyes but not to the eyes of the birds.

Conspecific brood parasitism, although very poorly documented, probably occurs widely among Fieldfares and Redwings. In one study, 11·5% of Fieldfare nests held an egg laid by a female other than the resident. There is even a documented case of a Fieldfare laying an egg in a Redwing nest. Redwings reject unfamiliar eggs, and in experiments they attacked a stuffed conspecific more strongly than they attacked a stuffed Common Cuckoo, strongly suggesting that this thrush has a major undetected parasitic habit. The phenomenon is, however, well documented for Eastern Bluebirds, and there is one recent record for

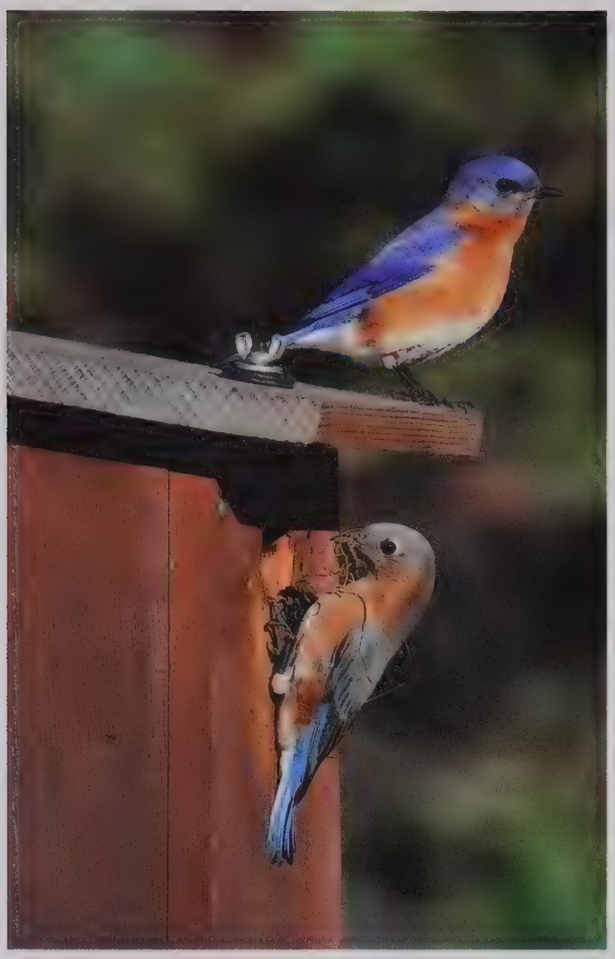
Less conspicuous than the parasitism of cuckoos is that of cowbirds. This photograph of a ***Wood Thrush*** *at its nest might appear to depict an ordinary domestic moment for this beautiful bird, until the taller stance, redder mouth and prematurely open eyes of one of its chicks is noticed. This little impostor is a Brown-headed Cowbird* (Molothrus ater), *a parasite that spares the brood but often reduces breeding success. Habitat fragmentation and pastoral farming in parts of North America have benefited cowbird populations, and in some cases the incidence of parasitism in nests of* Catharus *and* Hylocichla *thrushes is extraordinarily high.*



[*Hylocichla mustelina*, SW Ohio, USA. Photo: Dave Maslowski/ Maslowski Productions]

the Song Thrush. It may well be that this behaviour is much commoner than has been thought.

Co-operative breeding, in which nestlings are cared for by additional helpers at the nest, is relatively scarce among the Turdidae. It occurs regularly in 6% of the 194 thrush species for which the breeding system is reasonably well known, as against an 18·5% incidence among all biparental oscine passerines. Among the thrushes, this behaviour is found across the taxonomic spectrum, implying its repeated independent evolution in different lineages. One or two species in each of the genera *Sialia*, *Myadestes*, *Catharus*, *Copsychus*, *Saxicola*, *Oenanthe*, *Myrmecocichla* and *Erythropygia* are known to be regularly co-operative, as are those in the monotypic genera *Campicoloides* and *Psophocichla*. There are also occasional records of helping at the nest for species in the genera *Erithacus*, *Pentholaea*, *Sheppardia*, *Phoenicurus* and *Monticola*, as well as for additional species of *Saxicola*, *Oenanthe* and *Sialia*. For example, Black Redstarts exhibit co-operative breeding in Sweden, where the conditions of a strongly male-biased sex ratio and poor-quality habitats, with resident males offering few challenges to the helpers, are judged to be classic for this behaviour to arise. For most thrushes, especially tropical ones, however, the patterns of parental care are poorly known, and those species for which occasional co-operative breeding has been recorded have tended to be well-studied northern-temperate ones. Helping at the nest, therefore, probably occurs occasionally or even regularly among many more species, especially in the lesser-known tropics.



Helping, which in the Turdidae almost always involves only male individuals, is commonly explained through kin selection, whereby helpers are relatives of the breeding pair and therefore, if they are failed breeders, or are unable to breed owing to a shortage of suitable territories or mates, they gain indirect genetic benefits by helping to produce kin. Another benefit, however, especially in cases when helpers are non-relatives, may be potential paternity through sexual access to the breeding female. Only a small percentage of Western Bluebird nests have helpers, which are invariably male and which shoulder a varying proportion of the burden of raising the young. Kin selection predicts that helpers invest most effort in brood-feeding when assisting both of their parents, rather than one parent with a new mate, a "step-parent". J. Dickinson's long-term data from numerous Western Bluebird families demonstrate, however, that this is not the case: helpers feed young equally often, irrespective of the presence of a step-parent. Moreover, since the incidence of extra-pair paternity is about 20% in this species, a helper is more likely to be biologically related to the subsequent offspring of his mother and a stepfather than to those of his apparent father and a stepmother, and natural selection should hence favour helping in the feeding of maternal half-siblings more than in that of apparent paternal half-siblings. There is some indication, but as yet statistically inconclusive, that this is the case. A third prediction is that, in cases where the helper and the breeding female are unrelated, the helper should put most effort into raising a brood of young in which he might have a share of paternity, something which, owing to dominance, would be possible only when the breeding male is his brother, rather than his father. Sure enough, Western Bluebird helpers feed young more often when they have such a chance of siring nestlings, suggesting that helpers also use copulatory access in order to assess how much effort to invest in helping.

Fidelity to breeding site among adult turdids is often high, as already intimated with respect to older males reoccupying their previous year's territories (see also General Habits), which allows them to pair earlier and breed earlier, and hence to produce better-quality offspring. Varied Thrushes are so site-faithful that the nest of the current year is often surrounded by old nests and is sometimes simply placed on top of an old one, and so strong is the phenomenon in Wood Thrushes that their return rate allows a reasonable estimate of the species' annual survival. Fidelity to the natal site can also be high, although it is invariably more marked in male yearlings than in female yearlings. On the Hiddensee, in Germany, an interesting phenomenon has been noted in which, over several years, nesting Northern Wheatears moved closer and closer to their natal site. Thus, in one year 26 males settled within 1012 m of the natal site and 22 females within 628 m of it, and in the following year the distance from the natal site decreased by 41% in the case of eight males and by 22% in that of seven females. On the other hand, some species show little specific philopatry. In one study, only 14 of a total of 142 Veeries returned as breeders to the natal site, and, in another, only 2% of Townsend's Solitaires ringed in years 1–3 reappeared in the natal area in years 2–4. The definition of philopatry, how-

Left unmolested, thrushes have a propensity for extreme tameness. This trait is most noticeable in insular species which have evolved in the absence of predators, but it reappears wherever a benign public attitude to suburban wildlife prevails. One of the most famous example is the ***European Robin****, which in some regions has lost all fear of man. In Britain, it is exceedingly familiar and much loved (indeed, it is the national bird), in part because it is so tame. It can readily be trained to feed from the hand and it has a disarming habit of hunting invertebrates in freshly dug soil. In so doing, it perches on clods of earth, or on the handles of unattended spades, often little more than a metre from the human gardeners with whom it shares its territory. The robin's trusting nature, coupled with its beady-eyed look of cheeky intelligence, not to mention the bitter-sweet heart-rending melancholy of its winter song, endears it to people to such an extent that it has long been a cultural icon. It is wreathed in a history of folklore and superstition, which today is manifest most conspicuously in its close association with Christmas, and its appearance on seasonal greetings cards all over Europe. It seems useful to note that its tameness is not an intrinsic behavioural trait, but rather a response to the habits of man. Human behaviour is less benign a few hundred miles further south, where thrushes are still considered a delicacy and trapped for food in great numbers. Not surprisingly, robins and their relatives are shy and retiring birds in southern France, Italy, and throughout much of the Mediterranean basin.*

[*Erithacus rubecula melophilus*, Ringwood, Hampshire, England. Photo: Mike Read]

The much-publicized decline of America's cavity-nesting avifauna in the face of competition for nest-sites with House Sparrows (Passer domesticus) *and Common Starlings* (Sturnus vulgaris) *galvanized public opinion against those alien bullies, and in favour of direct action to save native species, especially the* ***Eastern Bluebird****. Local nestbox "trails" and programmes proliferated and proved immensely successful, not only in nurturing a resurgent bluebird population but in kindling a great deal of interest and pleasure in the general public.*

[*Sialia sialis sialis*, SW Ohio, USA. Photo: Dave Maslowski/ Maslowski Productions]

ever, depends on an agreed measure of distance. While adult American Robins tend to return to the same breeding sites, despite their winter nomadism, 70% of yearlings are estimated to breed within 40 km of their natal sites. Does this represent philopatry or dispersal?

Adult birds have higher breeding success than that of yearlings. This "age-related reproductive asymmetry" has been measured for several species. With Common Blackbirds, clutch-initiation date, breeding-season length and clutch size vary with age. First-year females start nesting on the latest dates, have the shortest breeding seasons, and lay the smallest clutches. Clutch-initiation dates are earliest at the age of 3·7 years and breeding-season length peaks at 3·6 years of age, but clutch size continues to increase gradually as the age of the individual progresses from one year to six years. Similarly, a recent study of Bluethroats found that young breeders were less likely to fledge young than were older ones, and the presence of a yearling in a pair strongly decreased the number of young produced per breeding season. With older males, higher success was related to the brood-provisioning rate during the first nestling period. For females, the laying date and the reproductive investment, in terms of clutch size, provisioning rate in the nestling period and brood condition, were the main determinants. Older Rufous Scrub-robins produce more and heavier fledglings than do yearlings, and adult Wood Thrushes, those past their first year, breed at higher rates than do yearling birds. All of these findings suggest that behavioural and physiological maturation is needed for young breeders to enhance their reproductive performance. They also provide a further reason why young females might seek older males to provide paternity for their offspring. Sexual maturity in thrushes is not certainly known to be reached before nine months, some northerly species hatching in August and breeding in May, but a Black-billed Thrush in Colombia, which had fully functional testes but a skull "more than half immature" in March, was probably less than nine months old and probably, therefore, some considerable period away from maturity.

Nest failure almost always results in a change of nest-site and fairly commonly in divorce. Just as the female bluebird is attracted to the nest-site, rather than to the site-holder, so the real divorce when nests fail is from the nest-site; sometimes the pair-members may stay together, so long as they both move away from the territory in which they failed. In years of frequent failure, notably when storms are responsible, a territory-holder has been observed to make as many as three nesting attempts with three different partners in the same season. In the case of Rufous Scrub-robins, divorce appears to be related to nest predation, which itself may reflect weak male contribution to nest defence. Among Common Blackbirds in Germany, the mean divorce rate, involving pair separation and the remating of at least one partner, was 19·3% between two breeding seasons and 5·1% within single seasons. The number of fledglings produced per season by partners which subsequently divorced was significantly lower than that of pair-members which stayed together. Females, but

The ***Red-throated Alethe*** *is a restricted-range species confined to the Albertine Rift Mountains Endemic Bird Area. Despite its limited extent of occurrence from Uganda to the Democratic Republic of Congo it is generally common in the undergrowth of montane forest and bamboo at high altitude, and therefore not thought to be in any danger of extinction. This is one of four species removed from* Alethe *because they were found to represent an entirely separate lineage. For the time being the English name "Alethe" is retained, but a more appropriate alternative may emerge.*

[*Pseudalethe poliophrys poliophrys*, Nyungwe Forest Reserve, Rwanda. Photo: Ariadne Van Zandbergen/FLPA]

not males, produced more fledglings in the season after divorce than they did with their former mates in the preceding year, and they successfully reared as many young as did females of the same age in stable pair-bonds. Divorce appears, therefore, to be female-driven. In England, divorce rates among Common Blackbirds were greatest in low-quality sites, and altogether involved 32% of 183 cases in which mates had survived from the previous year. After divorce, females tended to nest farther from their original site than did males, but, unlike the situation in Germany, breeding in a new site cost an average of one fledgling per year.

Breeding success is, of course, determined by important environmental variables beyond such factors as the quality of the territory or of the individual pair-members. For example, breeding success of the Common Blackbird corresponds well with the amount of rainfall in the period preceding egg-laying. Swainson's Thrush populations, at least those in America's West Coast riparian habitat, are strongly influenced by their own breeding productivity: there is a significant correlation between adult abundance in any given year and the number of young produced in the previous year, so that there may be density-dependent control of the overall population size. In Kenya, the presence of Fiscal Shrikes (*Lanius collaris*) in Common Stonechat territories appears to have a major depressive influence on the chats' breeding success, simply by stressing the adults through the threat of predation, not through active predation itself. Correlates of breeding performance can also be used. Thus, for Black Wheatears, the number of breeding attempts and the proportion of chicks resulting in fledged young, excluding broods that are preyed on, are the best predictors of seasonal reproductive success. Likewise, the number of young Wood Thrushes that hatch is the most important variable that positively influences the species' seasonal fledging success.

Juvenile Wood Thrushes move out of the natal area at 24–32 days of age. Juvenile dispersal from the territory may not, however, be driven entirely, or possibly even at all, by parental disownment. In one study, survival of juvenile Wood Thrushes was relatively high in the first two weeks after fledging and very high in weeks 4–8, but it was relatively low in the third week, which may well correspond with the first days of independence, when the youngsters probably linger in the interstices between territories before making a more decisive, longer-distance movement to better cover. In the case of Eastern Bluebirds, first-year birds suffer the highest mortality in October, probably because this is the month of dispersal, when they are first exposed to entirely new landscapes and contexts. The next highest mortality occurs in December, presumably as a result of severe weather, and the third highest is in March, just before breeding, perhaps as a result of the stressful events related to migration and to territory and mate acquisition.

Movements

In the Turdidae as currently constituted, full migratory behaviour is recorded for all or some populations of 73 species, or just 22% of all members of the family, while entirely sedentary behaviour is known for 134 species, or 40% of the family. This leaves 129 species, 38%, which make some sort of short-distance, usually elevational, movement in all or part of their ranges. It should be stressed that these calculations are made on often rather flimsy evidence or presumption, and discount cases in which movements have only been speculated, without good support; and that all of these figures may be subject to revision.

Thus, only one-fifth of thrush species are fully migratory, but three-fifths exhibit migratory behaviour of some sort, many of them doubtless being facultative, irruptive migrants in response to hard-weather conditions. It is perhaps reasonable to speculate that even the sedentary species, which are predictably mainly tropical in distribution, very probably for the most part undertake partial and/or very minor but as yet undetected movements in response to rains or drought or to local population build-ups. Indeed, their sedentariness is usually merely an assumption based on the absence of evidence of any movement. An intriguing instance of an apparently sedentary bird being suspected of having at least a semi-migratory habit, although this idea has not found universal favour, is presented by the record of a Blue-shouldered Robin-chat in Gabon imitating the song of a Common Nightingale, when the latter is unknown in the country.

The migration systems can be crudely grouped into eight as follows: Nearctic–Nearctic; Nearctic–Neotropical; Palearctic–Palearctic; Palearctic–Afrotropical; Palearctic–Oriental; and intratropical and/or vertical within each of the three tropical regions. Major migrations are undertaken by many of the most northerly Holarctic-breeding thrushes and chats, but there can be considerable variations within species, depending on latitude, severity of winter and other factors. Some movements involve simply a shift into the most southerly regions of the Holarctic, others take birds into the subtropical zone, and still others, but proportionately the fewest, result in occupation of the true tropics. In addition, of course, there are "leap-frog" movements, as demonstrated by the

The area of land in the Japanese Ryukyu archipelago inhabited by the ***Ryukyu Robin*** *is so small that it is classified as a restricted-range species. Fortunately, it is not thought to be threatened as its population is not only relatively large, at around 100,000 individuals, but also stable. In posture and pattern this beautiful bird recalls the European Robin* (Erithacus rubecula), *even as far as hopping about perkily and wing-flicking on roads at dawn. On biogeographical, behavioural and vocal grounds, however, it seems more likely to belong with the east Asian* Luscinia *radiation, into which it is here subsumed.*

[*Luscinia komadori namiyei*, Okinawa, Ryukyu Islands, Japan. Photo: Hirozo Maki]

*The **Chestnut-naped Forktail** occurs in the vicinity of small streams in humid lowland forests, from south Myanmar to Sumatra and Borneo, and thus its overall population must have declined substantially as a result of the catastrophic rates of forest loss in the Sundaic region. In many parts of its range it also occurs in the foothill zone, where habitat is slightly more secure, and for this reason it is treated as Near-threatened rather than threatened. It is one of the most forest-based of all forktails, and, like many of its relatives, rather shy, often revealing nothing more than a sharp distinctive call note and a streak of white flashing upstream through the gloomy understorey.*

[*Enicurus ruficapillus*, Hala Bala, Thailand. Photo: Morten Strange]

Song Thrush, in which northerly populations overfly and winter south of intermediate ones.

Owing almost certainly to their ability to exploit different types of food and their use of secondary, semi-open habitats, the great majority of migratory Old World thrushes and chats find their needs north of or in the northern subtropical regions stretching from West Africa eastwards, north and south of the Sahara, through East Africa, across the Indian Subcontinent and into Indochina and southern China. In the Americas, something of the same phenomenon applies, with species such as the bluebirds, Townsend's Solitaire, the Hermit Thrush, the Varied Thrush and the American Robin generally not shifting south into the tropical belt, and the majority of their wintering populations remaining within the USA.

Recent molecular studies, however, suggest that *Catharus* thrushes arose in the Neotropics (see Systematics), and that the colonization of North America has proceeded through seasonal emigration, with only the Hermit Thrush detaching itself, as it were, from its roots. Certainly, the Veery, the Grey-cheeked and Swainson's Thrushes, the Wood Thrush (albeit currently treated in *Hylocichla*) and, to a lesser extent, Bicknell's Thrush form the largest group of turdid species which migrate to the equatorial tropics, and this view of their origins strengthens the assessment that they are ecologically integral to the Neotropical Region, with particular, long-established niches. In the Old World, only the two nightingales in the genus *Luscinia* have vaguely equivalent status, and only one of them, the Thrush Nightingale, travels any real distance across the equator, reaching, in fact, as far south as northern South Africa. In the Far East, some of their congeners, namely the Siberian Blue Robin and, apparently, the Rufous-headed Robin, also journey far into the tropics. Just one Old World species, however, the Blue Rock-thrush, penetrates to the equatorial islands of the Indonesian archipelago, and it has even reached Australia, although, unlike the others, this is, in any case, a breeding species in the tropical Asian region.

Whether the farthest-penetrating representatives of these species are female or juvenile is not established, but an interesting phenomenon in turdid migration is the differential displacement of males, females and juveniles. This can be measured partly in the timing of the birds' departure from and, especially, arrival on the breeding grounds. Early arrival by males, termed "protandry", has been documented for the Eastern and Mountain Bluebirds, Townsend's Solitaire, Hermit Thrush, Veery, Swainson's and Wood Thrushes, Mistle and Song Thrushes, Grey-sided Thrush (*Turdus feae*), Ring Ouzel, Common Rock-thrush, European Robin, Thrush Nightingale, White-throated Robin, Whinchat, Common, Black, Daurian, Hodgson's (*Phoenicurus hodgsoni*) and Eversmann's Redstarts, and Northern, Black-eared, Cyprus and Finsch's Wheatears. For some species, the gap between male and female passages is so pronounced, ten days in the case of Ring Ouzels, 10–15 days for Black-eared Wheatears and up to 20 days for Hermit Thrushes, that two distinct waves have been reported. In Bahrain, for example, male Common Redstarts pass through in the first fortnight of April, while females turn up in the last ten days of the month and into early May. Reports from France of twin peaks in the spring migration of Song Thrushes, Redwings and Common Blackbirds probably derive from a similar pattern.

Studies of the Hermit Thrush have shown that females actually travel farther south than do males by a mean of 1·2° of latitude. Three possible explanations for this are that males dominate females and force them to move farther, that larger body size enables males to overwinter in colder areas, and that males, for reasons discussed earlier (see Breeding), seek to stay closer to the breeding grounds. Evidence of male dominance could not be found, nor could it be shown that males have greater cold endurance, although the fact that the males are larger would allow both of these explanations to stand; it appears however, that the advantage of arriving back early on the breeding grounds balances any cost of wintering or migrating under conditions more demanding than those experienced by the females. Even so, the explanations are not mutually exclusive, and the effects of aggression and/or size need, at least, to be borne in mind when considering the fact that the females of certain other species also move farther than do their males. For example, recoveries of Common Redstarts ringed in Britain have a median distance of 735 km for males and of 1117 km for females, and recent evidence suggests that the majority of European Robins immigrating into Spain in winter are female. In south-west Germany, there is a tendency, as they increase in age, for female Common Blackbirds to migrate and for males to remain, the latter being rewarded by greater breeding success compared with migratory

The genus Zoothera *has diversified in the Indonesian archipelago, producing some stunningly beautiful island forms. One such is the* ***Chestnut-backed Thrush****, a bird of lowland and mid-altitude forests in the Lesser Sundas. It occurs from Lombok to Timor and Wetar, but its populations have all but disappeared from certain islands, as a result of deforestation and trapping. Unfortunately, the cage-bird trade is rampant in Indonesia, and this thrush is heavily targeted due to its striking pattern and beautiful song. The resultant declines in its populations have led to its classification as Near-threatened.*

[*Zoothera dohertyi*. Photo: Konstantin Mikhailov]

males. During the April–August winter period on the Nyika Plateau, in Malawi, it is the female White-starred Robins that leave and the males that remain in place. Similarly, in the Himalayas, females of the White-throated (*Phoenicurus schisticeps*) and Güldenstädt's Redstarts make vertical movements in winter, whereas males move to local valleys. As a further example, most of the Indian Blue Robins spending the non-breeding season in Sri Lanka are females.

The phenomenon extends to juveniles. In Sri Lanka, most of the wintering Indian Blue Robins are *juvenile* females. Farther east, in Hong Kong, the "vast majority" of Orange-flanked Bush-robins are either first-winters or females, adult males turning up in volume only during unusually cold weather; the same is true of Plumbeous Water-redstarts. Likewise, first-winter Song Thrushes travel farther than do older cohorts. In studies of Black Redstarts in Spain, young birds are found decreasingly from November onwards, while adults are roughly constant in numbers through the winter, suggesting that young individuals continue southwards into north-western Africa, where most recoveries have been recorded, in December. Similarly, Common Redstart adults are proportionately more abundant in Spain in winter than are first-winter birds, and the proportion of juvenile European Robins in Spain falls over the course of the winter, suggesting that they move on. An interesting study of Common Stonechats in Israel examined the relationship between the numbers present at a wintering site and local rainfall, air temperature and arthropod abundance. In some years the stonechat population remained constant, but in others it declined to about a third of its original size, and in the latter cases it was young, unpaired individuals that disappeared. The declines correlated with the timing and quantity of rainfall, and with arthropod density. Clearly, the adults were capable of exploiting what food was available in straitened circumstances, but did the young birds leave simply because they were not so capable, or were they pushed out? And to what extent may this be true also of females which move farther than males? These questions have already been touched on (see Habitat).

Juvenile Bluethroats, and doubtless juveniles of all migratory species, are, wholly unsurprisingly, less efficient than adults in terms of foraging and migratory competence, and, at least initially, they move away from the breeding quarters much more slowly than do the adults. Juveniles cover only 11–21 km, and then 30–65 km, per day, as against the adults' 100–110 km per day, although their speed picks up as the autumn progresses. Older juveniles leave the natal areas earlier, and probably undertake short-distance movements to more favourable sites in which to fatten for the longer journey to the non-breeding quarters. Often, they leave their natal areas while still in active post-juvenile moult, or before commencing it, and do not put on any significant fat, probably because of generally poor foraging conditions; once the moult is finished, they usually acquire fat rapidly. Juvenile females, being smaller than males, arrive on their wintering grounds on average three days before juvenile males, and this has been speculated as possibly a means of avoiding competition with the latter. The migration period of adults is more concentrated. They carry more fat and make shorter stopovers than do juveniles, in addition to which they orient with greater precision, possibly because of experience, and possibly because imprecise orientation is selected out in year one. It is difficult to believe that these finer-tuned, highly efficient adults, especially males, would not exert a considerable influence over the behaviour of juveniles, and females, through their physical dominance in the areas which they choose to occupy.

Although some migration may occur by day, particularly in the case of more sociable species, which often extend their nocturnal movements, most thrushes and chats, if not all of them, undertake their major migratory flights at night. For European Robins, key variables in decisions over whether to migrate on a given night are the presence and amount of rainfall and the speeds of wind at an altitude of about 300 m, although how the robins assess wind speed at this altitude is not understood. The probability of migration is highest during nights with little or no wind at 300 m, and no rain; it is intermediate on nights (a) with no rain but with medium wind speeds, and (b) with rain and weak wind; and the probability is almost zero on nights with both rain and strong winds at 300 m. There is a common and entirely reasonable assumption that birds prefer light tailwinds, and some evidence from Germany that Song Thrushes use them when they can. Clear skies caused by high pressure are, however, probably more important, and are commonly favoured by most species, at least in the autumn, when celestial navigation is unimpeded. Under heavy cloud cover, on the other hand, some, if not all, bird spe-

cies, Northern Wheatears and Common Redstarts being examples, can also use magnetic cues for orientation. In fact, there is evidence that species descending from the far north compile information from a variety of available sources in order to navigate with maximum accuracy. Scandinavian research has even suggested that, over water and under cloud, day-moving thrushes use wind-induced wave direction as a means of maintaining the bearings on which they began their journeys.

Other major cues are food supply and body condition. Fieldfares move when rowanberry (*Sorbus aucuparia*) stocks in their nesting areas fall below a depletion threshold. In America, a study of migratory *Catharus* and *Hylocichla* thrushes showed that lean birds display less activity at night but more activity by day than do individuals with undepleted fat reserves, but that their nocturnal restlessness, a measure of readiness to migrate, increases with fat replenishment. Most interestingly, when caged Swainson's Thrushes in variously fat and lean conditions were tested for early-morning orientation, it was found that the fat birds chose directions across the Gulf of Mexico, while lean ones selected directions away from the coast, presumably in search of further refuelling habitats. Recent work with Thrush Nightingales indicates that not only fat, but also protein, is deposited before and during migration, in respective percentages of 82% and 18%, possibly in part to supply the muscular strength required to carry the newly much heavier bird. This species, and doubtless also all others, lays down fat faster at colder temperatures, although not as a consequence of feeding any more rapidly. Physiological constraints such as the building of gut tissues and enzyme systems are evidently in play. Experiments with a Thrush Nightingale in a wind-tunnel, where it flew for a total of 176 hours, equivalent to a distance as great as 6300 km, revealed that the bird was far more capable of fat deposition on day two than on day one of its "journey", indicating a build-up of the capacity of the digestive tract during the first day of fuelling.

Northern Wheatears stopping over on Heligoland, off the north-west German coast, during spring and autumn migration also suffer from metabolic limitations. They spend 51–67% of the daylight period in foraging, and use the remaining time largely for resting or vigilance, irrespective of body condition. On the beach, which offers the most favourable feeding conditions and allows high rates of body-mass gain, the total time which they devote to foraging is independent of day length, and when additional food in the form of mealworms was experimentally offered in bowls it was completely ignored. Those wheatears heading eastwards to Scandinavia, and therefore facing only a short sea crossing of 50–500 km, mostly move on within a day of arrival, irrespective of weather conditions. In contrast, those moving northwards to Iceland and Greenland, and therefore facing a sea crossing of anything from 1000 km to a hair-raising 2500 km, the longest transoceanic migration regularly undertaken by any passerine (and all the more impressive for being preceded or followed by a crossing of the western Sahara), typically stop over for at least one night, often establishing a feeding territory and gaining 1·7 g in weight per day, and wait until weather conditions favour their onward journey. Weight loss and gain for such migrants can be remarkable. Northern Wheatears travelling down from Greenland to Fair Isle might depart with a weight of 40 g and arrive weighing 20–25 g. A telling example involved a vagrant female Common Redstart trapped on Cousin Island, in the Seychelles, on 22nd October 1981, when it weighed 12·2 g; when retrapped on 9th November, it had fat visible on the breast and weighed 21 g, an increment of 72% in 18 days, and auguring well for the bird's successful relocation to Africa.

Typically, a nocturnal migrant thrush commences its flight about half-an-hour after sunset in clear conditions, and somewhat later, sometimes not until well after midnight, if the sky is overcast. If land is available, it terminates its flight about half-an-hour before sunrise. Studies of Swainson's Thrush and the Veery have established that, as with aircraft, there are distinct ascent and cruising phases. The former lasts for about 15 minutes as the bird reaches its cruising altitude, at which point the wingbeat frequency declines by 4 Hz to reach 9–11 Hz, and wingbeats are then continuous, with no evidence of a flap-and-glide strategy. A Thrush Nightingale trained to fly in a wind-tunnel, a different individual from the one mentioned earlier, also used continuous flapping flight even when undertaking a 16-hour stint. Radio-tagged Hermit Thrushes reached a cruising air speed of 36 km/h, and adjusted both heading and altitude to negotiate prevailing winds, even landing in order to avoid thunderstorms, while Swainson's Thrushes exhibited ground speeds varying from 15 km/h to 96 km/h and maintained a constant heading and air speed, irrespective of wind conditions, cloud cover or landmarks.

*The **Tristan Thrush** is endemic to Tristan de Cunha, and associated islands in the South Atlantic. Once thought to number about 1000 birds, this estimate has been revised upwards to 6000. Despite these relatively low figures, it appears hardly threatened by habitat alteration. Given the possibility of mammalian introductions, however, it is maintained in the Near-threatened category on a semi-permanent basis. Outwardly, it seems to be a neotenous representative of* Turdus, *but it is retained in its own genus on account of a modified tongue, an adaptation for sucking the contents of seabird eggs.*

[*Nesocichla eremita procax*, Nightingale Island, Tristan da Cunha. Photo: R. & C. LeDuc/ VIREO]

Another Near-threatened insular form is the ***Fuerteventura Stonechat****, endemic to the Canary Island of that name. Recent estimates conclude that over 1000 pairs survive, but these are threatened by habitat loss and desertification due to overgrazing and tourist development. It thrives in stony fields, on shrubby slopes, and along tamarisk-lined watercourses, habitats which require protection to ensure its long-term survival. It is notably divergent from adjacent North African forms of the Common Stonechat* (Saxicola torquatus)*, but its status as a species nonetheless requires clarification.*

[*Saxicola dacotiae*, Triquivijate, Fuerteventura, Canary Islands. Photo: José Juan Hernández Martínez]

Migration altitudes vary with conditions. Hermit Thrushes kept mainly to between 900 m and 1500 m, and Veeries to 200–1000 m, although one Veery was tracked at over 2000 m, and Swainson's Thrushes to 65–2000 m, the lowest heights being used in fog or rain. Over the North Sea, Scandinavian migrant thrushes have been observed on radar to drop to near the surface of the water during the course of the night, but to gain altitude again at dawn or even, later in the autumn, 1·5 hours before dawn; this latter phenomenon may have to do with the seeking of visual cues for a landfall, or the avoidance of predation by seabirds.

In the spring, Swainson's Thrush has been timed as it crossed North America from Veracruz, in Mexico, where the median passage date is 12th May, to Maine, in the north-east USA, where the median passage date is 18th May. It was found to cover a distance of 520 km per day, whereas the average rate of autumn migration, travelling from the breeding grounds south to the Alabama coast, is a mere 119 km per day for adults and 108 km per day for juveniles. Telemetry data disclose flight distances of 105–375 km per night and flight durations of 333–503 minutes. Remarkably, while individuals lose a substantial amount of body mass during long southward flights of up to 1000 km across the Gulf of Mexico, the birds tend to put on, rather than lose, weight on the return migration, despite the rapid speed of this northward movement. Thrushes arriving in the north-east USA are some 3·5–5 g heavier than they were when they left Louisiana, probably as a result of using a "feed-by-day, fly-by-night" strategy, rather than the "pile-it-on, burn-it-off" one used perforce by over-water migrants and involving several days of feeding-up followed by several days and nights of almost continuous travel. During their daytime spring stopovers, *Catharus* thrushes fix on tiny areas, sometimes as little as 400 m², in which to refuel.

Migrants sometimes return to the same stopover sites in successive years, and it is clear that thrushes and chats share with many other passerines a striking level of precision in their navigation and itineraries. Displacement experiments with telemetry showed that Wood Thrushes can quickly navigate back to their territories if moved 6·5–15 km away. Allied to this is the very exact programming which leads two groups of European Robins passing through geographically close migration points in southern Sweden to adopt very different fat-deposition strategies. Thus, robins at Falsterbo are heavier and carry less fat by comparison with those at Ottenby, and they are presumed to be short-stage migrants travelling over land and needing only small fat reserves, whereas Ottenby robins are long-stage migrants needing relatively large fat reserves to get them across the Baltic Sea. The supposed genetic basis for migration has been elegantly supported by experimentally hybridizing Common and Black Redstarts, the offspring of which were intermediate between the two parents not only in the duration of migratory activity in captivity, but also in the timing of its onset. This does not necessarily mean, however, that all birds from the same lineage always share the same programming, as evidenced by the notable, if rather anomalous, record of two Redwings ringed as brood siblings in Finland which were recovered in the same month, February, of the following year, one in Wales and one in south-east France.

It may be that the Redwing, along with several other highly sociable northern Eurasian species, including in particular the Fieldfare, are among the few turdids in which, owing to their strong dependence on unpredictable supplies of berries, philopatry has been virtually programmed out of the genetic behavioural code. The Fieldfare is strongly nomadic and fluid in its use of areas. So, too, is the American Robin, at least in the non-breeding season, ringing records showing that individuals wintering in a particular place are from widely scattered areas. There is no evidence that individuals return to the same winter territories. In this species, as with the Fieldfare, migration is facultatively driven by resource availability. From the existence of simultaneous peaks in migratory numbers of American Robins in both Maryland and Arkansas, in middle to late October, it appears that entire populations shift south, replacing each other, rather than exhibiting the "leap-frog" pattern shown by some northerly populations of certain other species, such as the Song Thrush. Nomadism appears to occur, in limited form, even in the Island Thrush on Taiwan and Borneo, with populations suddenly appearing in areas where the species had for long been absent, presumably in response to fruit availability.

Migrations and, indeed, elevational displacements are undertaken as a means of exploiting temporarily available resources in two different areas of the world, and the ability to switch between geographically separate homes obviously bestows huge benefits without which the species, or large populations of the species, could not survive. Nevertheless, migration is itself a pre-

carious venture. The greatest risk comes from unexpected bad weather, which can push migrants far off course and leave them far from land, or can result in death simply through hypothermia; when storms break over water, the birds have nowhere to land and are driven into the sea. There is the particular risk of death at lighthouses and other disorienting illuminated structures in cloudy weather (see Status and Conservation). As exhausted over-sea migrants approach the coast at dawn, flitting above the waves, they can be picked off by gulls. Even the process of fattening-up for the flight presents a risk. This was demonstrated by first-year European Robins exposed to experimental attack from model Merlins: the robins took off at lower angles the heavier they were, and they were unable to adjust to different angles of simulated attack, indicating a lower fitness to escape.

Relationship with Man

The lives of men and women have been greatly enriched by the lives of thrushes and chats, always allowing that, as with many birds, there are occasional complaints about the depredations of fruit crops by such species as the American Robin, the Fieldfare and, of all things, the Pied Thrush in Sri Lanka. The reverse cannot so easily be said, however, for thrushes and chats have in the past suffered and, in some parts of the world, still suffer egregiously from ruthless human exploitation. All the same, it is the case, as already discussed (see Habitat), that members of the Turdidae have increased their ranges and numbers through the anthropogenic creation of semi-open habitats, and some of our best-loved species are those which today live in closest association with us.

Thrushes and chats are of interest to humans in two basic ways: as food and for their songs. Centuries ago, winter in Europe was always a time of scarcity, so that the flocks of Fieldfares and Redwings pressing in from the north and east must have been like manna. There is a seventeenth-century record of 600,000 Fieldfares being taken in east Prussia during a single winter. The Romans, predictably, made the most of these birds, keeping them by the thousand in darkened cages, to be fattened up on a paste of flour and figs, and then sold for three *denarii* each. Fieldfares, Redwings and Song Thrushes are still today hunted for food in parts of southern Europe and north Africa, as evidenced by the small body of scientific studies conducted in Spain over the levels of radioactivity in, and the safety to human consumers of, Song Thrushes killed in the country but originating from around the Ukrainian city of Chernobyl, site of the appalling nuclear-reactor disaster in 1986. Indeed, so ingrained is such hunting in Mediterranean man's life that the practice went with him to places such as Brazil, where Sick, singling out the "descendants of Italians", inveighed against it as a scandal, but even in North America, from colonial times well into the nineteenth century, American Robins were widely trapped and shot for food. Until relatively recently, there was a familiar industry in France involving the conversion of many Song Thrushes, Redwings and Fieldfares into a delicacy known as *pâté de grives*. Indeed, where in England the acceptance of straitened circumstance was signalled by the phrase "beggars can't be choosers", the Gallic equivalent was once the rather more bullish *faute de grives on mange des merles*, meaning "if no thrushes, we shall eat blackbirds", which reveals an interesting point of discrimination over the taste of the latter—is the black of the Common Blackbird proaposematic?

Not if the English nursery rhyme is to be believed. This tells of "four-and-twenty blackbirds baked in a pie", although, in this instance, the birds survived the experience to sing when the crust was broken, thereby also proving that they were not in fact crows. In truth, the English were no different from the peoples to their south in these matters but just, as usual, a lot less stylish: while the French were making their tender, berry-eating thrushes into paste, the English chose to eat their way through the hordes of Northern Wheatears passing through the country. Thousands of these birds were caught on migration in nooses deployed on drystone walls across southern England, and many of the victims were sent to the cities for consumption there as a delicacy. Of course, the early persecution of thrushes and chats could not have been carried out with guns as it is today, but would have involved lime and nooses. The scientific name of the Fieldfare, *pilaris*, is of uncertain origin, but it may derive from the Latin *pilus*, a hair, and thus refer to the old method of catching the species in hair traps. In parts of Egypt and Greece, the use of lime to trap many passerine species, including European Robins, Northern Wheatears and Common and Thrush Nightingales, has been replaced by the more efficient mist-net.

Elsewhere in the world, thrushes and chats were caught apparently more for the satisfaction of the sounds that they make than for the sustenance that they offer. Several hundred years ago, nightingales were immensely popular in Europe, and in 1751 the definitive guide to the keeping and management of these in captivity was produced in France— A. de Nobleville's *Aedologie,*

Stoliczka's Bushchat *is an enigmatic bird of barren xerophytic plains in northwest India. Its population appears to be small, and its occurrence sporadic, an impression exaggerated by minor but poorly understood migrations. The key issue for this species is habitat loss, as a result of both irrigation schemes and overgrazing of sparsely vegetated habitats. These threats have caused a spectacular contraction in range, such that it has virtually disappeared from Pakistan and the northern Thar desert. It is therefore listed as Vulnerable. Habitat protection is needed in remote deserts of western Rajasthan, where it remains locally or seasonally common.*

[*Saxicola macrorhynchus*, Little Rann of Kachchh, Gujarat, India. Photo: Otto Pfister]

Until recently the Western Ghats of southern India were thought to host an endemic shortwing in the genus Brachypteryx, *but this has been reclassified in* Myiomela *and split into two species, one of which is now known as the* ***Nilgiri Blue Robin****. Even when both forms were lumped their overall range was small, as was their predicted population size, and thus they qualified as Vulnerable. As currently viewed, this species is virtually endemic to the Nilgiri hills, but it is not thought to be severely threatened as it remains fairly common in several patches of well-protected forest.*

[*Myiomela major*, India. Photo: Tim Loseby]

ou traité du rossignol franc, ou chanteur; he recommended heart and ants' eggs as food for these birds. Nineteenth-century bird-catchers were so adept at attracting nightingales up to their traps in April by whistling that a man could catch one in five minutes, and up to 30 in a day. Rather more recently, the Oriental Magpie-robin was reported to be a popular cagebird around Hong Kong in 1967, and it presumably still is, the birds' owners holding singing contests at which they gather together at a place, uncover and suspend their cages in a tree, and let the birds sing full-pelt at each other. The extent to which this was done competitively or simply for aesthetic effect is not always clear, but in India the same species is reported to have been used by the rich for "cock-fighting" in the nineteenth century. Song contests there involved, when possible, the magpie-robin's close relative, the White-rumped Shama. The distinguished naturalist E. Blyth recounted that "Many thousands of these elegant birds are kept in Calcutta. It is a practice of the rich natives to employ servants to carry about their Shamas and other birds; and the number which are thus borne about the streets of Calcutta is astonishing; the poor birds are shut out from all light and air… but they nevertheless sing forth most lustily and melodiously." The Japanese are reported to have supplied the substantial demand for Ryukyu Robins by means of "fly-fishing"; no further details are given, but one must assume that horrific damage was done to the mouths of the birds. The Indonesian love of cagebirds and songsters has in recent years produced an unsustainable pressure on the small *Zoothera* thrushes of the country.

Speckle-breasted thrushes on both sides of the Atlantic Ocean may be difficult to keep in cages, or they may fail to sing in captivity. At any rate, they seem to have suffered little persecution for the trade. On the other hand, White-throated Thrushes are commonly kept as cagebirds in Colombia and Venezuela, and the thrushes of Middle America have been heavily exploited for their singing capabilities. In Costa Rica and Panama, the Clay-coloured Thrush is extensively trapped for its voice, a practice which one observer berated as entirely unnecessary since wild individuals have penetrated every city and, in season, sing all day long for the pleasure of anyone who has ears. A population of this species around Oaxaca City, in Mexico, probably derives from escapees. In the same country, two recently established populations of Rufous-backed Thrushes, one in Distrito Federal, where it lives at elevations far greater than do those encountered elsewhere, and the other in Oaxaca City, are assumed also to stem from escaped cagebirds. On the other hand, populations of the Slate-coloured Solitaire (*Myadestes unicolor*) in eastern Mexico have been reduced and possibly extirpated by the trade. Other species of solitaire, which are prized as among the best songsters of any avian family, are kept in many parts of Middle America and the Caribbean. The voice of the Black-faced Solitaire, the *jilguero*, although exquisitely beautiful in the wild, is said to sound harsh and jarring in urban surroundings, although perhaps most of all to the ears of those who wish them free.

Poets have not needed captive birds for their inspiration. Indeed, the notion of captivity was anathema for the visionary artist and poet William Blake, who famously declared in *Auguries of Innocence*:

> "A Robin Red breast in a Cage
> Puts all Heaven in a Rage."

Several English poets, including Alfred Lord Tennyson, Thomas Hardy, Siegfried Sassoon and Ted Hughes (see also Food and Feeding), wrote noteworthy poems in which they took as their point of reference thrushes, or more specifically, as an ornithologist can tell from context, the Song Thrush. In *The Throstle*, Tennyson, the celebrated Victorian poet laureate, transliterated the repeated phrases of the Song Thrush and indulgently humoured them in the knowledge that spring had scarcely arrived:

> "'Summer is coming, summer is coming,
> I know it, I know it, I know it.
> Light again, leaf again, life again, love again!'
> Yes, my wild little Poet."

The affection is carried beautifully, however slight the sentiment. Hardy, more familiar as a novelist of some distinction, is as grimly funereal as ever about the condition of mankind in his poem *The Darkling Thrush*, written on 31st December 1900 and hence not only in the dead of winter, but also on what he deemed to be the last day, the dying day, of the nineteenth century; but he, as Tennyson, drew inspiration of sorts from a thrush that chose this of all moments to "fling his soul Upon the growing gloom" and

The differences between ***Bicknell's Thrush*** *and its closest relative, the Grey-cheeked Thrush* (Catharus minimus), *are so subtle that its status as a species was only publicized in the 1990s, and remains contentious. If maintained as such, it is estimated that 21,000–53,000 mature individuals survive, mostly in the USA, and only marginally in Canada. The entire population migrates to the Caribbean in winter, particularly Hispaniola, Jamaica, Cuba and Puerto Rico. It appears to be in steep decline because of habitat loss and deterioration in its breeding and non-breeding ranges, as a result of which it is classified as Vulnerable.*

[*Catharus bicknelli*, Stratton Mountain, Vermont, USA. Photo: Sarah Frey]

offer the listener a token of hope and renewal where none otherwise seemed to exist. Sassoon, a distinguished poet of the First World War, simply felt the dislocation of nature and man, and in *Thrushes* he juxtaposed, with clear but understated bitterness, the bright, coherent, self-contained life of the birds "whose voices make the emptiness of light A windy palace" with the "haunted… baffled" life of man "Who hears the cry of God in everything And storms the gate of nothingness for proof."

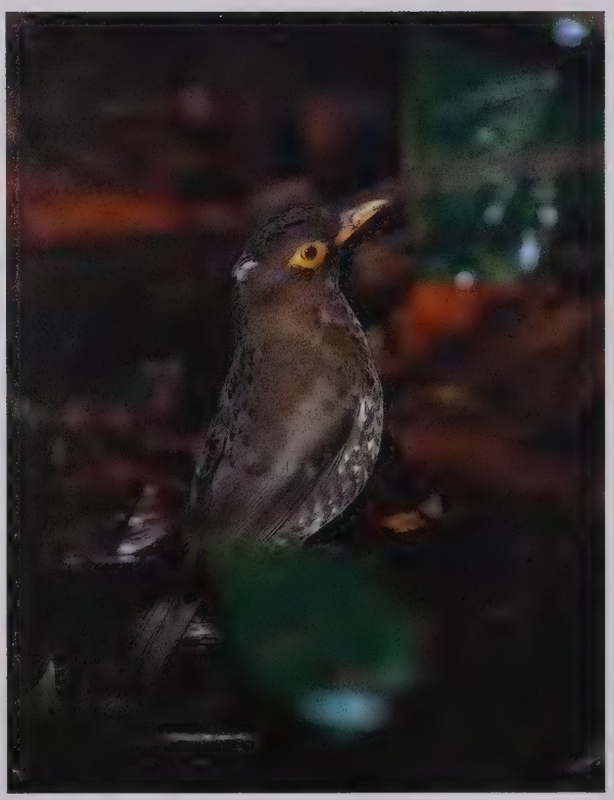
Although not good as cagebirds, the North American thrushes have done well in the continent's poetry. A thrush, called a "hermit" and indeed presumably of this species, sings through the extraordinary lament that Walt Whitman wrote for Abraham Lincoln, *When Lilacs Last in the Dooryard Bloom'd*. The sense of mourning and loss in this poem, which extends to all who died in the Civil War, is enfolded by the song of the thrush, the "gray-brown bird", in a "carol of death" that becomes a celebration of death and, finally, an admission of life. The immediate subject of what is possibly Emily Dickinson's most famous poem, *A Bird Came down the Walk*, must surely have been a thrush, although the poem is not really about the bird at all: it dismembers a worm, and has a worried demeanour with eyes "like frightened Beads", which brings to mind Hilty's description of Swainson's Thrush (see General Habits). What is certainly one of Robert Frost's most delightful short pieces, *Come In*, hinges on the conceit, dismissed in the last line with a wry smile, of a thrush singing him an invitation into a dark place of lamenting, when it is, after all, just a thrush, singing from the darkness of a twilight wood. Frost captures the bird, the moment and the mood in seemingly the simplest of styles.

Then there is T. S. Eliot. He no more wrote a poem "about" a thrush than did his foregoing countrymen, but the birds make momentary, haunting appearances in his verse. There is the

> "sound of water over a rock
> Where the hermit-thrush sings in the pine trees
> Drip drop drip drop drop drop drop
> But there is no water"

in *The Waste Land*, in which Eliot includes a deliberately irrelevant footnote to the effect that "This is *Turdus aonalaschkae pallasii*, the hermit-thrush which I have heard in Quebec Province… Its 'water-dripping song' is justly celebrated". There is, in *Marina*, the "scent of pine and the woodthrush singing through the fog". Both references have a peculiar evocative power created largely by their very spareness, like a Chinese painting on silk, something which the repeated reference to pines reinforces. The same is true of the moment at the start of *Burnt Norton*, the first of his *Four Quartets*, when—and this is now England rather than New England—we read:

> "Other echoes
> Inhabit the garden. Shall we follow?
> Quick, said the bird, find them, find them,
> Round the corner. Through the first gate,
> Into our first world, shall we follow
> The deception of the thrush?"



That repeated "find them, find them" and those alliterative repetitions of "follow" and "first" remind us of Tennyson's transliterations: if this thrush is a thrush at all, it is a Song Thrush.

Eliot also made several hard-boiled references to nightingales, but in the English language, at least, the greatest piece of writing to which the Common Nightingale is central is by John Keats. His *Ode to a Nightingale* is one of the greatest triumphs of romantic poetry, a richly textured, profoundly felt meditation on everyday human suffering and mortality as set in relief by the experience, unequivocally something that Keats personally had, of hearing the species in full song at dusk. The beauty that he perceives is so overwhelming that it actually hurts:

> "'Tis not through envy of thy happy lot,
> But being too happy in thine happiness—
> That thou, light-wingéd Dryad of the trees,
> In some melodious plot
> Of beechen green, and shadows numberless,
> Singest of summer in full-throated ease."

These lines, with that brilliantly invented adjective "beechen", evoke with genius the feel of the experience, as anyone will testify who has been privileged to stand in the still spring air of late twilight near a singing nightingale, of whichever species, whether with beech trees or not. But Keats takes it much further, revelling in the richness of the moment to the point where

> "Now more than ever seems it rich to die,
> To cease upon the midnight with no pain,
> While thou art pouring forth thy soul abroad
> In such an ecstasy!"

The ***Forest Thrush*** *occurs on the Caribbean islands of Montserrat, Guadaloupe, Dominica and St Lucia. Of these four populations, the only one thriving was that of Montserrat, but this suffered a dramatic decline in the wake of a series of volcanic eruptions in the 1990s. Numbers have apparently recovered, but it remains threatened on all islands by habitat loss and fragmentation, predation by introduced mongooses* (Herpestes), *brood-parasitism by cowbirds* (Molothrus), *and human exploitation for food. Strict protection of forest reserves is needed, along with hunting bans where necessary.*

[*Cichlherminia lherminieri dominicensis*, Morne Trois Pitons National Park, Dominica. Photo: Roland Seitre]

The total range size of the ***Izu Thrush*** *is tiny, owing to the fact that it only occurs on scattered islets off Japan, mostly in the Izu archipelago south of Tokyo. There is some indication that populations are falling in response to heavy predation by introduced rats* (Rattus), *Siberian weasels* (Mustela sibirica), *Large-billed Crows* (Corvus macrorhynchos) *and domestic cats. Given a likely population under 10,000 birds, and an apparent decline, this thrush qualifies for treatment as Vulnerable. On several islands, however, it remains an abundant bird of gardens and roadsides, and it seems unlikely to disappear in the immediate future.*

[*Turdus celaenops*, Japan. Photo: Hirozo Maki]

Then, while the poet contemplates how this same song was heard in Roman and in biblical times, the singer shifts his ground and loses his listener, leaving him questioning his senses. Poor Keats, who was tubercular, was taken soon enough by "easeful Death", but there is perhaps no greater instance of the inspiration that a singing bird can be to the human heart or mind than that which one Common Nightingale gave him on that night in May 1819.

Composers of music, too, have drawn inspiration from thrushes and chats, but the associations are for the most part loose and transitory. For example, Ravel, in his piano piece "Oiseau Triste", from *Miroirs*, elaborates the idea of a Common Blackbird lost in a hot summer forest; it is lovely music, but one should not look for evidence of *Turdus merula* in it. On the other hand, at least two composers have deliberately gone closer to the original. Messiaen's obsession with birdsong, as the voice of God in nature, led him to compose his monumental piano work *Catalogue d'Oiseaux* and his much shorter *Petites Esquisses d'Oiseaux*, the former with several species of chat, the Common and Blue Rock-thrushes and the Black and Black-eared Wheatears, and the latter with the more expected subjects of the Common Blackbird, the Song Thrush and the European Robin, all represented in his unique style which, nonetheless, brings a strange flavour of veracity to each species. Respighi, in his orchestral *Pines of Rome*, went still further by introducing a tape recording of a Common Nightingale, lasting about 50 seconds, towards the end of the piece, in one of the earliest examples of the use of electronics in music.

Nightingales feature prominently in European and western Asian poetry, folklore and stories. In Greek fable, Tereus, King of Thrace, violated his wife Procne's sister, Philomela, and then cut out Procne's tongue for fear that she would report the crime. As the revenge of the sisters reaches its climax, he is changed into a hoopoe (*Upupa*), Procne into a swallow and Philomela into a nightingale. Later versions have Philomela losing her tongue, which makes more sense as a criminal's strategy but less sense in terms of the transformation, following which Philomela sings her heart out in lament while Procne can only twitter. So pervasive was the influence of this story that most European poets and writers portrayed the singing nightingale as (a) female and (b) grief-stricken. At some point, too, the pain of grief gave rise to the conceit that the nightingale sang with its breast against a thorn, so as to stay awake through physical pain in order to give voice to the emotional one. This may have come into western literature from stories originating in Persia perhaps with the fourteenth-century poet Hafiz, who wrote about the nightingale as nourishing the rose with drops of his blood. And at some stage Oscar Wilde caught this idea and turned it into the most exquisitely poignant of his children's stories, *The Nightingale and the Rose*. A hundred years later, R. Mabey pulled together many of the stories and many other engaging references relating to the species in his delightful *Whistling in the Dark*.

The only other turdid species that figures deeply in European writings and folklore is the European Robin. Many obscure but notable passages of old poetry and prose relating to the species were traced and used by Lack in his ground-breaking book *The Life of the Robin*, but the folklore attaching to it is extensive. A disarming number of superstitions existed telling that the harm of a robin resulted in harm to the perpetrator, who would suffer such things as palsy, epilepsy, swellings, broken limbs, smashed

Like its congeners, the ***Javan Cochoa*** *is a beautiful but inconspicuous bird of humid forest canopies in the montane zone. It is restricted to the highlands of western Java, where constant erosion of habitat due to agricultural expansion ensures that its small population is steadily declining. It is therefore treated as Vulnerable, although much of its range lies above the agricultural zone or within protected areas. The most important of these, Gunung Gede-Pangrango and Gunung Halimun National Parks, deserve strict protection and effective management.*

[*Cochoa azurea*. Photo: Stan Osolinski/ Oxford Scientific Films]

crockery, burnt-down homes, and even bloody milk from his cows. Robins were believed to care for the dead by covering the eyes or face of the departed with moss, and to sing sorrowfully by the body until it is buried. Robins singing from high perches presaged fine weather, while robins around or, worse, entering the house in autumn foretold hard weather. Robins brought fire from heaven, and quenched the fire of hell; and in due course they became closely associated with the religious festival of Christmas, being portrayed on the majority of seasonal greetings cards produced in Europe. The species was and still is, particularly in Britain and northern France, a cultural icon.

In fact, the European Robin is the "national bird" of the United Kingdom. Sweden has the Common Blackbird and Malta the Blue Rock-thrush, while Turkey has, for some reason, the Redwing. The national bird of Bangladesh is the Oriental Magpie-robin. In Costa Rica, this title is held by the Clay-coloured Thrush, something of which some of the country's more permissive inhabitants may be extravagantly proud if ever they learn about the private life of this species. In Brazil, a group of cagebird fanciers proposed the Rufous-bellied Thrush as the national bird, although they were ultimately thwarted by a counter-proposal for something more colourful, if less pleasant to listen to, the Golden Parakeet (*Guarouba guarouba*). Species chosen as "State birds" in the USA include the American Robin in Connecticut, Michigan and Wisconsin, the Wood Thrush in District of Columbia, the Hermit Thrush in Vermont, the Mountain Bluebird in Idaho, and the Eastern Bluebird in Missouri and New York.

National and state birds are, in their way, birds of good omen. The Indian Robin is considered a good omen among certain Rajput clans, and therefore held as sacred. Among the Iban people of Borneo the White-rumped Shama is always auspicious owing to its habit of keeping near longhouses, which implies an intimate interest in human affairs. Similarly, the White-crowned Wheatear is revered by the desert nomads of north Africa, within whose camps it moves freely, searching for scraps and picking ticks off livestock; it gave its Arabic name, *zarzur*, to the semi-mythical oasis Zerzura, thought to be Wadi Abd El Malik in the Gilf Kebir of Libya, where lost treasures were sought by various Europeans in the 1930s, inspiring the plot-line in the book and film *The English Patient*. All three of these species enjoy the kind of status that the European Robin has with the British, and it is perhaps the simple pleasure of the companionship of these beautiful, trusting species that inspires such warmth of human feeling. Why else do North Americans spend so much on bluebird nestboxes and trails?

One reason why they do so is that the causes and cures of the major post-1950 decline in bluebird numbers across the continent were addressed by scientific research. The need for nestboxes turned bluebirds into local subjects for action, and the provision of boxes allowed the research to focus on the biology of the genus *Sialia*. The three bluebird species have, as a consequence, yielded a great deal of information of value to science generally on the processes of sexual selection and sperm competition. Their important contribution to the development of biological understanding is, however, by no means the only one made by members of the family.

In Europe, another thrush, the Bluethroat, has emerged as a major test-bed species for evolutionary theory, and, belatedly picking up the trail opened half-a-century ago by D. W. Snow, behavioural ecologists have found in the Common Blackbird another species, right on their doorsteps, amenable to similar experimental study, with particular respect to survival and foraging competitiveness. Farther south, new light has been thrown on sexual selection by the stone-carrying capacities of the Black Wheatear and the singing performances of the Clay-coloured Thrush. The Common Stonechat has proved an ideal species for studying the relative influence of environment and heredity in different life-history strategies in the tropical and temperate zone. Studies of the European Robin have elucidated key issues over the value and use of territory in relation to avian survival, food supply and breeding performance. Common and Thrush Nightingales have yielded new information on song-repertoire development, storage and deployment in birds, and on fat-deposition patterns during migration. The American *Catharus* and *Hylocichla* thrushes have been leading subjects of research on the effects on animal populations of habitat fragmentation, and, again, on the energetics of migration. The Fieldfare has been instrumental in the exploration of anti-predator breeding strategies and their evolution. Moreover, it was the die-off of American Robins after DDT was used to control Dutch elm disease on the Michigan State University campus, in the mid-1950s, that alerted scientists to the long-term effects of chlorinated hydrocarbons in the environment. Indeed, so much are thrushes and chats used as experimental subjects by biologists that there is now a growing body of studies that examine the effects of these very studies themselves!

Status and Conservation

Of the 336 species of thrush and chat currently recognized, six are classed as Critical, seven are Endangered and 23 are Vulnerable, representing respective percentages of 1·8%, 2·1% and 6·8% of the family's members. A further 26 species, 7·7%, are considered Near-threatened. These proportions are well in line with the global figures for birds, in which Critical species make up 1·9% of the world's avifauna, Endangered species 3·3%, Vulnerable ones 6·9% and Near-threatened ones 7·4%. Thus, only the figures for Endangered turdids differ distinctly from the global percentage. In addition, of all the 9925 bird species extant in AD 1500, 128, or 1·3%, are now extinct. Among the thrushes and chats, the percentage is 0·6%, two species, although it would be 0·9% or 1·2% with the addition of one or both of two doubtful cases.

What are these species, and what are their characteristics? The extinct species are the Grand Cayman Thrush (*Turdus ravidus*) and Kittlitz's Thrush (*Zoothera terrestris*), the last also known as the Bonin Thrush. The Grand Cayman Thrush was an exquisite pale grey thrush with a vermilion bill, eyering and legs. It lost its scrub and mangrove habitat in the first half of the twentieth century, and promptly became extinct. Kittlitz's Thrush was discovered in 1828 on Chichi-jima, the largest island of the Ogasawara-shoto, or Bonin Islands, south of Japan. Following much disturbance and the introduction of rats (*Rattus*), it had disappeared by 1889. Both of these cases were outlined in E. Fuller's foreword to Volume 7 of the *Handbook of the Birds of the World*.

It is an apt reflection of the dreadful crash of Hawaii's avifauna that of four endemic solitaires three are considered Critical, two of them probably extinct, while the ***Omao*** *is viewed as something of a success story. In the 1890s this species was abundant and widespread, but a century later its range had contracted to 25-30% of its former extent, its population was doubtless a fraction of its original size, and it was classified as Vulnerable. Nonetheless, it seems to have endured the same litany of threats that exterminated its congeners, chiefly habitat destruction and disease, and with continued protection it seems likely to survive.*

[*Myadestes obscurus*, Hawaii Volcanoes National Park, Hawaii. Photo: R. & N. Bowers/ VIREO]

Restricted to the Eastern Zimbabwe Mountains and Tanzania-Malawi Mountains Endemic Bird Areas, ***Swynnerton's Robin*** *is thought to be declining rapidly in a small range and thus meets the requirements for treatment as Vulnerable. Although generally rare and very patchily distributed, it remains common at a few localities, including Zimbabwe's Chirinda Forest and Mozambique's Mt Gorongoza, both of which require urgent and effective protection to arrest the loss of key habitats to cultivation, logging and firewood collection.*

[*Swynnertonia swynnertoni swynnertoni*, Vumba, Mutare, Zimbabwe. Photo: Geoff McIlleron]

Not included in Fuller's foreword was the Amaui ("*Myadestes woahensis*"), a form known from a single specimen collected on Oahu, in the Hawaiian Islands, in 1825, at which time it was reported by its discoverer to be common in the forest; the cause or causes of its extinction are unknown. The specimen is of a juvenile, and it is very like juveniles of the race *rutha* of the Olomao. It is dark brown above, with pale buff dots and flecks, has a greyish throat slightly flecked brown, and has whitish-buff underparts with broad dark brown scalloping, perhaps more extensive than in *rutha*; the wings and tail are plain grey-brown. An adult specimen was obtained at the same time. Although the present whereabouts of this are uncertain, a skin in the collection of the Academy of Natural Sciences of Philadelphia, in the USA, is thought very likely to be this specimen. This differs from the adult Olomao only in having a longer tail. In view of the evidence, admittedly incomplete, it seems probable that the Amaui was, in fact, no more than a subspecies of the Olomao.

Although Fuller included another supposed turdid, the Bay Thrush ("*Turdus ulietensis*"), this may not even have been a thrush. Fuller reports that it had "a notch in its bill", and its only home, Raiatea, in the Society Islands, where it was reported in June 1774, is a long way east of any other thrush-inhabited islands in the South Pacific. H. D. Pratt and co-authors make the very plausible point that the bird was more probably an *Aplonis* starling, and it is discounted hereafter in this discussion.

Among the 36 globally threatened members of the Turdidae, the Critical species are the Kamao (*Myadestes myadestinus*), Olomao, Puaiohi, Taita Thrush, Somali Thrush and Seychelles Magpie-robin. The Endangered turdids are the La Selle Thrush (*Turdus swalesi*), Spotted Ground-thrush, Thyolo Alethe (*Pseudalethe choloensis*), Sri Lanka Whistling-thrush, Gabela Akalat, Usambara Akalat and Black Shama (*Copsychus cebuensis*). It is worth considering these two classes and the extinct species together. The most obvious feature of the three lists is the influence of insularity on the degree of their conservation status. Both (or all) of the extinct thrushes were found on remote, or relatively remote, small islands, and four of the six Critical species are likewise; but none of the seven Endangered thrushes is, although three are insular. The two other Critical species and all seven Endangered species have small natural ranges rendered tiny by anthropogenic deforestation.

The Vulnerable species are the Omao, Sumatran Cochoa (*Cochoa beccarii*), Javan Cochoa (*Cochoa azurea*), Izu Thrush (*Turdus celaenops*), Grey-sided Thrush, Yemen Thrush, Forest Thrush, Ashy Thrush (*Zoothera cinerea*), Guadalcanal Thrush, Bicknell's Thrush, Rusty-bellied Shortwing (*Brachypteryx hyperythra*), Malaysian Whistling-thrush (*Myophonus robinsoni*), Swynnerton's Robin, East Coast Akalat, Iringa Akalat, White-headed Robin-chat (*Cossypha heinrichi*), Black-throated Blue Robin, Rufous-headed Robin, Luzon Water-redstart (*Rhyacornis bicolor*), Nilgiri Blue Robin, White-bellied Blue Robin, Stoliczka's Bushchat (*Saxicola macrorhynchus*) and Hodgson's Bushchat. Here, things change somewhat. There are four insular forms with tiny ranges, the Omao and the Izu, Forest and Guadalcanal Thrushes; two continental forms, the bushchats, with diminishing ranges owing to grassland modification; and an insular waterside redstart with too disturbed a habitat. The 16 remaining species have small natural ranges that have been made smaller, but not tiny, by deforestation; 15 are continental, including the Greater Sundas, and one is insular.

The Near-threatened thrushes and chats are the Cuban Solitaire, Geomalia, Gulf of Guinea Thrush, Unicoloured Thrush (*Turdus haplochrous*), Tristan Thrush, Slaty-backed Thrush (*Zoothera schistacea*), Buru Thrush (*Zoothera dumasi*), Seram Thrush (*Zoothera joiceyi*), Red-backed Thrush (*Zoothera erythronota*), Red-and-black Thrush (*Zoothera mendeni*), Chestnut-backed Thrush (*Zoothera dohertyi*), Orange-banded Thrush (*Zoothera peronii*), Everett's Thrush (*Zoothera everetti*), Crossley's Ground-thrush, Oberländer's Ground-thrush (*Zoothera oberlaenderi*), Spot-winged Thrush, Fawn-breasted Thrush, New Britain Thrush, Benson's Rock-thrush, Angola Cave-chat, Firethroat, Rufous-tailed Shama (*Trichixos pyrropygus*), Przevalski's Redstart, Fuerteventura Stonechat, White-bellied Bushchat and Chestnut-naped Forktail. Here, things change again. Of these 26 species, no fewer than 16 are insular forms, and only eight are continental, taken here as including the Greater Sundas and Madagascar.

So, nearly 80% of the Extinct and Critical turdids are insular, whereas 43% of the Endangered species and only 26% of the Vulnerable ones are; but 61% of the Near-threatened thrushes and chats are insular species. What is happening? The relationship between high levels of endangerment and insularity is well

*The **Grey-sided Thrush** breeds in a limited area of montane forest in north-east China, and migrates south-westward in the non-breeding season to similar habitats in north-east India, Myanmar and northernmost Thailand, where this photograph was taken. The summer and winter ranges encompass vast areas of inaccessible or rarely visited terrain and the total population is very difficult to judge. It is estimated at fewer than 10,000 birds, and declining, an assessment which triggers classification as Vulnerable. Further surveys are required to clarify its distribution, especially in the breeding range, where protected areas need stronger management.*

[*Turdus feae*, Doi Inthanon National Park, Thailand. Photo: Suppalak Klabdee]

established. Although more than 80% of all bird species have continental distributions, no fewer than 88% of global extinctions since 1500 have occurred on islands, owing to a combination of factors including natural small range and population sizes, habitat loss, exploitation and, most crucially, lowered defence and competitive mechanisms against introduced animals. Indeed, the greater the isolation of an island in both space and time, the sharper the susceptibility of its native wildlife, Mauritius and Hawaii being notorious examples. In this respect, it is worth noting that several subspecies of the Island Thrush, the nominate race from Norfolk Island, *vinitinctus* from Lord Howe, and *mareensis* and *pritzbueri* from the Loyalties in New Caledonia, have disappeared from the smallest, most ravaged islands in the species' wide range.

Lesser levels of threat, albeit real ones, are experienced by continental species, sometimes simply because they have larger ranges and populations, but more importantly because, even when just as constrained in these two variables, they are much less affected by the evolutionary process which automatically alters the behaviour and competence of insular forms. Nonetheless, what emerges in the list of 36 Critical, Endangered and Vulnerable species of thrush and chat is just how many of them, 18, or 50%, occupy what may be termed "ecological islands", small, isolated tracts of forest usually situated on ranges of mountains or hills. With highly restricted ranges and encroaching human populations, species in these circumstances inevitably run an elevated risk of extinction: not only do they occur within a very small area, but they also, as a consequence, possess very much lower population sizes than those of most wider-ranging species, so that their security must be a matter of permanent human vigilance. Indeed, of all the Extinct, Critical, Endangered and Vulnerable thrushes and chats, only three can be said to have an area of occupancy that is not highly constricted. These are the Grey-sided Thrush and Stoliczka's and Hodgson's Bushchats.

This helps to explain why the complement of Near-threatened species reverses the trend of a decreasing proportion of insular forms with decreasing level of threat. The remaining continental species have ranges too large or, if they are small, habitats too secure to allow them to approach the criteria for being at risk. What emerges in the Near-threatened list is, instead, a suite of birds which are restricted to *relatively* large, *relatively* secure islands, few of which are very isolated, and, thus, with species less likely to fall victim to introduced animals; but nevertheless islands on which human enterprises are starting to, or have the capacity to, exert a negative and disruptive influence. So, again, there is a small-range/small-population factor in these listings, but it is not so pronounced, nor are the evolutionary circumstances of the species in question so precarious. It is worth noting here, however, that three of them, the Red-backed, Red-and-black and Chestnut-backed Thrushes, are listed not because of habitat destruction, but because of the trapping of *Zoothera* thrushes in their particular region of Indonesia, a trade so intensive, owing to these birds' singing abilities, that there are real fears for whole populations on certain islands. With the possible exception of the Green Cochoa, not itself a threatened species, no other species of thrush or chat faces human trade exploitation as a major threat, and probably only a minority even experience trade at all.

The taxonomic composition of the 64 extinct, threatened and Near-threatened species is uneven. Although the family Turdidae, as presently constituted, breaks down as 20 Myadestinae, 133 Turdinae and 183 Saxicolinae, respectively 6%, 40% and 54% of the total species, the above 64 are made up of five myadestines, 31 turdines and 28 saxicolines, which correspond to 8%, 48% and 44%. Thus, the chats emerge as considerably less extinction-prone than the myadestine and the true thrushes, which can immediately be related to their comparatively weak ability to colonize oceanic islands. Moreover, it is at once apparent that certain genera are far more susceptible than are others. This is demonstrated in the following analysis, in which the figures in each case include the extinct forms. Sixty-four extinction-prone species out of 338 represents 19% of the family, but *Zoothera*, with 17 of its 36 species globally threatened or Near-threatened or extinct, has a 47% level of susceptibility, *Myadestes*, with five out of 12 species, a 42% level, *Sheppardia*, with four out of ten species, a 40% level, and *Saxicola*, with four out of eleven species, a 36% level of susceptibilty. The genus *Turdus*, on the other hand, with nine out of 71 species thus classified, has only a 13% level of susceptibilty, and *Phoenicurus*, with just one out of 11 species, a 9% level, while the large genus *Oenanthe*, containing 21 species, notably achieves 0%.

The recent susceptibility of *Myadestes* is clearly related to its early success in colonizing islands, and the same applies to

*The **Sri Lanka Whistling-thrush** is classified as Endangered because it is restricted to a small range in the forested highlands of Sri Lanka, where habitat loss continues. Fewer than 2500 mature individuals are thought to survive, although this estimate is based on rather a lot of guesswork, and may be unduly pessimistic. However many birds are involved, their limited habitat is being cleared to make way for agriculture and timber plantations, and the forest streams along which they live are being polluted with chemical run-off from upland farms. Strict protection and expansion of reserves are important steps towards conserving this species for perpetuity.*

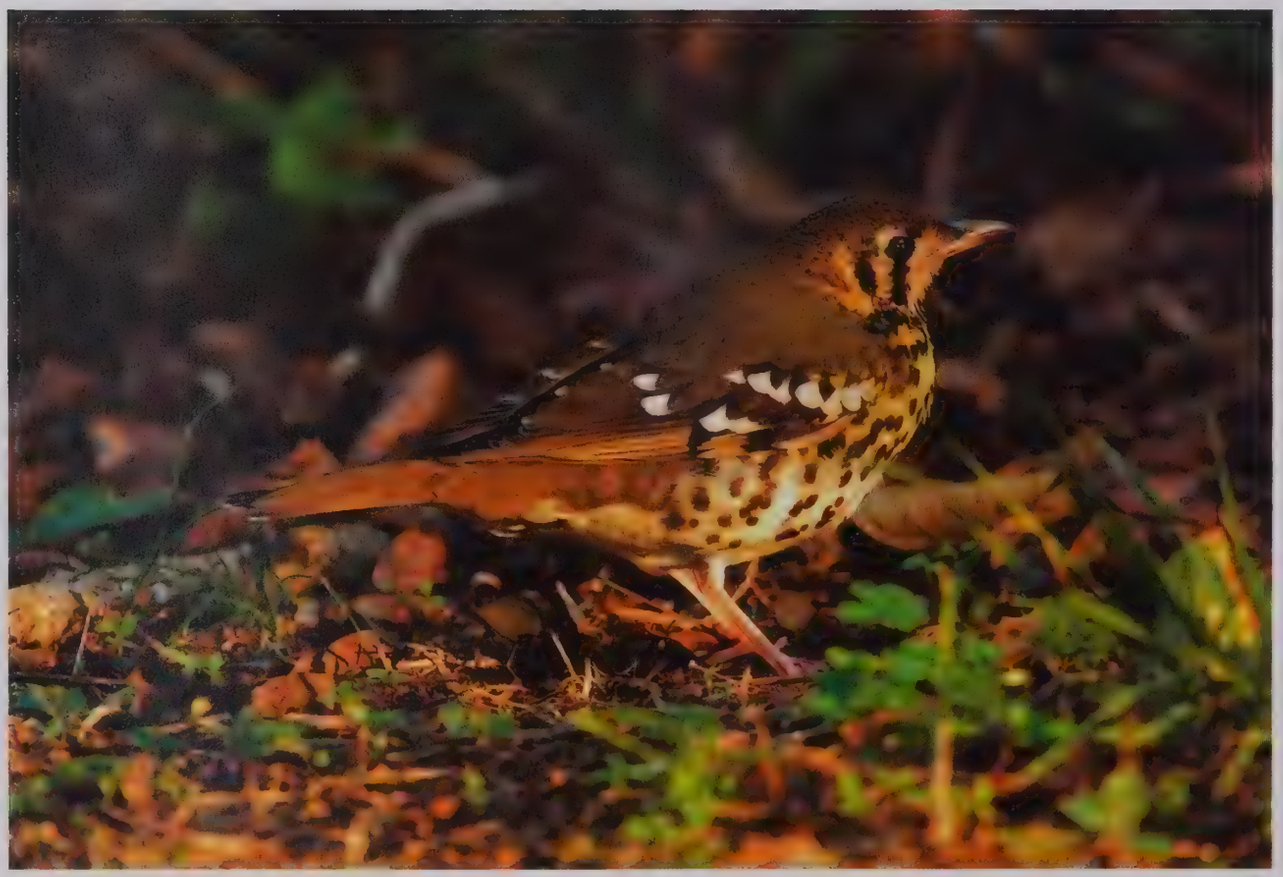
[*Myophonus blighi*, Nuwara Eliya, Sri Lanka. Photo: Edward Vercruysse]

Zoothera, with 13 of its 17 extinction-prone forms being insular, and even *Saxicola*, two of the four such forms of which are insular species. *Sheppardia* has, instead, been successful in colonizing and speciating in "forest islands", some of which are particularly small and therefore inherently vulnerable. *Turdus* thrushes, in contrast, have simply been successful; their full settlement of four continents is matched among the passerines only by the pipit genus *Anthus* and, if different continents are allowed, by *Corvus* and by the swallow genus *Hirundo*, and they are usually relatively common and robust components of an avifauna. *Phoenicurus* and *Oenanthe* are both emphatically island-averse, the former at its most speciose in the relatively secure mountains of Asia, while the latter divides up the northern Old World's boundless drylands, where threats exist but are apparently not sufficient or of the appropriate type to trouble the future of these hardiest of species.

This may change when the conservation status of the Chestnut-rumped Wheatear is formally assessed against the IUCN criteria. This taxon has been treated as a separate species before, but ephemerally; it has an unusually small range for a wheatear, being confined to eastern Turkey and western Iran, it seems to be uncommon, and little is known about it, classic conditions for Near-threatened status. The same is true of the Sumatran Whistling-thrush (*Myophonus castaneus*), recently split from the Javan Whistling-thrush (*Myophonus glaucinus*); the Sumatran taxon seems to be very local within its restricted and steadily diminishing montane forest habitat. A third potentially Near-threatened turdid is the Rufous-brown Solitaire of South America, a bird with an extraordinary relict distribution, insufficiently protected and feebly understood.

Two examples involving Neotropical thrushes illustrate the importance of solid information in making conservation assessments, or, at least, the danger of depending on assumption, however reasonable. The first is the work done by J. V. Remsen in analysing the winter distribution of the Veery by using dated museum specimens. Previous research, some of it quite detailed, had plotted the localities for the species across the South American continent, and had then mapped the winter range by shading over the dots; the result implied that the Veery has a very broad winter range, commensurate with that in summer, and that its populations would therefore be relatively unaffected by deforestation. Remsen, however, also *dated* his dots. What he found was that, of 105 specimens, 91 had been taken during what were still essentially the autumn and spring migration periods, that only 14 specimens existed for the period December–February, and that all these latter grouped in a relatively constrained range in south-central and south-eastern Brazil. These are areas of rapid deforestation, and suddenly the Veery emerges as a species over which a new vigilance is needed. The second example involves the Grand Cayman Thrush. After expressions of concern over its status in 1916, one was seen in 1938, during an Oxford University expedition focusing on other biota. Evidently in response to this information, J. Bond, the father of Caribbean ornithology, concluded in print, two years later, that, while the species was rare and local, it was "probably in no immediate danger of extinction". Alas, it was never seen again.

There is also the example of the Fuerteventura Stonechat. Up to the mid-1980s no work had ever been done on the species, and N. J. Collar, assembling and reviewing the available evidence, which was mostly 50–100 years old, concluded, in a supposedly well-informed guess, that as few as 50–150 pairs might remain. He classified it as globally threatened. In response to this, C. J. Bibby and co-workers undertook a survey of the species and determined, through quantification and extrapolation, that its true population was 650–850 pairs; this, in turn, stimulated still more work, which concluded that as many as 1300 pairs might exist on the island. There is, then, immense difficulty in assessing the status of even open-country thrushes and chats, even in relatively confined spaces. Moreover, in the case of the Fuerteventura Stonechat, populations may fluctuate strongly with annual rainfall, so that baseline figures may vary from decade to decade, if not from year to year. In forest habitats, the situation can be still more challenging. Species such as the Equatorial Akalat and the Brown-chested Alethe are extremely retiring and unobtrusive, and it is often possible to assess their abundance, and sometimes even to confirm their presence, only through the use of mist-nets.



Of course, even if Bond had concluded that the Grand Cayman Thrush was in the direst of plights, which he had no strong reason to believe, it is almost certain that nothing would have been done to save it. The science, techniques, materials, skills, institutions and *ethos* were not in place in the 1930s, and certainly not where a species of ambiguous status on a remote Caribbean is-

land was involved. The Grand Cayman Thrush disappeared half a century too soon. It was, at any rate, only in the 1970s that moves to examine the ecology and needs of several other highly threatened turdines began. The Seychelles Magpie-robin, reduced to 20 or fewer individuals and confined to a single tiny island, Frégate, became the subject of increasingly intensive work and required various management actions. These included ridding the island first of cats and, later, of rats, transforming tracts of woodland and garden into suitable habitat, preventing the use of domestic insecticides, and controlling invasive Common Barn-owls (*Tyto alba*) and Common Mynas (*Acridotheres tristis*), as well as the provision of nestboxes and supplementary food, and the translocating of birds to other suitable islands, where many of the above measures needed to be repeated. No less important in this case, however, has been the growth in the institutional capacity to maintain this work. From a virtual "one-man show", by the pioneering J. Watson, in the 1970s, with the backing of ICBP, the forerunner of BirdLife International, the programme developed into a BirdLife-led recovery effort involving the Royal Society for the Protection of Birds and BirdLife Seychelles, the latter taking the lead since 1998. There were 140 Seychelles Magpie-robins in mid-2004.

Conservation work on the Hawaiian thrushes, beginning in the 1970s, appears to have come too late to help two of them. The Kamao, once the commonest forest bird on Kauai, has not been seen for at least ten years, and the Olomao, with three of its four subspecies accepted as extinct, has not certainly been seen on Molokai for at least twice as long. While even a small chance of their survival exists, however, the effort to control the factors judged to harm them should continue. Indeed, what such effort can achieve is exemplified by the case of the third Critical species, the Puaiohi, for which a suite of actions not dissimilar in general scope to those deployed for the magpie-robin is beginning to produce results. The Puaiohi has proved a little bit more resistant than the Kamao and the Olomao to habitat destruction and to the effects of disease vectored by introduced mosquitoes (Culicidae), but these are real threats compounded by the spread of feral pigs into its range, thereby creating better conditions for mosquitoes, and by the impact on nests of introduced rats. All of these introduced animals need ideally to be excluded, so far as is possible, from the Alakai Wilderness Preserve, the species' only home. The pigs are probably the easiest to deal with; nests can at least be baited in order to prevent rat predation; and there are signs that the birds may be developing resistance to the avian malaria that the mosquitoes carry. Meanwhile, a captive population of Puaiohis has been established as a reservoir and source for the restocking of appropriate areas.

More recently, ground-breaking work, combining evolutionary theory and a detailed population ecological study, has been undertaken by L. Lens and co-workers on what might be called a pseudo-insular species, the Taita Thrush. This turdid, distributed among three cloudforest fragments in the Taita Hills of Kenya, is in almost as serious a state as that of some of the Hawaiian thrushes. The study concentrated on fluctuating asymmetry, which is random deviations from perfect symmetry in bilaterally symmetrical traits such as paired limbs. When developing in stressful circumstances, individuals may be forced to allocate more resources to simple survival, at the expense of producing perfectly symmetrical structures, and an individual's degree of asymmetry is thought, therefore, to give such indication of the degree of environmental adversity endured during its development. So, could degree of asymmetry provide an easily measured indicator of how individuals in threatened populations are faring? The situation with the Taita Thrush indicates that it could: individuals with more asymmetrical tarsi survive less well than do others, suggesting that asymmetry is, indeed, able to provide reliable information about the condition of individuals. Moreover, the most asymmetrical thrushes occur in the most disturbed of the three forest patches, and the least asymmetrical in the least disturbed. Furthermore, survival is lower in the most disturbed patch, but there is no difference in this respect between the moderately and least disturbed patches. These patterns imply that the degree of asymmetry in morphological characters could serve as an early-warning system in conservation, by identifying populations under the greatest environmental stress.

More generally, among seven forest species studied intensively in the Taita Hills, also including the White-starred Robin, individuals in more disturbed forest patches were four to seven times more asymmetrical with regard to tarsus length than were those in less disturbed patches. In addition, a comparison of meas-

The rarest Zoothera *thrush, and the only one accorded Endangered status, is the elusive* ***Spotted Ground-thrush****. It is thinly distributed in forests along the eastern seaboard of Africa, where it is generally rare and local, but seasonally common at some sites, such as Arabuko-Sokoke, Kenya, and forest patches near Durban, South Africa. Nonetheless, the global population is not thought to exceed 2500 individuals, with a general downward trend due to low breeding success, high mortality during migration periods, and the inexorable loss of coastal woodlands and upland breeding sites.*

[*Zoothera guttata guttata*, Zululand.
Photo: HPH Photography/ Photo Access]

urements of museum specimens collected in the 1930s and 1940s with those of live birds mist-netted in the 1990s revealed that the degree of asymmetry considerably increased in the most degraded forest fragment, but did not increase in the least degraded patch. The dispersal rates of species, combined with their sensitivity to disturbance, as reflected by their degree of asymmetry, appear also more generally to predict the proportion of forest patches that they inhabitat. Of the nine species studied, Taita Thrushes are among the most sensitive to forest disturbance, showing a degree of asymmetry second only to that of the Stripe-cheeked Greenbul (*Andropadus milanjensis*).

The key messages coming out of these conservation studies and last-gasp endeavours are that, first, species *can* be saved with enough will-power, commitment and resources, but that, second, it is crucially important not to let them slip so close to the edge of extinction in the first place. This means that, while the targets of further conservation work should continue to be other insular or pseudo-insular species, since without such intervention most of them are likely to become the next "Hawaiian thrushes", there should nonetheless be a concerted programme of monitoring and management for the non-threatened species as well, to check that these relatively common species are maintaining their numbers. Such work is widespread in North America, where a great deal of research has focused on the problem of habitat fragmentation and its effects, in particular through levels of nest predation and brood-parasitism by cowbirds, on populations of forest thrushes. Some of these turdids, notably the Veery and Swainson's Thrush, are judged to be in decline. It is widely believed that large areas of intact forest are major "source" habitats, where productivity exceeds mortality and hence supplies recruits to neighbouring habitats, whereas small woodlots and patches intersected (or with the perimeter lengthened) by clear-cuts are considered "sinks", where mortality exceeds productivity and hence drains birds from neighbouring habitats. This seems to hold for the mostly ground-nesting Hermit Thrush. For the tree-nesting Wood Thrush, however, there is recent evidence that large areas of habitat may be capable of only moderate levels of surplus productivity, that medium-sized areas which should, in theory, produce surpluses do not do so, but that, at least in some areas, small woodlots can, after all, be important sources for the species. The parallel question of the negative influence of deforestation in the species' winter ranges continues to be raised, but research on this topic is far less developed.

So great have been the advances in understanding of the ecology of North America's thrushes, and so great have been the concerns for them, that in 2003 the Cornell Laboratory of Ornithology issued *A Land Manager's Guide to Improving Habitat for Forest Thrushes*. Key recommendations include the maintenance of large, intact forest blocks, the promotion of understorey growth, and the prevention of overbrowsing by deer and livestock, as well as, in the western USA, the protection and enhancement of riparian growth. If these prescriptions are followed with the zeal with which North Americans took up the cause of the bluebird in the 1970s (see Relationship with Man), the thrushes should prosper, so long as their winter quarters are also protected. Thirty-plus years ago, concern over the chronic decline of bluebirds in the face of House Sparrow evictions and natural habitat loss led to the foundation of the National Association for the Protection and Propagation of the Purple Martin and Blue-birds of America. This, and such contributions as L. Zeleny's *The Bluebird: How You Can Help its Fight for Survival*, published in 1976, made the recovery of bluebird populations a strongly citizen-led initiative. Provision of nestboxes has been immensely successful, and human pleasure at the presence of these particularly attractive birds has meant that nestbox "trails" and programmes have become attractive to many members of the public not otherwise particularly motivated for birds or conservation. Even so, there may be a cost elsewhere: in Arizona, increases in abundance of cavity-nesting birds following the deployment of nestboxes were accompanied by decreases in the abundance of open-nesting birds, possibly as a result of interspecific competition for food resources.

Lack of nest-sites is certainly a constraint on hole-nesting species of thrush and chat around the world, and can strongly depress breeding numbers. It can, of course, be particularly acute when there is competition from another species, especially an alien, but it occurs commonly in woodlands where management disfavours old trees. Provision of nestboxes for such species as the Common Redstart is often, therefore, vital to counteract these deleterious effects. Even outside woodland, the importance of nesting holes can be dramatically demonstrated. As an example, H. E. Axell, by

*The **La Selle Thrush**, an Endangered species possibly numbering fewer than 2500 individuals, is endemic to the Caribbean island of Hispaniola, which is subdivided into two rather different political entities: the Dominican Republic, and Haiti. Their fates, and that of this rare thrush, are inextricably linked, particularly as Haiti is the poorest, and perhaps least stable, of New World countries. Its natural forest cover has been almost entirely eliminated, and its protected areas are ineffective. Fortunately, the Dominican Republic is relatively secure, and its parks provide the best hope for conserving this thrush.*

[*Turdus swalesi*, Sierra de Bahoruco National Park, Dominican Republic. Photo: Doug Wechsler/ VIREO]

*The population size of the **Common Scaly Thrush** on the Japanese island of Amami is unclear, but the most optimistic estimate is that 75 pairs survive in the last remaining 10–15 km² of mature broadleaved forest. The resident race* major *is distinguished by its larger size and a few subtle morphological features, including heavier mottling on the face and a bare pink area behind the eye, visible here. These differences are sufficient in the eyes of some taxonomists to justify treatment as a separate species, the Amami Thrush, in which case it is classified as Critical. This is an example of a rather common scenario wherein systematics plays a crucial role in adjusting conservation priorities.*

[*Zoothera dauma major*, Kagosima, Japan. Photo: Hirozo Maki]

the simple expedient of half-burying old ammunition cans measuring 36 × 18 × 9 mm along a stretch of shore at Dungeness, in south-east England, contrived to increase the local post-war population of Northern Wheatears from 26 pairs to 70 pairs.

While research into population declines of North American thrushes has focused mainly on forest diminishment on the breeding and wintering grounds, research into the declines of European thrushes, which utilize mixed habitats to a greater extent, has focused primarily on the intensification of agriculture. For example, work on Song Thrushes in Britain has shown that changes in the survival rates of first-winter individuals, and perhaps also of juveniles in the post-fledging period, are sufficient to account for the decline of the species since the mid-1960s, but the driver of this altered rate remains elusive. Modern farming practices of various types, notably undersoil drainage, may be tipping the balance against younger thrushes, or, alternatively, that balance may be shifting because of factors elsewhere.

Research in Britain has also, for instance, disclosed a worrying long-term trend of eggshell thinning among Common Blackbirds, Song Thrushes, Mistle Thrushes and Ring Ouzels. This is not related to the stepwise decline in the thickness of eggshells of European raptors recorded in the 1960s, which was clearly a physiological response to their accumulation of organochlorine-pesticide residues, and which led to major declines in some species owing to chronic loss of recruitment as a result of eggshell breakages during incubation. For thrushes, the trend dates back at least 150 years, and, while it is not yet known to have had any negative impact on populations of the species concerned, it is a phenomenon that needs to be explained before too long. One suggestion is that "acid rain" has depleted the amounts of calcium in prey items, but in the Netherlands, where soils are rather less sensitive to acidification, precisely the same trend has been identified. Taking its cue from this work, however, recent analysis in the USA reveals a strong, highly significant, negative effect of acid rain on the predicted probability of breeding by the Wood Thrush, and that this effect intensifies at higher elevations with low-pH soils and habitat fragmentation. Pesticides have been investigated for their effects on American Robin populations in commercial orchards and in suburban environments where ornamental trees are treated. To date, however, the evidence is equivocal.

Many migrant birds, including thrushes and chats, are exposed to potentially terrible risks at tall buildings. In 1995, for example, 600 Redwings were killed in one night at the lighthouse at Bardsey, in Wales. Such incidents, fortunately, are mostly isolated ones. On the other hand, the proliferation of television transmission masts and cellphone towers in parts of the USA is a wider cause for concern, Swainson's Thrush being among the commonest casualties at such structures. Data compiled by the American Bird Conservancy indicate that, of all birds killed at large structures, Swainson's Thrushes account for 2·1%, Grey-cheeked Thrushes for 1·0%, Veeries for 0·8% and Wood Thrushes for 0·4%. The Fish & Wildlife Service has estimated that 5 million to 50 million bird deaths per year are caused by building. If this holds, then Swainson's Thrush would suffer 105,000–1,050,000 casualties annually, and even the Wood Thrush would lose 20,000–200,000 individuals.

Some species of thrush can, nevertheless, adapt over time to human environments, when not being asked to fly through them at night. At Port Louis, in the Falkland Islands, Austral Thrushes were already making use of sheds as nest-sites in 1833, as Darwin himself observed. This was at a stage before the Common Blackbird had really become an urban species in Britain. Its colonization of cities appears to have begun in western Europe around the mid-nineteenth century, spreading east and south. In what is now Israel, for example, it bred in natural woodlands throughout the nineteenth century, but widespread felling in the first 20 years of the twentieth century led to its disappearance from many areas, and in the period 1920–1940 it bred only in Galilee and Carmel and locally along the coast. With the foundation of Israel, however, many agricultural schemes and settlements were set up, creating gardens, orchards and citrus groves, and afforestation programmes. Common Blackbirds rapidly recolonized these areas in the 1950s and, assuming a momentum of their own, invaded Judea and the southern coastal plains in the 1960s, in the 1970s entering all parts of the Jordan Valley south to Jericho, and in the 1980s penetrating the northern Negev Desert. The spread into the region of this glorious songster and charming garden companion must count as one of Europe's less orthodox, but perhaps more successful, contributions to the quality of life in the Middle East.

*A less contentious scenario is that of the **Seychelles Magpie-robin**, a species that declined to an all-time low of 12–15 birds on Frégate in 1965, a slump in numbers that nearly consigned it to extinction. Fortunately, it was rescued by a programme of active management and translocations to suitable islands. By mid-2004, this had resulted in 67 birds on Frégate, 36 on Cousin, 22 on Cousine, and 15 on Aride: a global total of 140. The Seychelles Magpie-robin remains listed as Critical, but it is nonetheless a heartening example of what can be achieved when tiny, imperilled populations are carefully managed. The bird seen here is the male of the first pair introduced to Aride.*

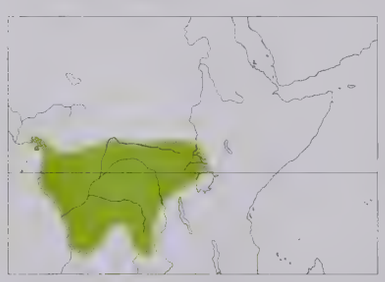
Subfamily MYADESTINAE



Genus *STIZORHINA* Oberholser, 1899

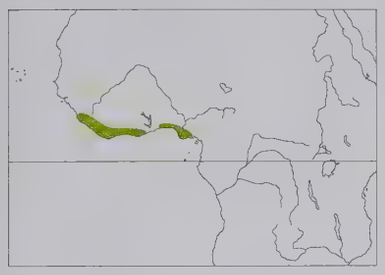
1. Rufous Flycatcher-thrush

Stizorhina fraseri

French: Stizorhin de Fraser **German**: Kurzlaufdrossel **Spanish**: Zorzal de Fraser
Other common names: Rufous Thrush, Rufous Flycatcher, Fraser's Rusty Flycatcher

Taxonomy. *Muscicapa Fraseri* Strickland, 1844, Bioko.
Genus often merged with *Neocossyphus*; the two form a group which, in turn, is most closely related to New World *Myadestes*. Close relationship to *S. finschi* supported by phylogenetic analyses; hybridization occurs in Nigeria, suggesting that it may be more appropriate to regard the two as conspecific, but present species does not repond to playback of *S. finschi* elsewhere. Three subspecies recognized.
Subspecies and Distribution.
S. f. fraseri (Strickland, 1844) – Bioko I (Fernando Póo).
S. f. rubicunda (Hartlaub, 1860) – SE Nigeria E to N DRCongo, S to Angola and NW Zambia.
S. f. vulpina Reichenow, 1902 – S Sudan, NE DRCongo and Uganda.

Descriptive notes. 18–20 cm; 27–44 g. A short-billed, short-legged and rather stout, flycatcher-shaped thrush with a noticeably upright posture; has the habit of flirting the outer tail. Nominate race has greyish-brown head, rufous-brown mantle to lower back and scapulars, brighter chestnut rump; olive-brown wings, with rufous-tawny wingbar above and rusty-buff diagonal bar below; olive-brown tail with rufous-tawny outer feathers; throat greyish, rest of underparts rich tawny; bill blackish, with pale lower base; legs pale brown. Sexes similar. Juvenile is duller and darker. Race *rubicunda* is slightly paler than nominate; *vulpina* has paler tail than other races. VOICE. Territorial song a series of 4–5 high ascending whistles, "wiii-wiii-wiii-wiii", in countersinging a faster, shorter "wiit-wiit-wiit-wiit", in more direct conflict a hoarser vibrant "swit-swit-swit-swit-swit"; in courtship a subdued phrase, commonly beginning with loud trill. Calls include a slow series of 3–4 slightly ascending whistles, "weeeee-ee-eee-eeeee", as contact between pair-members, up to 7–8 series in 30 seconds; short "siit" on take-off; also feeble vibrant ascending "sweet" in anxiety, louder "weez weez weez" version as alarm, and hoarse scolding "tswit-tswit-tswit" when mobbing; calls often accompanied by lifting and spreading of tail.
Habitat. Lowland primary forest and old secondary growth, typically occupying edge habitats such as light gaps with decaying, snapped-off trunks 5–20 m high, streamsides, dense vegetation with numerous lianas, old plantations (cacao, coffee, banana), gallery forest, overgrown disused agricultural land with old parasol trees (*Musanga*) and gingers (*Afromomum*). Chiefly found in understorey but also middle strata and canopy. Recorded from sea-level up to 1500 m; 0–800 m on Bioko, 700–1500 m in Uganda.
Food and Feeding. Mainly insects c. 1 cm in length, especially ants (Hymenoptera), termites (Isoptera), beetles (Coleoptera) and flies (Diptera), also moths, caterpillars, grasshoppers (Orthoptera) and cicadas (Cicadidae), occasionally small snails and millipedes (Diplopoda); sometimes small fruits. Forages from perch by aerial sallying, taking prey from trunks, foliage, air or, more rarely, ground. Often joins mixed bird flocks, particularly in dry season; attends army-ant swarms, but not habitually.
Breeding. Breeding season closely tied to rains; Aug, Oct and Dec, also breeding-condition female and juvenile recorded in Mar, and spotted young in Apr, in Cameroon; Sept-Mar in Gabon; breeding-condition Sept, Oct, Jan and mainly Mar on Bioko; breeding-condition Feb-Mar in Angola; at least Sept in DRCongo; Apr and Sept in E Africa; Oct in Zambia. Territory c. 4–6 ha. Nest a rudimentary, shallow cup of thin rootlets, moss and leaves, placed 1·6–25 m (usually 10–20 m) above ground in open cavity in trunk, branch or epiphyte roots, once in old nest of *Turdus pelios*. Clutch reportedly 1–2 eggs; no information on incubation period; nestling period 14 days; post-fledging dependence at least 1 month. Two individuals ringed as adults were controlled after 8 years.
Movements. Sedentary in Gabon, and probably throughout range.
Status and Conservation. Not globally threatened. Common, but hard to detect, on Bioko. Common to locally abundant in NE Gabon, with density of c. 22 pairs/km². Common in Itombwe Mountains, in E DRCongo.
Bibliography. Benson *et al.* (1971), Borrow & Demey (2001), Brosset & Érard (1986), Brown & Britton (1980), Chapin (1953), Christy & Clarke (1994), Clement & Hathway (2000), Dean (2000), Demey *et al.* (2003), Dowsett & Dowsett-Lemaire (1993, 1997), Eisentraut (1973), Érard (1987, 1990a), Keith *et al.* (1992), Nikolaus (1987), Pasquet *et al.* (1999), Pérez del Val (1996), Plumptre & Mutungire (1996), Prigogine (1971), Quantrill (1995), Rodewald *et al.* (1994), Sinclair & Ryan (2003), Stevenson & Fanshawe (2002), Thiollay (1985), Willis (1986).



2. Finsch's Flycatcher-thrush

Stizorhina finschi

French: Stizorhin de Finsch **German**: Finschdrossel **Spanish**: Zorzal de Finsch

Taxonomy. *Cassinia finschi* Sharpe, 1870, Fantee, Ghana.
Genus often merged with *Neocossyphus*; the two form a group which, in turn, is most closely related to New World *Myadestes*. Close relationship to *S. fraseri* supported by phylogenetic analyses; hybridization occurs in Nigeria, suggesting that it may be more appropriate to regard the two as conspecific, but *S. fraseri* does not repond to playback of present species elsewhere. Species name often listed as *finschii*, but original spelling is *finschi*, which must stand. Monotypic.

Distribution. Sierra Leone E to Nigeria.

Descriptive notes. 18 cm; 33–44 g. A short-billed, short-legged and stout, flycatcher-shaped thrush with upright posture; habit of flirting outer tail. Has dull grey-brown head, dull rufous-brown upperparts, brighter on rump; brownish wings, indistinct rufous-tawny wingbar above, rusty-buff bar below; dark grey tail with extensive white tips on outer feathers, decreasingly small tips on two adjacent rectrices; dull tawny below, greyer on throat; bill blackish, pale lower base; legs pale brown. Distinguished from very similar *S. fraseri* by duller coloration above and below, less distinct pattern in wings, greyer tail with white outer tips. Sexes similar. Juvenile apparently undescribed. Voice. Territorial song, usually from high (c. 7 m) concealed perch, and given even during middle of day, apparently variable, in Sierra Leone long-drawn whistle of medium to low pitch, a pause of equal length, another similar whistle followed by 2 shorter, somewhat higher notes, generally like that of *S. fraseri* but lower and slower; elsewhere as a slow, mournful syncopated whistling, "whooo… whoo… whoo-peer", also as rapid 4-note "tswi-tswi-tswi-tswi" and as slow 4-note "hooii, hooii hooii-huee", slightly rising, also a throaty, deliberate "tsw-tswii… tswiiii" and long-drawn plaintive "wii… wiiii-iii"; at E end of range hybrids produce intermediate-speed songs. Calls include loud buzzy "wurd-wurd-wurd" when mobbing a raptor, and are lower than those of *S. fraseri*.
Habitat. Understorey and lower canopy (up to 30 m in Liberia) of primary and secondary lowland evergreen and semi-deciduous forest and swamp-forest; prefers densest patches of vegetation. Sea-level to 1500 m; to 900 m in Liberia.
Food and Feeding. Small insects, e.g. ants and wasps (Hymenoptera), termites (Isoptera), beetles (Coleoptera), grasshoppers (Orthoptera), flies (Diptera), bugs and moths. Forages by aerial sallying from perch, taking prey from trunks, foliage and air, rarely from ground. Joins mixed-species flocks, attends army-ant swarms.
Breeding. Little information. Nest material being gathered in Feb–Mar in Nigeria; birds in breeding condition Jun, Sept–Oct and Dec in Liberia and Mar in Ghana.
Movements. Presumably sedentary.
Status and Conservation. Not globally threatened. Rare to locally common. Fairly common in S & C Liberia.
Bibliography. Genus *NEOCOSSYPHUS*

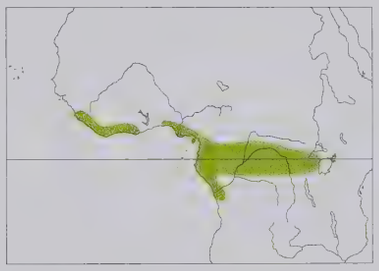
Fischer & Reichenow, 1884

3. Red-tailed Ant-thrush

Neocossyphus rufus

French: Néocossyphe à queue rousse **Spanish**: Zorzal Colirrufo
German: Rotschwanz-Fuchsdrossel

Taxonomy. *Pseudocossyphus rufus* Fischer and Reichenow, 1884, Pangani, Tanzania.
Genus closest to *Stizorhina*, the two forming a group which, in turn, is most closely related to New World *Myadestes*. Two subspecies recognized.
Subspecies and Distribution.
N. r. gabunensis Neumann, 1908 – S Cameroon and Gabon E to N DRCongo and W Uganda.
N. r. rufus (Fischer & Reichenow, 1884) – E Kenya and E Tanzania, including Zanzibar I.



Descriptive notes. 22–25 cm; 53–80 g. Nominate race is rufous-brown, duller and greyer brown on head and upperparts; tail bright rufous except for darker central feather pair; underparts tawny cinnamon, with pale greyish-olive throat; bill brownish-black; legs fleshy to pale brown or purplish-grey. Differs from similar *Stizorhina* species in larger size, longer bill, stronger legs, mostly rufous tail, no pattern in wing; behaviour also different. Sexes similar. Juvenile is duller and browner. Race *gabunensis* is darker than nominate on throat and breast, has clear greyish tinge on breast. Voice. Song consists of 2 clear high even whistles (commonly used as calls, and during aggression at ant swarms) followed by long, high descending trill, "psiii-piii tsisisisisisrrru". Calls include low "wruuw"; sibilant descending "psiiiiiuu", sometimes followed by the first 1 or 2 notes of song, sometimes more complex as "tsip-wi-whiiiiiir"; a series of short crackling "prrr… prrr" trills at ant swarms and on take-off; high whistled "psiii" as contact, and sharp rasping "treet" and thin high "tsiim" as alarm or in anxiety. Difference between calls of races noted in E Africa, *gabunensis* giving sharp crack followed by several rising and falling whistles, ending in chatter, while nominate gives ratchet-like "trrt", often followed by long falling "fweeeee".
Habitat. Floor and lower understorey, occasionally middle strata, of primary lowland forest, rarely adjacent old secondary growth (especially when with mixed-species flocks); nominate race also in riverine and coastal forest; occasionally emerges into open areas adjacent to forest. Recorded from sea-level up to 1400 m; 700–1400 m in Uganda; nominate race up to 900 m, but below 500 m in Kenya.
Food and Feeding. Mainly insects such as grasshoppers (Orthoptera), beetles (Coleoptera), ants (Hymenoptera), caterpillars, but also spiders, small millipedes (Diplopoda) and other terrestrial arthropods; occasionally small snails. Forages on ground among leaf litter and from low branches and stumps, making sallies to the ground; also reported as sally-gleaning above 5 m. Sometimes in small groups. Regular follower of army-ant swarms where available, dominating all smaller bird species; also joins mixed-species flocks feeding away from ants.
Breeding. Little information; only three nests found. Nov in Cameroon and Dec–Jan in Gabon; Apr–May, and breeding-condition bird in Sept, in DRCongo; Apr in Kenya; birds in breeding condition in Sept in Tanzania (Zanzibar) and Oct in Uganda. Nest a slender pad of rootlets, flower stems, tendrils and/or fine plant fibres, with some dead leaves and rodent fur, placed in top of broken-off stump or in large knothole in dead tree, 1·5 m (stump) or 4–10 m off ground. Eggs 2, whitish with rufous-brown spots and blotches; incubation by female; no information on incubation, nestling and post-fledging dependence periods.
Movements. Presumably sedentary. Occasional wandering or dispersal indicated by single records from Central African Republic and S Somalia.
Status and Conservation. Not globally threatened. Rare to locally common. Average density 3–4 pairs/km² in Gabon, where commoner at 800–1000 m than at lower levels. Nominate race fairly common in coastal E Africa.
Bibliography. Bannerman (1953), Borrow & Demey (2001), Britton (1980), Brosset & Érard (1986), Brown (1970), Chapin (1953), Christy & Clarke (1994), Clement & Hathway (2000), Dowsett & Dowsett-Lemaire (1997), Keith *et al.* (1992), Lewis & Pomeroy (1989), Lippens & Wille (1976), Pakenham (1979), Pasquet *et al.* (1999), Plumptre & Mutungire (1996), Quantrill (1995), Sinclair & Ryan (2003), Stevenson & Fanshawe (2002), Stuart & Jensen (1985), Svendsen & Hansen (1995), Thiollay (1985), Willis (1986).

4. White-tailed Ant-thrush

Neocossyphus poensis

French: Néocossyphe à queue blanche **Spanish**: Zorzal de Fernando Póo
German: Weißschwanz-Fuchsdrossel

Taxonomy. *Cossypha poensis* Strickland, 1844, Clarence, Bioko.
Genus closest to *Stizorhina*, the two forming a group which, in turn, is most closely related to New World *Myadestes*. Described races *pallidigularis* (from N Angola), *kakamegoes* (from Kakamega Forest, in Kenya) and *nigridorsalis* (N Nandi Forest, in W Kenya) all considered indistinguishable from *praepectoralis*. Two subspecies recognized.
Subspecies and Distribution.
N. p. poensis (Strickland, 1844) – Sierra Leone E to Cameroon, Gabon and S PRCongo, also Bioko I (Fernando Póo).
N. p. praepectoralis Jackson, 1906 – W DRCongo and NW Angola E to W Uganda and W Kenya.

Descriptive notes. 20–22 cm; 43–60 g. Nominate race is dark brownish slate above, with prominent white tips on outer three tail feathers; conspicuous broad orange-rufous wingbar (obvious in flight); throat paler and greyish, underparts rufous-orange; bill blackish; legs pale flesh. Distinguished from very similar *Stizorhina finschi* by darker upperparts, dark rump, more prominent wingbar, larger bill, longer legs; also by tail-pumping behaviour. Sexes similar. Juvenile undescribed. Race *praepectoralis* is browner above than nominate, has less white in tail. Voice. Song, sometimes from 10–15 m up in tree, rich and *Turdus*-like but subdued and rarely heard, "wurriiit t'rii uiiiiiit…"; often given around ant swarms. Calls include single shrill, second-long, ascending whistle, "huwiiiiit" or "tlooeeet" or "wiiiiiiiit", and descending sibilant "tsiiiiuw", usually frequently repeated; also sharp "sip-sip" in alarm, loud "hiiir-her-hih" in intraspecific chases, and commonly a ticking "prrt-prrt", which may be followed by single rising or falling downslur, at ant swarms and in flight.
